Dr. Macdonald, of the Washington board of education, gave experiences in measuring twenty thousand children. It was found that the public were active in their interest in scientific research in the polar regions, in rocks and wild animals, but could not readily see the utility of studying the human species. It was ideal science versus practical. Boys and girls were found to diverge at fourteen years, the girls maturing more rapidly. Observation had been made on three thousand cases to learn the ability to feel or endure pain, to learn if the first-born was most acutely sensitive, etc. Thirteen thousand observations showed clearly that children born in summer did best in every way. Interesting figures, possibly practical, were obtained abroad, *i.e.*, that twenty per cent. of the aristocracy were blondes. It was interesting to compare the strength with the vital capacity, or weight with the same, etc.

Dr. Yale, of New York, presented the practical application. It was well known that a child grew "weedy," tall, but not tough—grew beyond his strength. It was not over-study that the child suffered from; it was that he had not the physical strength to keep up the study. He could not study because he was ill.

Dr. Fruitnight noted the lack of vigor toward noon. The school-day should be divided so that the child was out of doors from 10:30 A.M. until 2 P.M., especially in winter.

Dr. Cotton laid stress on the importance to the future of all these observations on the developmental period. He was gratified that so much of this work emanated from the Pediatric Society. There was a want of appreciation by the lay public, though they were keenly alive to commercial investigations.

Dr. Chapin spoke of investigations in one thousand children at the Juvenile Asylum. Many of these were committed for petty offences, and all were of poor heredity and surroundings. Many with five stigmata of degeneration were considered brightest by their teachers.

Dr. Rachford declared that we did not as yet know what the ergograms meant, muscle or nerve fatigue. The nervous girl, for instance, did more work than a strong man, but the tracing was itself like a choreic action. If brain strain could be measured the energy of the pupils should be less at the end of the term than in the beginning. He asked if there was a physical basis for precocity, and what amount of development was necessary for sustained work in school. There should be a physical examination for entrance to school as well as mental.

Dr. Ware asked if it was to be inferred that children had less likelihood of eye strain if they remained out of school until the eighth year; also if the tracings for both ends of the school year were alike.

Dr. Yale replied that there was very little difference. Some lost weight in summer, depending upon the manner of spending the vacation, whether at home, at work, or in the country. The observations of teachers varied so greatly that the grade standing was found the more positive indication of ability. Color blindness in whole or part was found very common.

Epidemic Paralysis in Children.—Dr. Henry D. Chapin, of New York, read this paper. He said the prevailing view was that this was a special form of paralysis due to an infection. The abrupt onset, convulsions, epidemic and endemic outbreaks favored this view. The symptom complex resembled that of Landry's paralysis. Some evidences suggested a chemical change in the blood as in rheumatism, or change in metabolism not understood. Cold, refrigeration, was a suggested cause. Paralysis from microbes was not always confined to the extremities. There were often groups of cases in one family. The Poughkeepsie epidemic occurred in July and August. The city was usually healthy otherwise. There was no paludism. The speaker saw seven cases and learned of more than twenty-five in the vicinity. A type was the case of a child, four years old, taken with vomiting, high fever, pain in the limbs; temperature, 104° F.; pulse, 120. On the fourth day both legs and arms were paralyzed. All the cases were similar. The blood examination was negative. A few minute diplococci were found but might have been due to contamination. The blood plaques were increased, showing dissolution of the red elements. The great amount of pain in the limbs suggested neuritis. One child, two years old, died in convulsions twenty hours from the onset. The microscopical examination of the cord showed nothing especial. There was cloudiness about the anterior horns, with diplococci and marks of degeneration. One would hesitate to infer much from these appearances. In all the other cases the patients recovered, though not all were free from paralysis. Several cases were of typical anterior poliomyelitis; one child was still paralyzed. Two forms were evident—those with spinal and those with peripheral lesions. A third set seemed to include both forms. The epidemic at Bridgeport was of the same character.

Dr. Griffith narrated two cases that occurred in the same family without apparent cause. They must have been infectious. One list of cases of epidemic paralysis included a scurvy case.

Atresia of the Larynx due to Faulty Intubation, with Specimen.—This was presented by Dr. W. P. Northrup, of New York. He said that the causes of retained tube were a faulty tube or a faulty operator. The specimen of larynx was shown; it happened to be the last case seen by the late Dr. O'Dwyer. The child had snatched the thread and tube out too quickly for the young operator, and several attempts were made at reintroduction. Later urgent dyspnœa demanded tracheotomy. The child died later of pneumonia. The larynx showed an hour-glass contraction below the glottis, caused by a band of new inflammatory tissue where the walls had been abraded by the frequent introduction of the tube.

Dr. Miller thought the speaker too severe on the operator, as the most skilful had like troubles.

Dr. Cotton said it would be interesting to know how many cases there might be with malformed larynx. He had seen a girl, aged thirteen years, die with symptoms of diphtheria, at all events of dyspnœa. Intubation failed, and after death stenosis was found and a cul-de-sac in the larynx. The author's moral was, not every one could intubate.

Three Cases of Head Nodding and Head Rotation.—This paper was read by Dr. Milton Miller, of Philadelphia. He said that in Budapest fourteen cases occurred among fifty-two thousand persons in two years. Seventy-eight were now in the literature. The term spasm was misleading; head nodding was more appropriate. He described the case of a negro male child, five months old. He was breast-fed but had gastro-intestinal disorders. His weight at birth had been eight pounds. The ribs were beaded. He cut the first lower incisors at nine months. Massage, baths, and cod-liver oil improved him. The head nodded ninety times per minute, but ceased during sleep. There existed vertical and diagonal nystagmus. The movements lasted four months, when he became well. The second case was that of a girl, aged twelve months, fed upon condensed milk. She had alternating constipation and diarrhœa. Rickets was well marked. The head movements had existed since she was seven months old. She recovered. In the third case there was no nystagmus, only nodding. Hygiene and salt baths cured. The cause in these cases seemed to be gastro-intestinal disturbance. The second case was aggravated by intercurrent measles.

Of the seventy-eight cases recorded, eleven had convulsions; falls preceded twenty-two; nystagmus of both eyes existed in forty-three, in one eye in forty-two; five had strabismus. Twenty-two were examined with the ophthalmoscope, and twenty-one of them were found normal. The nodding had been thought due to uncertain line of sight, and bandaging had been suggested to lessen the habit. The bromides were less efficient than diet in cure.

Dr. Koplik had had twelve cases investigated. As a rule nystagmus was more marked in one eye than the other.

Dr. Lewi had visited the homes of patients and found that eye strain could not be attributed to their surroundings. Rachitis was always present.

Dr. Miller, in closing, said in his cases the children were living in good rooms and were rachitic. His view was that the disease was a functional one due to exhaustion.

Cresoline Poisoning.—Dr. S. S. Adams, of Washington, described two cases. The first case was that of a child a year old, who was found in coma, with stridulous breathing and cold clammy sweat. The urine had been black for twenty-four hours. Recovery was prompt in the open air. The second case was that of a baby six months old, said to be dying of broncho-pneumonia. The pupils were dilated; breathing was stridulous; temperature, 100° F. Pulmonary œdema was present. The urine was not black. Recovery was complete in the open air.

Officers Elected.—*President*, Dr. Booker, of Baltimore; *First Vice-President*, Dr. Frederick A. Packard; *Second Vice-President*, Dr. Morse; *Treasurer*, Dr. J. Park West; *Secretary*, Dr. S. S. Adams; *Editor and Recorder*, Dr. W. L. Carr; *Member of Council*, Dr. F. M. Crandall.

The society adjourned to meet at Niagara Falls on May 27, 28, and 29, 1901.

AMERICAN DERMATOLOGICAL ASSOCIATION.

Meeting Held at Washington, D. C., May 1, 2, and 3, 1900.

First Day—Tuesday, May 1st—Morning Session.

President's Address.—The annual address was read by the president, Dr. Henry W. Stelwagon, of Philadelphia, who said that the ultimate aim of physicians, the diminution of suffering and the cure of disease, could be attained only by the combined results of the clinician, the therapeutist, the pathologist, and the bacteriologist. Bacteriology, especially, played an important part; and the hereditary receptivity and family vulnerability, the environment, and the state of the general health, were factors of moment in many cases. Dr. Stelwagen spoke of the increased importance now attached to the teaching of dermatology in the medical colleges, and also referred to leprosy as a disease which could be properly handled only by the national authorities.

Bullous Dermatitis (Dermatitis Herpetiformis?) in Children.—Dr. J. T. Bowen, of Boston, presented five cases following vaccination. He exhibited photographs of the cases, in three of which the eruption appeared within two weeks after vaccination, and in at least four of which there seemed to be reason for the assumption that the vaccination in some way influenced the appearance of the eruption. The localization of the lesions was striking, there being a tendency to grouping about the mouth, chin, nose, and ears, and upon the backs of the hands and feet; moreover, the extensor aspects of the extremities were prominently affected. The itching was not pronounced. Dr. Bowen said that our present knowledge of the bullous dermatoses was such that it was imprudent to draw deductions from any but a large number of carefully reported cases.

Dr. George T. Jackson, of New York, read a paper on "Loss of Hair," which will appear in full in the Medical Record.

An Unusual Phenomenon of Syphilis: Othæmatoma.—Dr. Joseph Zeissler, of Chicago, reported a case in a physician, forty years of age, who had a small wart-like lesion on his right thumb, which was removed by excision and cauterization with nitric acid. The glands of the axilla became much enlarged, and six weeks afterward a copious roseola made its appearance. Mercurial injections and inunctions were given. A year later an othæmatoma appeared on the right auricle. Iodide of potassium was liberally administered, and the othæmatoma promptly and permanently disappeared. Dr. Zeissler explained the case on the basis of perichondritis due to syphilis.

Dr. Ravogli, of Cincinnati, referred to two cases of othæmatoma which he had seen in idiots.

Evening Session.

Case of Brocq's Erythrodermie Pityriasique en Plaques Disseminées.—This case was reported by Dr. J. C. White, of Boston. The patient was a healthy Irishman, with a negative family history, who twelve years ago noticed red spots of considerable size on his lower leg, which disappeared in the spring and reappeared each autumn, invading more and more the general surface, until the entire surface was almost covered. They showed themselves every year at the beginning of cold weather, remained unchanged throughout the winter, and vanished in April. They had never given rise to any subjective symptoms. On inspection his face and neck were largely occupied by bright red areas of irregularly circular outline, varying in size from one-half inch to two inches in diameter. They were mostly smooth, not at all elevated even at the margin, and were not thicker than the normal skin. Another case was seen about the same time by Dr. Charles J. White, in a young German aged twenty-six years. The two cases bore a strong resemblance to each other in the general appearances, but were far from identical, the second one covering much larger individual areas uniformly and being more scaly, as in Brocq's case. It also lacked the peculiar brownish tint of the first case.

Dr. Sigmund Pollitzer said these cases bore very little resemblance to parakeratosis variegata, or lichen planus.

The Prophylaxis and Control of Leprosy in this Country.—This paper was read by Dr. Prince A. Morrow, of New York. He referred to the growing likelihood of contagion from our recently acquired possessions in the Philippines and Hawaii, and the necessity for national action in order to prevent the spread of the disease. He suggested the employment of skilled experts as quarantine inspectors. He deprecated the mediæval conception of the horror and virulence of the disease, which was now known to be no more contagious than tuberculosis. Isolation or segregation undoubtedly was the most effective means known to sanitary science for the control of this and other contagious diseases. Homes or asylums with suitable hygienic surroundings should be provided by the national government for the care and maintenance of lepers. Such asylums should be made comfortable and attractive, and be arranged with especial adaptation to the requirements and peculiar needs of its inmates. In view of the chronicity of the disease, lepers should not be condemned to close confinement in inactivity, but should be provided with interests, means of employment, and recreation. As a large proportion of lepers are able to engage in some kind of industry, such institutions might be made partly or wholly self-sustaining from the proceeds of these industries.

The Prevalence of Parasitic Diseases of the Skin, and Measures Necessary to Limit their Spread.—This paper was read by Dr. William Thomas Corlett, of Cleveland. In considering the class of diseases known as parasitic, the author spoke of the necessity of enlarging the group, since recent investigations have demonstrated that other microorganisms of the vegetable kingdom, such as the bacteria, blastomyces, and actinomyces, were active agents in producing diseases of the skin. The distinction that these latter were not limited to the skin, but produced grave disturbances of the viscera, was held untenable, as instances were recorded of ringworm and favus attacking the mucous membranes. As to the frequency of the parasitic dermatoses, the speaker quoted from the statistics of the American Dermatological Association, showing that next to eczema parasitic diseases were the most common of all diseases of the skin. Favus was of minor importance, being almost wholly an imported disease. The writer had met with it mainly in Poles and Hungarians, seldom in persons from Scotland and only once from France. Tinea versicolor, he held, derived its importance mainly from the danger of its being mistaken for more serious affections. Of the greatest importance among the vegetable parasitic diseases of the skin he placed the ringworm family. He maintained that the severity as well as the frequency of ringworm differed in different countries, being especially prevalent and more severe in low, tropical countries than in high northern altitudes. This afforded a striking contrast to that observed among the animal parasitic diseases, particularly scabies, which throve best in cold countries. As an example he mentioned scabies Norvegica. In the writer's experience ringworm was mainly a disease of children and adult males, although all conditions and ages were liable to become affected. In children the scalp was the part most frequently attacked, while in men the chin and sides of the bearded face and crural region were most frequently involved. He had observed the disease but seldom after middle life. Pediculosis capitis had been most commonly encountered in children and women, pediculosis pubis in young men, and pediculosis vestimentorum he regarded as almost wholly limited to the uncleanly, and as seen in public clinics was one of the tortures of old age. As to whether or not parasitic diseases of the skin were diminishing in frequency in this country, the speaker again referred to the statistics of the American Dermatological Association during the last twenty years, in which it was found that while there had been a slight decrease in the animal parasitic diseases there had been an increase in the number of diseases of the skin due to vegetable parasites. He attributed the decrease in the former to improved hygienic conditions, and especially to the free bathing establishments in large cities, which encouraged frequent ablutions. Among the most potent factors in increasing the prevalence of vegetable parasitic diseases, especially ringworm, he mentioned asylums, schools, barber shops, the roller towel in the washroom of hotels, and domestic animals. Among the measures recommended to limit the spread of the vegetable parasitic disease of the skin, he spoke of the imperative need of admitting children to asylums, which oftentimes rendered it impossible to exclude certain infectious diseases. When isolation was found impossible, the scalp must be shaved and an impermeable dressing worn to prevent the diffusion of the contagium throughout the apartment. The medical director should exercise great caution against admitting cases of ringworm to asylums. The speaker strongly urged the exclusion of ringworm from kindergartens and schools. That this might be successfully carried out he advised that there should be in all communities a medical inspector of schools. Nothing short of rigid quarantine would succeed in eliminating the various forms of ringworm. Barber shops should at least be under the supervision of the board of health. Minnesota already had a law in force requiring all barbers to obtain a license. No barber should be allowed to use the same brush, sponge, or towel on different patrons, without these articles being first boiled, subjected to dry heat (250° F.), superheated steam, or otherwise disinfected. Absolute alcohol, a solution of formaldehyde, fifteen per cent., or corrosive sublimate (1 : 1,000) were among the necessary adjuncts to a barber's outfit. Any disease existing on the skin or hide of domestic animals, especially dogs, cows, and horses, should be looked upon with apprehension, and care exercised by those coming in contact with them.

A Report of Two Cases of Persistent Exfoliation of the Lips.—This paper was read by Dr. Henry W. Stelwagon, of Philadelphia. The first case was that of a young woman, aged about eighteen years. The urine showed considerable deposit of urates. The condition was limited to the vermilion of the lips, overstepping neither the mucous portion of the mouth nor the cutaneous integument. The lips when free from the scale or crust formation appeared normal, at times showing scattered points of superficial abrasion. The first stage in the formation of an exfoliating film consisted of a slight, scarcely perceptible thickening. In a short time, from two to five days, the affected parts broke up into plaques by a cracking of the film, and the edges of the plaques gradually became everted, and slowly loosened and detached themselves. If pulled off or forcibly detached, the lips were red, slightly abraded, and somewhat tender. The exfoliative process went on unceasingly. The disease was still persistent, but was no longer under the reader's care. The second case was that of a woman aged thirty years. The patient was profoundly neurasthenic. Both lips were to a great extent involved, although the central parts were most markedly affected. There was slight seborrhœa capitis in both cases. The reader was inclined to consider the disease as allied to eczema seborrhoicum.

The Etiology and Pathology of Cutaneous Cancer.—Dr. A. Ravogli, of Cincinnati, said that from the greatest antiquity the clinical conception of cancer had been an ulcer, especially of the skin and glands, with exuberant growth of granulations, which, when removed, had a tendency to relapse, gradually spreading and under marasmic conditions causing death. The true etiology was first given by Billroth, who considered as carcinoma only those new growths which resulted from epithelial production, together with an infiltration in the connective tissues. It was quite natural that the masses of epithelial cells, crowding themselves into the midst of the connective tissues, must produce an irritation which caused a proliferation of the connective-tissue corpuscles. These corpuscles, which had the task of providing for the nutrition of the connective-tissue fibres, were greatly developed in the embryonic stage. In adult life they were very much smaller, but on account of some inflammatory exudation they returned to their embryonic stage, increasing in their volume; their nuclei proliferated, and they increased in quantity, producing hypertrophy of the connective tissues, until they reached the form of papillary growths. In carcinoma the presence of sharp epithelial cells, crowding down upon the delicate structure of the connective-tissue fibres, caused the connective-tissue corpuscles to take part in the proliferation; hence carcinoma was a malignant production consisting of masses of epithelial cells embedded in a connective-tissue structure, inflamed and infiltrated.

Second Day—Wednesday, May 2d—Morning Session.

General Discussion—Malignant Diseases of the Skin. Their Classification and Clinical Features.—Dr. E. B. Bronson read this paper. The import of the epithet malignant as applied to disease varied according to the circumstances under which it was employed. As most generally used the term implied a rapid, destructive course, tending to a fatal issue. It was thus used to designate certain forms or varieties of a disease of a severe and dangerous type, in contradistinction to other forms of the same disease that pursued a relatively milder or "benigner" course. Thus we had malignant and benign forms of syphilis and tuberculosis. Pernicious cell growths might originate either in the epithelial structures or in the connective tissue. In the one case the resulting disease was carcinoma, in the other sarcoma. All known "malignant" growths pertained to one or the other of these two diseases. An epithelioma, though in the common acceptation of the term a skin cancer, was not necessarily a malignant growth; only potentially so. A promising field for the study of malignancy in diseases of the skin and of the conditions relating to it was found in those diseases that, beginning as an inflammation or simple perversion of growth, ended in malignant cancer. The epitheliomas that developed on old syphilitic lesions, on lupus, or from some indifferent local irritation of the skin, were common instances.

Their Etiology and Pathology.—Dr. M. B. Hartzell discussed this part of the subject. He said that heredity, age, traumatism, and long-continued slight irritations had long been considered as predisposing, in greater or less degree, to the occurrence of cancer. While heredity was no longer believed to play the important rôle formerly attributed to it, yet it was apparently well settled that cancer was apt to occur in successive generations of some families, due, as was now believed, not to the inheritance of the disease, but to an inherited susceptibility. The influence of age upon the appearance of carcinoma was so very evident that it was no longer a matter for debate; in the great majority of cases the patient with cancer was past forty years of age, the exceptions to this rule being in most cases examples of rodent ulcer. Ribbert produced numerous tumors in the abdomen, uterus, diaphragm, and pleura of an animal (a rabbit) by allowing free epithelial cells to diffuse through the peritoneal cavity. Cancer possessed a considerable number of features, clinical and pathological, which suggested the possibility of its being an infection, although other explanations were not absolutely precluded. We might regard it fairly well demonstrated that this neoplasm resulted from a profound and more or less permanent alteration of the mechanism of cell-division. This alteration might result from long-continued irritation of a mechanical or chemical kind. The immediate causes were therefore multiple. In cases of xeroderma pigmentosum it might be assumed that some inborn defect of the skin existed.

Their Treatment.—This paper was by Dr. F. J. Shepherd, of Montreal. As a surgeon had to treat all kinds of malignant disease, wherever situated, excision of the growth and the adjacent lymphatic channels and glands seemed the most scientific procedure in the majority of cases. He said that all now believed in the local origin of cancer, and also that whenever found it should be quickly and completely removed. The disease being local, only local treatment was curative. Constitutional treatment was of no avail. There were two forms of local treatment—removal by knife and removal by caustics. Surgeons favored the former and dermatologists the latter. The weak point in the treatment of malignant disease of the skin by caustics was that it postponed the removal of the neighboring lymphatic tissue and glands. Dr. Shepherd held that there might be malignant disease of the glands, and yet they could not be always felt, as in the axilla and submaxillary region. Even the microscope failed to detect the disease in the glands, the cancer cells in the very early stage being so few and far between. He instanced the magnificent results of the removal of mammary cancer by modern methods of very extensive operations. In Paget's disease of the nipple he advocated removal of the whole breast. In cancer of the lips, scrotum, penis, vulva, and wherever the skin was loose, removal by excision was advocated. Certain malignant ulcerations of the skin he admitted might be successfully treated by caustics, especially rodent ulcer and the slow-growing forms of epithelioma situated in regions somewhat removed from glands, as the nose, forehead, temples, cheeks, hands, and when the glands were not early affected. He had successfully employed free curetting and the after-application of caustics in such cases. The best caustics were arsenic, chloride of zinc, and caustic potash. Some held that arsenic had a selective action, *i.e.*, an inflammation might be produced which would destroy cancer cells but not normal tissue. Before employing arsenic the ulceration should be curetted, or the epidermis over it should be destroyed by caustic potash. Several other methods of treatment were alluded to, such as the parenchymatous injections of alcohol, nitrate of silver, or chloride of zinc, with electrolysis, aniline dyes, and the injection of toxins. Coler's treatment was more suited to sarcoma than carcinoma. In sarcoma of the skin early and complete removal was the best treatment if the growth was local. When general some cases had been successfully treated by the injection of a solution of arsenic. The injection of toxins had not proved successful in Dr. Shepherd's hands.

The discussion of the entire subject was participated in by all the members.

A Case of Nævus-Cancer; Metastasis; Operation; Cure.—Dr. S. Pollitzer, of New York, read this paper. The patient was thirty years old when a small, slightly pigmented mole on the back, about an inch to the left of the eighth dorsal vertebra, began to ulcerate. During six years of treatment the ulcer never healed, and finally began to exceed the limits of the original mole. It was then excised, the skin stitched up, and the wound healed well, producing a linear scar. Six months later the skin in the neighborhood of the scar became raised, red, and glistening over an irregular area about two inches in diameter, and broke down at two points, producing small ulcers. Soon after the patient consulted the speaker. There was then, in addition to the condition described, a small, hard, round tumor clearly below the skin, and an inch and a half from the edge of the red glistening patch. The patch including the scar and a large extent of healthy skin were excised. The subcutaneous tumor was found within the substance of the trapezius muscle, and the latter was stripped up from its attachment to the spines of the ninth to twelfth dorsal vertebra and cut out to an extent that included the tumor. Microscopical examination showed the cutis throughout the red glistening area to be filled with round, oval, and irregular tracts of cancer cells, without connection with the surface epithelium. Examination of the tumor in the muscle showed it to be made up of large nests of cancer-cells separated by dense masses of connective tissue which had replaced the muscle fibres. Six years had elapsed since the operation, and the patient was entirely free from any sign of a recurrence. Cases of nævus-cancer were usually of such striking malignancy that the favorable result in this case, in which a metastatic deposit had already occurred, made it worthy of record.

Syphilitic Lesions of the "Wheal" Type.—Dr. H. G. Klotz, of New York, described an unusual eruption observed during the early period of secondary syphilis, and quoted similar descriptions from Taylor and Langlebert. The lesions resembled wheals, except for the absence of itching and other sensory symptoms, and their long duration. Nevertheless he believed it justifiable to accept the lesions as wheals, especially as the conditions found in the wheal of urticaria by several authors would fully account for the clinical features. Dr. Klotz called attention to the want of actual knowledge in regard to angioneurosis, and mentioned a recent paper by Brillippsoro which attempted to establish the origin of the so-called angioneurosis from embolism.

Dr. Joseph Zeissler said he had never had his attention called to this distinct syphiloderm as an independent form, but he had seen a case much like that described by Dr. Klotz.

Dr. J. Hyde, of Chicago, saw no reason why the introduction of a poison, such as syphilis, into the system should not bring about a series of changes in the skin.

Dr. J. Grindon, of St. Louis, said we should expect, reasoning *a priori*, to see such eruptions in syphilis.

Dr. Klotz stated that he was inclined to consider it a syphilitic eruption, differing from erythema and similar affections.

Endothelioma of the Skin Developing in the Scar Tissue of Lupus Vulgaris.—Dr. John A. Fordyce reported this case. A nodular growth developed in the scar tissue following various operative procedures on the lupus tissue on the forearm. The tumor upon excision proved microscopically to be an endothelioma, probably starting in the perivascular lymph spaces surrounding the smaller vessels. It was impossible to differentiate the growth in question from a small-celled epithelioma from the appearance of the cells alone. Their grouping about the dilated blood spaces enabled a diagnosis of endothelioma to be made. Although epitheliomas springing from lupus tissues had been not infrequently reported, Dr. Fordyce believed the case in question to be a unique one in that connection. Several cases of angiosarcoma were referred to in which tumors were found identical in structure with the so-called idiopathic pigmented sarcoma of Kaposi. These growths were histologically to be differentiated from the true endotheliomas.

Two Cases of Rhinoscleroma.—Dr. C. W. Allen, of New York, presented by title, with colored drawings and photographs, two cases of rhinoscleroma, one of which had been under his observation since 1889, the other for about three months. Both were already known to literature. In the first case the portion of the growth involving the centre of the upper lip, gum, and inferior portions of the nose broke down in a gangrenous suppuration, and within the period of a fortnight was completely thrown off, leaving the bones denuded. These subsequently became covered over with a reproduction of the new growth, so that eating, breathing, sleeping, etc., became more natural, and life was prolonged after it had been despaired of. In the case of the man, whose affection had existed for nineteen years at least, there was enormous enlargement of the external nose, with dilatation of the nostrils, which were also practically occluded. For nine years a tracheotomy tube had alone made breathing possible, and the stenosis extended the whole length of the pharynx, shutting off the posterior nares by bands and masses of fibrous tissue. Despite the severity of the condition present in both cases, there had been recent improvement in the general health.

An Unusual Form of Tumor of the Scalp.—Dr. Allen also presented a colored painting, gross specimen, and microscopical preparation. The tumor, which had been of slow growth upon the scalp of a woman advanced in years, had been widely excised after the diagnosis of probable carcinoma was made. The chief clinical feature of the tumor was its extreme hardness, almost like that of ivory. This was due to a central encapsulated mass which had undergone hyaline or colloid degeneration. Sections made by Dr. Martin Ware, to whom the reporter was indebted for a description of the appearances, showed an alveolar arrangement of polyhedral cells, growing in a very atypical manner. These cells were arranged about a central canal indicating that the growth emanated from glandular structure, either sebaceous or sweat gland. The cells did not take the hæmatoxylin and eosin stain well, because of the degeneration they had undergone.

A Case of Xanthoma Tuberculatum Diabeticorum, Showing Rapid Disappearance of Lesions under Anti-Diabetic Regimen and Treatment.—Dr. S. Sherwell reported and showed some excellent photographs of a case of this rare and interesting disease of the skin occurring in the person of a married woman, aged forty years. She was a somewhat plethoric and robust woman, as was usual in these cases. The patient was first seen January 9, 1900. The disease being recognized she was put under anti-diabetic regimen and diet alone until she was shown at a meeting of the New York Dermatological Society on January 23, 1900. A marked improvement had followed this course in the fortnight's interim. The subjective glycosuric symptoms had become less, the objective markedly so, say about twenty per cent. improvement. She was thereafter continued on strict diet, and some medication appropriate to the condition, with the result that in two months the lesions, even the pigmented stains resulting from the papular and tuberculate masses, had also disappeared. The amount of sugar, primarily enormous, was now slight, though always present. The speaker cited some of the more important authors on the subject, as Trök, Robinson, Walker, James C. Johnston, Toepfer, etc., and agreed with the opinions of those who had seemed to go into the question of etiology and pathology most closely, that it was an inflammatory disease resembling xanthoma, rather than a true xanthoma; but still he advocated retention of the name as sufficiently descriptive. Only somewhat over thirty cases of this peculiar disease had been so far recorded. Another case of the sort had been sent by him to Dr. Robinson in the fall of 1890.

Dr. James C. Johnston in another paper gave findings (histo-pathological) of one or two tumors excised from the patient's leg.

Blastomycetic Dermatitis and its Relations to Yaws.—Dr. Isadore Dyer, of New Orleans, read this paper. In many particulars the case fulfilled the clinical characteristics of yaws. Dr. Dyer examined specimens and confirmed the diagnosis of blastomycetic dermatitis. Under the iodide treatment the improvement was rapid; the lesions flattened, and the exudate diminished. Finally mercurial plasters were applied to all of the lesions, successfully reducing the granulations. At the present time the face showed a smooth, glossy area, marked here and there by a fibrous tab, and with a large, branching, somewhat keloidal scar in the lower part of the area. Over all there was a fine linear network of scars, soft but marked.

Three Cases of Blastomycetic Infection of the Skin, One of Them Producing a "Tumor" of the Lower Lip.—These were shown by Drs. F. H. Montgomery and H. T. Rickets.

A Review of the Subject of Blastomycetic Infection of the Skin, with a Report of Two New Cases.—Dr. J. N. Hyde, of Chicago, read this paper.

These two papers formed the basis for a general discussion of the subject of blastomycetes.

A Case of Erythema Elevatum Diutinum (?).—This was reported by Dr. T. C. Gilchrist, of Baltimore, who said that the case did not recall the diagnosis of lichen planus, and did not at all resemble Galloway's case of ringed eruption.

Dr. Hyde said he had seen a case which was almost identical with that of Galloway.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Twenty-second Annual Meeting, Held at Washington, D. C., May 1, 2, and 3, 1900.

Second Day—Wednesday, May 2d.

President, Samuel Johnston, M.D., of Baltimore.

Discussion: The Early Diagnosis and Treatment of Laryngeal Cancer.—The discussion was opened by Dr. J. N. Mackenzie, of Baltimore, who spoke on "Methods of Diagnosis and General Principles of Treatment." The speaker said he would confine his remarks to certain phases of the question which were at the present time more pressing and of immediate importance. Omitting the matter of a possible cancer bacillus, there were three methods of arriving at a diagnosis: (1) The naked-eye appearances combined with the clinical history; (2) thyrotomy, as affording a more complete inspection of the parts; (3) microscopical examination of a removed fragment. The second method was frequently a part of the first. The latter was the most practical of all, though we had unfortunately relegated it to a subordinate place. The removal of a fragment for examination generally so stimulated the malignant growth that it marked the beginning of the end. As to the clinical history no one solitary symptom was of unequivocal value. Many cases might be positively diagnosticated by this first method. He asked whether, when reasonable doubt existed, a piece should be removed for microscopical examination. In the view of the speaker, he should answer absolutely in the negative. Under the term thyrotomy, we might include even a more extensive division of the cervical tissues than mere laryngo-fissure. This was allowable in cases of reasonable doubt or when there was failure to define the exact territory occupied by the disease. Even here it might be impossible to map out the whole of the affected area. There might be a diffuse infiltration difficult, if not impossible, to recognize fully. As to removal of a piece for microscopical investigation it must be said that the patients were at once exposed to the danger of auto-infection or of metastasis. There was also the danger of stimulation of rapid increase of the neoplastic area. The method was unsatisfactory, inconclusive, misleading, and often impossible. As to the nature of the infectious element in cancer we were still in the dark. It might be a bacillus or inhere in some peculiar vital characteristic of the cancer cell. As to treatment, the time would probably come when the treatment of cancer would be not surgical but medical. An antitoxin would probably be discovered. At the present time the only safe procedure was the total extirpation through healthy tissue of the cancerous mass, together with complete ablation of the neighboring glands and lymph channels. Surgical methods in the past had been incomplete, and eradication had been only partial. It was indeed often difficult to determine the limits of disease, and the microscope would show infiltration in areas which to the eye appeared normal. There was often a diffuse infiltration or there might be a deep-seated epitheliomatous mass which only slowly approached the surface. If the disease approached the middle line, removal of tissue should be early and complete. Such operations should be undertaken only by surgeons of skill, and there should be the proper ethical relation between surgeon and patient, so that the latter should authorize the former to do whatever seemed most advisable. Under these circumstances the laryngologist must come to the aid of the general surgeon. The removal of the lymph structures in the area under consideration was one of the easiest dissections of major surgery. A low tracheotomy should be done. The chief danger was the recurrence of the disease in the cervical lymphatics. In cases seen very early, in which the growth was small and papillomatous in appearance, circumscribed, not in the median line, and not especially malignant looking, we might remove one-half of the larynx. Sometimes growths which seemed pathologically malignant were clinically benign. If there was no evidence of malignant infiltration in the pedicle, we might possibly be justified in removing simply the growth as it appeared without the more formidable operation. But even here there was doubt as to whether we had completely removed all the malignant deposit. As to removal of one-half of the larynx, the remainder was not of especial service so far as voice production was concerned. Intra-laryngeal operations in cases of extensive disease were to be condemned. Simple thyrotomy with curettage was not up-to-date surgery, and was a reversion of procedure to the status of fifty years ago. No operation could be assumed as correct which did not include the removal of the lymphatics. Success by partial removal might be explained by a mistake in diagnosis. Many adenomata had mistakenly been classified as true carcinoma.

Methods of Treatment and the Statistical Results.—This aspect of the question was discussed by Dr. D. Bryson Delavan, of New York, who exhibited elaborate statistical tables not included here. The speaker had made, seven years ago, an earnest plea for the full reporting of all cases, not only those which were successful, but those which were not. The tables presented were a careful compilation of one hundred and sixty-three cases occurring in the practice of some eight continental surgeons. No one had been included who had not had at least ten personal cases. This excluded all American operators. The current statistics on the subject were faulty because they were too promiscuous. The cases were confused and there was a resulting repetition. In some instances the patient had undergone more than one operation, and so appeared in more than one category. Finally in the published statistics there was no sharp line of demarcation between thyrotomy and partial resection. Out of the entire number of cases studied there had been only six per cent. of recoveries, that is, the patients were alive three years after operation.

The Surgical Procedures.—Dr. J. Solis-Cohen, of Philadelphia, said that before undertaking operation permission should be secured from the patient to do whatever seemed necessary. If the mass was of such a shape that a section could be punched out through the whole thickness, thus allowing examination of the cut surface, this procedure was permissible. If the growth affected the vocal band, a thyrotomy might be done and a knife be employed to remove the circumscribed diseased area. Partial extirpation was not reliable. In the performance of laryngectomy he would call attention to the following points: (1) In order to prevent the entrance of septic matter into the lungs, we should operate with the head of the patient in a semi-inverted position. Some material might be aspirated into the lungs, but this happened with a tracheal tampon, for absolute protection with the latter device is impossible. (2) Preliminary tracheotomy should be done, otherwise we may be troubled by the descent of the trachea. (3) The epiglottis should be retained if possible. (4) We should shut off all communication of the mouth with the air passages. In attaching the upper part of the trachea to the skin, the tube should be slit longitudinally for a short distance. (5) All dressings should be avoided. No packing should be allowed, as it caused a constant desire to swallow. Feeding by enema should be done and no tube be used per os. (6) The larynx should be removed from below upward, and after operation the foot of the bed should be elevated. For the proper attitude toward the practical problems of these operations a combination of the laryngological and surgical minds was needed.

Dr. C. C. Rice, of New York, expressed the conviction that the laryngologist should not turn over these cases to the general surgeon until the diagnosis was positively established. It was difficult to make an early diagnosis. He believed in giving the iodides and carefully watching the progress of the case before advising operation.

Dr. Emil Mayer, of New York, called attention to the fact that cases often diagnosticated as laryngeal cancer showed the origin of the growth to be in the œsophagus. He thought that there was a very decided limit to the extent of applicability of endo-laryngeal methods.

Dr. W. K. Simpson, of New York, could not advise total extirpation without a microscopical examination of a fragment removed for this purpose. No one could always make a diagnosis from appearances alone. If the case came to us early and showed an isolated deposit, we might use endo-laryngeal methods. In one of his own cases thus treated the man was alive four years after operation. In view of his personal experience, he could not advise total extirpation.

Third Day—Thursday, May 3d.

Secondary Hemorrhage after the Use of Suprarenal Extract.—This paper was read by Dr. F. E. Hopkins, of Springfield, Mass. He gave the histories of three cases of posterior exostoses of the septum in which the extract had been used, and in which secondary hemorrhage resulted. The object of the paper was to give the opinions of various clinicians to whom the author had written, as to the liability of hemorrhage under the conditions named. Almost all agreed that there was considerable danger, and that safety required the use of intranasal packing after the extract had been employed. In regard to the remedy causing coryza after being sprayed into the nose, there seemed to be an idiosyncrasy in this respect, and it could not be determined beforehand just who would and who would not be benefited by this procedure.

Dr. H. L. Swain stated that he had had more hemorrhage with cocaine and the extract combined than with either alone. It should be remembered that the latter acted on the muscular fibre of the arterioles and did not lead to the formation of any coagulum. Consequently when the vessel relaxed there was liability of bleeding.

Dr. J. W. Farlow, of Boston, had had no hemorrhage with the extract and had seen some remarkable cures of coryza follow its use. Yet it might benefit a patient at one time and cause him much discomfort at another. This experience had recently been met with in one of his patients. He had succeeded in removing headaches from intranasal conditions, sometimes in a very remarkable way. The question arose in such cases, how long it was judicious or safe to continue the use of the remedy.

Dr. A. W. Watson, of Philadelphia, had seen more hemorrhage with the use of the extract than without. He thought that after its use patients should be kept in the office for half an hour or so. Then if any dangerous degree of vascular relaxation occurred, they would be under direct control. He had seen acute coryza follow the intranasal use of the extract, and in his own person had had under these conditions what he believed to be a general acute sinusitis lasting ten days. He had thought that in the latter instance the solution might have become infected.

Dr. Swain said that if the fresh glands could be obtained, it was possible to make a solution of their active principles in acetic acid, and that this solution might be put up in glass tubes and kept indefinitely.

A Case of Ozæna of Probable Sphenoidal Origin.—This paper was read by Dr. J. W. Farlow, of Boston. His patient was a girl aged twenty-one years, with a crusty, odorous discharge from the left naris. There was considerable atrophy of the intranasal structures, but the discharge seemed to come definitely from the posterior portion of the naris. The probe seemed to pass into a cavity which was regarded as the sphenoidal sinus. Syringing with peroxide of hydrogen and an alkaline antiseptic, and later curetting, practically relieved all the symptoms.

Dr. S. W. Langmaid, of Boston, remarked that the recent epidemic of influenza would probably cause much sinus disease. That it did produce much acute trouble was in accord with his own experience, for he had recently seen five acute cases in two weeks. If the influenza attack passed off quickly, trouble in the sinuses would not result, but if for any reason the latter became obstructed, inflammation would be very probable.

Dr. A. W. Watson believed that ozæna could occur independently of atrophy, or there might be crusts without ozæna. He was inclined to regard true ozæna as due to sphenoid and posterior ethmoid disease. He preferred a very weak formalin solution for the irrigation of these upper and posterior regions.

Dr. Farlow, in closing the discussion, said that it was always advisable in looking at these cases to have the patient wait after the nose had been thoroughly cleared out, for then it would be possible to ascertain the exact site of discharge.

Bullous Middle Turbinates.—Dr. J. Payson Clark, of Boston, read this paper. He reported two cases, both in women, the prominent symptom being headache. The enlarged turbinates were removed without incident by the cold snare, with complete relief to symptoms.

Cyst of the Larynx.—Dr. Clark also read this paper. The mass was situated on the middle of the right vocal cord and from its hardness suggested a fibroma. The forceps slipped from its surface at the first attempt at removal, but it was cut with a laryngeal knife, when a fluid escaped showing degenerated epithelial cells and leucocytes. The firmness was probably due to the deep situation of the cyst in the substance of the cord.

Dr. Jonathan Wright, regarding the first paper of Dr. Clark, said that he was inclined to doubt the statement which had been made that these bullous conditions were the result of development from fœtal conditions and presented no inflammatory evidences. He had examined several of these masses and had found on the convex surface what appeared to be osteoblasts, and on the concave what appeared to be osteoclasts. The former produced bone while the latter absorbed it. The conditions met with might be due to the unequal activity of the two classes of cells beneath the embryonal layer of mucosa. It was a striking fact that most of these cases occurred in women and after the establishment of puberty.

Fibroma of the Larynx.—This paper was read by Dr. A. B. Thrasher, of Cincinnati. The patient was a woman aged fifty-six years, who had complained of dyspnœa and hoarseness. Her family history was negative. The posterior and lateral walls of the larynx seemed to be the seat of some deposit, so that the true cords appeared pushed in and were defective in abductor movement. A fragment of the mass was taken for examination. The report was fibroma. Iodide of potassium was given in increasing doses, but in a week the patient was seen again and was much worse. After a preliminary tracheotomy with the head dependent and gauze packing, the larynx was split, and it was seen that there was a submucous hypertrophy extending down to the cartilage. It appeared to be simply connective tissue. It was removed with forceps and the patient made a good recovery. The voice was now rough and hoarse, but audible. Two similar cases were described. The rarity of the case consisted in the extensive connective-tissue deposit.

Singular Exhibitions of Partial Paralysis of the Vocal Cords due to Over-Use of the Telephone.—Dr. C. C. Rice, of New York, read this paper. He said that he would make its title a query, for he desired to obtain the consensus of opinion as to the possible effect of over-use of the telephone on the voice. He had had two cases. The first was a nervous man, aged forty-five years, who had been accustomed to use a desk transmitter with his head in a cramped position. The cords showed evidence of fatigue of the thyro-arytenoid muscles, and there was a loss of sustaining power in the other outer muscles, for the cords trembled and the arytenoid cartilages separated immediately after approximating for phonation. The man was directed to take a rest from business and to use the telephone with head erect so as to afford perfect freedom of the cervical muscles. Recovery had been only partial. The other case was that of a man who was stout and not at all nervous. On the right side of the larynx there was fair adduction. The edge was straight but there was a lack of tension, with an incomplete view of the cord, which was obscured by the overhanging and congested parts. By rest and the assuming of a proper attitude while using the telephone, this patient completely recovered.

Dr. T. A. DeBlois opened the discussion by relating the case of a man whose head was violently bent forward as the result of a fall. As a result, a sudden strain was put upon the muscles of the neck, and he became hoarse from inability to approximate the cords.

Dr. W. E. Casselberry mentioned the case of a clergyman who was accustomed to become very much excited in his pulpit work, and gradually developed a similar condition to that seen in the cases mentioned by Dr. Rice. Rest and the formation of the habit of more quiet speech greatly improved the condition.

A Case of a Pin in the Larynx for Two Years; Removal by Endo-Laryngeal Methods.—This paper was read by Dr. A. W. de Roaldes, of New Orleans. The patient was a young girl in whose larynx a pin was found situated on the posterior portion, having pierced the apex of the right arytenoid at its inner side. Its head was embedded more deeply on the right side just above the false cord. Forceps was applied, the left index finger being placed behind the larynx to steady it. The forceps slipped, but the finger caught the pin, which was thrown out of the mouth. In such cases, when the head of the pin was below, it might at first have passed some way down the trachea and then have been coughed upward so that the point engaged. Moreover, the head of the pin impeded its migration so that it did not move about in the tissues as a needle would. The Roentgen rays might often locate the pin when it was impossible to make out its exact position by the mirror. Another point of interest in this case was a hard swelling in the neck which was probably due to infection which had stopped short of suppuration.

A Peculiar Case of Migratory Foreign Body with X-ray Illustrations.—Dr. D. Braden Kyle, of Philadelphia, read this paper. The patient was a woman, who constantly complained of a feeling as if a foreign body was moving about under the scalp. She suffered from intense neuralgias, which at times seemed to focus in the mastoid, and at other times in the ethmoid or antral regions. In one of these latter attacks there had been a discharge of purulent material from the naris and in the discharge was a piece of a needle. The symptoms continuing, it was concluded that still another piece was somewhere in the tissues, and an *x*-ray picture was made, showing a dark line in the neighborhood of the antrum, though it was impossible to tell whether the body was actually in the antrum or on the bone corresponding to one of its walls. The antrum was opened and its cavity illuminated, but nothing was found. In a short time a gumboil formed which discharged, giving escape to another piece of the needle. From this time all symptoms disappeared.

Dr. S. W. Langmaid called attention to the fact that attempts at swallowing often caused great changes in the location of foreign bodies in the upper air tract.

Dr. W. K. Simpson commended the trial of forceps and other instruments upon material similar to the foreign body before actually attempting the removal of the latter. He found sharp forceps better than merely roughened blades.

Dr. Kyle closed the discussion. He stated that the patient had suffered from an *x*-ray burn, and remarked that the time of the exposure causing the burn was not so long as the exposure on previous occasions when no burn had resulted.

Tracheal Injections in the Treatment of Pulmonary Tuberculosis.—This paper was read by Dr. T. Morris Murray, of Washington. He gave a short history of the development of this procedure, and then mentioned his personal experience with thirteen cases of pulmonary tuberculosis. In all there was at first a slight explosive cough, but in all the general effect on the cough had been good. No spasm had been noted. The solution used consisted of thyme and eucalyptus oils in olive oil. His experience had been that cough and expectoration had both been lessened, while the temperature had fallen and the general condition had been improved.

Dr. W. E. Casselberry believed that the benefit from this plan of treatment was confined entirely to the bronchitic element of the disease. He had no confidence in its alleged effect upon the general course of the tuberculosis. It did, however, benefit some of the symptoms attributable to the mixed infection which pulmonary tuberculosis presented.

Dr. J. Solis-Cohen observed that this was not a new plan of treatment, as it had been practised forty years ago. Its greatest benefit was seen in cases of bronchiectasis.

Correction of Deviations of the Nasal Septum.—Dr. John O. Roe, of Rochester, read this paper. It was an exposition of the plan of operation previously presented by the writer, whereby the septum was fractured by a fenestrated comminuting forceps. Of all deviations five per cent. involved the posterior part of the bony septum, twenty-five per cent. the anterior cartilaginous part, and from sixty-five to seventy per cent. the osseo-cartilaginous junction. Other descriptive terms simply referred to varieties and not to location. For anterior deviations he advocated a horizontal incision and an oblique bevelled incision, forming more or less of an angle with the first. By this device, the flaps would more easily slide by each other.

Surgery of the Turbinal Bodies, with a New Method of Operating.—This paper was read by Dr. J. E. Boylan, of Cincinnati. He advocated the removal of large portions of the turbinates when the obstruction had resulted from hyperplastic changes. The obstruction was more apt to be located at either end of the turbinate. Posterior obstruction was rarely of a hyperplastic nature. For instruments he used the saw, snare, and scissors, especially the snare. In this way he obtained better results than from the cautery.

Dr. W. E. Casselberry used the cautery but was careful to make deep linear incisions, and in this way had had no septic or other trouble. He urged caution in its use on the middle turbinate, care being taken to confine its action to the lower dependent portion of the bone, which he never cauterized on its upper surface.

Hemorrhage from a Peritonsillar Abscess.—Dr. W. F. Chappell, of New York, related this case. His patient was a young man aged twenty-seven years, who had had several quinsies, the most recent of which had been opened by an incision through the posterior pillar. Half an ounce of pus was evacuated. Five days later there was a severe bleeding. The urine showed albumin and casts. The bleeding recurred, and the abscess cavity appeared filled with clots. An incision was made through the anterior pillar, and the cavity washed out and packed daily for ten days, at which time the patient was well. Later a rheumatic attack came on without cardiac lesions. The condition of the kidney had continued up to the time of latest observation. When the cavity was opened for washing out, the ascending pharyngeal artery could be seen, but there were no evidences of ulceration. Dr. Chappell had been able to find the records of ten similar cases. All had occurred in patients in whom the quinsy had burst spontaneously. In no case had there been immediate hemorrhage. Of ten cases, eight had been fatal. In the two recoveries the carotid had been tied. The lesson from these figures was to open early.

During the different sessions of the association the following papers were read by title: "Laryngeal Irritation a Cause of Asthmatic Paroxysms," by Dr. W. L. Glasgow, of St. Louis; "Severe Hemorrhage after Operations on the Throat and Nose; Report of Five Cases," by Dr. A. A. Bliss, of Philadelphia; "Angioma Cysticum of the Nose; Histological Analysis and Physiologico-Chemical Research of its Contents," by Dr. H. L. Wagner, of San Francisco; "Dermoid Cysts of the Nose," by Dr. H. S. Birkett, of Montreal.

Officers Elected.—Officers for the coming year were elected as follows: *President*, Dr. H. L. Swain, of New Haven, Conn.; *First Vice-President*, Dr. H. L. Wagner, of San Francisco; *Second Vice-President*, Dr. A. A. Bliss, of Philadelphia; *Secretary and Treasurer*, Dr. James N. Newcomb, of New York; *Librarian*, Dr. J. H. Bryan, of Washington; *Member of the Council*, Dr. Samuel Johnston, of Baltimore.

The next meeting will be held at New Haven in the spring of 1901.

AMERICAN ASSOCIATION OF GENITO-URINARY SURGEONS.

Fourteenth Annual Meeting, Held at Washington, D. C., May 1, 2, and 3, 1900.

Second Day—Wednesday, May 2, 1900.

The Best Method for Obtaining Urine Direct from the Ureters for Diagnostic Purposes (being the subject decided upon by the Council for especial consideration and discussion).—Dr. F. Tilden Brown, of New York, opened this discussion. He said that in the majority of all cases presenting he would offer the statement that the best way to obtain urine direct from the ureters for diagnostic purposes was (1) by one which was equally applicable to both sexes; (2) by one which secured the individual secretion of each kidney beyond any question of its contamination by the secretion of its fellow-gland, or by other extraneous material from the lower part of its urinary tract; (3) by one which effected these requirements with a minimum amount of discomfort to the patient, while involving the least possible risk of immediate or remote harm to the parts involved in the total procedure; (4) and of least moment in so important a matter, by that method which called for the simplest technique. After excluding all cutting operations for collecting separate urines he proceeded to discuss the relative merits and demerits of the Simon-Pawlik-Kelly method, the Harris method, and the ureteral-cystoscope method. The many details of this led him to express a decided preference for the third method, although citing a brief series of exceptional cases in which this method would have to give place to that of Kelly or Harris. Dr. Brown took advantage of this opportunity to make the first public presentation of his double-barrelled ureteral-cystoscope, the advantages of which were summed up as follows: (1) In favorable cases both ureters could be catheterized at approximately the same time. (2) In less favorable cases, after passing one catheter the second channel could be used to draw the distending fluid from the bladder, thus giving the organ repose. (3) In still more difficult cases the second barrel could be used for frequent irrigations until fluid of proper transparency distended the bladder and permitted localization of the ureter, when a catheter, which has been reposing in the other barrel, could be used to engage the ureter; by taking hasty advantage of a momentary clear fluid success may be made of an otherwise failure. (4) In some cases in which but one ureter can be catheterized, this double-barrelled instrument permitted access to one ureter through one canal, and urine coming into the bladder from the opposite kidney could be collected from that source by catheter siphonage through the second barrel.

Dr. W. K. Otis, of New York, did not believe that there was, at the present day, any satisfactory way of differentiating urines in all cases, and probably never would be. In many instances it was impossible to locate the ureteral openings at all, and even when the opening was localized it was often difficult to gain an entrance. He referred to the danger of causing an ascending pyelitis in attempting to catheterize the ureters when this attempt was made through an infected bladder. In the use of Harris' instrument much pain was frequently given to the patient. When the ureter was catheterized through a ureteral cystoscope, when the ureter can be catheterized at all, it seemed to him a most satisfactory method of differentiating urines by catheterizing both ureters; then just what was coming from each kidney could be discovered; that method was the only satisfactory one yet devised. So far as the female was concerned, he thought that Dr. Kelly had solved the problem as thoroughly as it would be solved; but in the male the conditions were different, and he doubted whether any simple instrument would ever become popular, *i.e.*, any instrument with lenses. His reasons for this statement were the difficulty that was experienced from the size of the instrument, the difficulty of manipulation, etc., which were likely to do damage and produce much pain, and, at the same time, it gave a comparatively small field of vision. He had always been in favor of the so-called direct catheterizing cystoscope of what Dr. Brown calls the convex tube. In the instrument he had devised, a metal instrument could be used, and a metallic sound could be passed as well as a catheter for sounding the ureters for calculi. His instrument was identical to the Brennan instrument so far as the opening was concerned. In all these instruments, as the Casper, Nitze, etc., ocular apparatus was sacrificed to reduce the size of the instrument itself. Instead of constructing an instrument carrying so many tubes he had devised a cystoscope with a single tube, as used in the Leiter instrument; the wire was on the outside of the tube, which took up an exceedingly small amount of room; so he got the full-sized field for catheterizing the ureters, and, at the same time, he utilized the full size of the ordinary cystoscopic telescope. He obtained exactly the same field as in the Leiter instrument.

Dr. Malcolm L. Harris, of Chicago, continued the discussion at the invitation of the association. In summing up his remarks he stated that catheterization of the ureters had a field of application which was absolutely distinct, in the sense that no other means at our disposal accomplished the same end, namely, to determine the nature and location of obstruction of the ureter; to locate the ends of a divided ureter or act as a guide in certain intra-pelvic operations; for tapping and draining fluid accumulations in the renal pelvis; for therapeutic purposes such as dislodgment of calculi, irrigation of the renal pelvis, etc. Catheterization of the ureters simply for the purpose of collecting urine for diagnostic purposes had its drawbacks and limitations, among which might be mentioned temporary anuria, due to the presence of the catheter in the ureter; contamination of the urine with blood and epithelial cells from the ureter; danger of infecting a healthy ureter and kidney. This last point he thought to be of such a serious nature that catheterization of a healthy ureter, when the bladder was infected, or the opposite kidney tuberculous, had been condemned. If this injunction was heeded as it should be, it would deny the benefits of this diagnostic aid to a large class of patients. The segregator, likewise, had its limitations. There were certain cases which were not suited for its use. In certain intra-vesical lesions its use must be supplemental to that of the cystoscope. But for the differential diagnosis of certain tumors of the abdomen; for determining which kidney was diseased and the "functional activity" of each and whether the bladder was infected or not; for differentiating between certain bladder and kidney infections, the segregator gave results that were perfectly reliable, as had been repeatedly demonstrated by numerous anatomical findings. Furthermore, in the infected cases it had the advantage over the ureteral catheter of being free from the danger of infecting a healthy kidney.

A Ureter Cystoscope (for Male or Female) Built on a New Model.—Dr. Bransford Lewis, of St. Louis, demonstrated this instrument, which had the definite object in view of catheterizing both the male and female ureters. It consisted of a tube which carried on its upper surface the conducting wires for the electric light, and within, on its lower surface, a small tube for guiding the ureteral catheter to the desired point, *i.e.*, into the ureteral opening. At the ocular extremity was a handle for controlling the direction of the instrument; at the distal end, contained within the curved tip, was the electric lamp, of low tension, affording sufficient light for illumination, but generating hardly any heat; permitting, therefore, the use of the cystoscope within the empty bladder and without the complicating presence and often interference of fluid. The light from the lamp was shed on the adjacent mucous membrane through the glass window sealed in the roof of the tube just below it. The tip of the cystoscope was a hollow cap, attached by a screw, and could be removed for replacing a burnt-out lamp. This latter was easily accomplished in the manner made use of in the Chetwood urethroscope. To facilitate introduction, an obturator was furnished which closed the distal orifice until it was removed, preventing scraping of the membrane against the edge of the opening; but, at the same time, these edges were rounded so that they could be brought in contact with the membrane within the bladder, or the instrument, being withdrawn into the prostatic urethra a certain distance, could be pushed back into the organ without injury to the surface coming in contact with them. A small silk-web ureteral catheter completed the instrument. For several years ureteral catheterization in the female had been *un fait accompli*, and to a high degree of satisfaction to the profession. The Pawlik-Kelly method was in daily use the world over for both diagnostic and therapeutic purposes. Yet, if this method could be improved upon by being made easier or more certain of accomplishment, or if the duration of the search for the ureteral openings could be shortened, or if the pain so often suffered by the patients from the preliminary dilatation of the urethra, or the introduction through it of a cystoscope sufficiently large to afford a good view, could be obviated, then these objects should be accomplished, even though the instruments already in use had proved of such inestimable value. He believed that these features, two in number, of fixed internal heatless illumination and of complete control over the internal end of a flexible ureteral catheter, when applied to a tube of proper form, would secure the advantages mentioned.

Dr. W. T. Belfield, of Chicago, stated that six years ago or longer he presented an instrument such as presented by Dr. Lewis; the latter instrument was a duplicate of his except that it possessed two features of difference: First, the substitution of a low-tension cold lamp for that employed in his; second, the presence of a groove for the conduction of the ureteral catheter. He found a great difficulty to be overcome was the heating of the lamp; at the time his instrument was produced the low-tension light was not known. He hoped soon to be able to produce such an instrument, so perfect in detail that it would do away with the necessity of such discussions.

Dr. W. K. Otis thought the idea of having the little groove for the conduction of the catheter at the bottom of the instrument was an excellent one. He found that one of the principal difficulties he encountered was the size of the instrument. He thought he used as large-sized urethral instruments as any one present; but when it came to using a tube as large as the one presented, and moving it around to find the ureteral orifice, the difficulties encountered must be great; the patient must suffer a great deal of pain, and if the patient was under the influence of an anæsthetic one was liable to damage the tissues. In the male he found that it was not easy to find the ureteral opening.

Dr. L. Bolton Bangs, of New York, thought the great difficulty with this instrument was from the amount of heat produced. He related the experience of Dr. Howard Kelly, whom he invited to New York to demonstrate the use of the cystoscope in the male; there were many cases in which the straight tube could not be introduced; the same might be said of short curved instruments. Three patients were provided for Dr. Kelly, but on two only was the attempt made to pass the catheter. In one he succeeded. He failed in getting the tube in when the attempt was made in the second case. In the third case it was not attempted. He had not used the straight tube except to get a view of the deep urethra and the contiguous portion of the neck of the bladder. His own repeated failures made him decide to go to the dead-house, where he had bladders opened; there he was surprised to find that he was unable to locate the ureters except by inserting carefully the point of a probe. He asked if others present had experienced the same difficulties. He could not see the ureters; he thought the position of them must be guessed at; the swirl caused by the fluid which gushed out prevented him from finding the openings. He referred to the case reported by Dr. Howard Lilienthal, of New York; this patient died of sepsis from infection; traumatism was produced, and the patient became infected and died. He had come to the conclusion that, unless there was some positive reason for doing otherwise, Harris' segregator was to be preferred.

Dr. John P. Bryson, of St. Louis, said that his experience in the use of this instrument had been the same as that of Dr. Bangs; he had never been able to use the straight tube.

Antero-Posterior Subdivision of the Bladder; An Important Anomaly.—Dr. Eugene Fuller, of New York, read this paper.

Radical Treatment for Curvature of the Penis.—This paper was also read by Dr. Fuller.

Officers Elected.—The following were elected for the ensuing year, 1900–1901: *President*, Dr. Samuel Alexander, of New York; *Vice-President*, Dr. W. T. Belfield, of Chicago; *Secretary*, Dr. J. R. Hayden, of New York; *Member of Council*, Dr. W. N. Wishard, of Indianapolis.

Members Elected.—The following new members were elected: Dr. Henry H. Morton, of Brooklyn; Dr. Charles H. Chetwood, of New York; Dr. Alfred C. Wood, of Philadelphia.

The next place of meeting will be Old Point Comfort, April 30, May 1 and 2, 1901.

Third Day—Thursday, May 3d.

The Effects of Ammonio-Formaldehyde.—Dr. Edward L. Keyes, Jr., by the courtesy of the association, presented this paper, which was founded upon clinical observations illustrating the effects of this drug. His conclusions were as follows: (1) Ammonio-formaldehyde (urotropin) seemed to be a specific in the treatment of some cases of acute catarrhal pyelitis, uncomplicated. (2) To prove effective it might have to be administered in large doses until the urine was practically clear of bacteria, after which a smaller dose might suffice. (3) In judging the effects of the drug, the centrifuge and microscope should be employed. (4) The dose must not be sufficient to cause pollikiuria and dysuria by irritation of the neck of the bladder. (5) The possibility of such an irritation could be overlooked, even when small doses were employed. (6) Ammonio-formaldehyde was extremely serviceable as a prophylactic to the various forms of urinary septicæmia and urethral chill. (7) Its routine employment, both before and after operation on the urinary passages, was indicated. (8) The urine containing ammonio-formaldehyde occasionally had an escharotic effect upon wounds, which might constitute a contraindication to its employment.

Dr. George Chismore, of San Francisco, considered this a very valuable agent in controlling bacterial conditions, but thought that one should be careful to use Merck's preparation, which was more woolly in appearance and less clearly crystalline. He thought that the sudden accession of temperature and the exhibition of certain other symptoms in cases in which irrigations had been used were attributable rather to the irrigation than to the urotropin (ammonio-formaldehyde).

Dr. John P. Bryson said that the experiences recorded in the paper agreed so thoroughly with his own that he had but little to add except to indorse what had been said. He had seen cases of tuberculous disease in which urotropin had been used alone result in polyuria; but as soon as carbonate of creosote was given in conjunction, relief was obtained. In some cases the urotropin had to be withdrawn, for it made the granulations pale and flabby. He referred to two cases in which there was a certain form of diplococci, which did not yield at all to large doses of urotropin; these diplococci persisted in the urine in spite of everything done.

Dr. L. Bolton Bangs thought the observations made in the paper were worthy of being placed on record. In order to get the beneficial effects of the drug the urine must be acid at the kidney. Professor Morton, of Stevens University, observed the same, that it was a useful bactericidal weapon if set free in the acid urine.

Dr. W. F. Glenn, of Nashville, referred to one case in which gr. viiss. in twenty-four hours could not be borne on account of the extreme vesical irritation. He had never seen a single nervous chill arise when urotropin had been given one week before the time for operating; large quantities of water should also be administered. He thought the paper a very valuable one, and believed that urotropin would solve the trouble resulting from urinary fever and nerve chills.

Prostatic Deformities due to Loss of Tissue.—Dr. Ramon Guitéras, of New York, read a paper with this title. He related the instance of a Greek who entered the City Hospital; the interesting features presented were the absence of the entire lobe of the left side, and an unnatural lateral curve in the prostatic urethra, due to cicatricial contraction. He also related an instance of the destruction of one lobe of the prostate by a tuberculous abscess. This case was evidently one of tuberculosis of the genitals with an abscess springing from the cord in the inguinal canal, with a tuberculous inflammation of the right seminal vesicle, which had converted the vesicle into an abscess cavity that had drained down the ejaculatory duct out of the hole in the prostate made by another abscess in the ejaculatory duct or in the right lobe of the gland. The next case cited was one of prostatic abscess, which was followed by a septic pneumonia and death. There was another class of patients in whom the prostate had been almost entirely destroyed, and there remained simply remnants of the gland tissue along the ejaculatory ducts, or along the margin of the gland. Two cases were recalled in which the ejaculatory ducts could be distinctly felt extending down to a point where they probably opened into the urethra, and in which no prostatic tissue could be felt, and another in which they extended in the same way, but with some remnant of glandular tissue by their sides. In both these instances the normal outlines of the gland could not be detected. He said there were other instances in which the outlines of the glands could be distinctly felt, and yet the entire centre of the glands was depressed. These deformities of the prostate usually resulted from abscesses that had broken into the urethra, and consisted of collapsed sacs surrounded by a pyogenic membrane, which continued to discharge pus for a considerable time. Old sinuses were often found opening into the prostate in autopsies or on the dissecting-table. Another type of prostatic deformity had been that produced by a considerable amount of exudate about the prostate, with resulting cicatricial contraction which distorted the gland very much by pressure, and also interfered with the action of the vesicles; here, too, the circulation was much interfered with, which caused a great deal of discomfort in the perineum and deep genital regions. The symptoms arising from prostatic deformities were generally those of chronic prostatitis. The treatment of such cases was usually unsatisfactory.

Prostatic Cancer; Three Cases with Specimens.—Dr. E. E. King, of Toronto, thought that the relative infrequency of primary prostatic cancer justified him in bringing this subject before the association. He gave histories of cases and remarked upon them. His cases did not differ from the general rule of cancer of the prostate being found in the young, or in those past the age of fifty years, although just why the ages between fifteen and fifty should be exempt he did not know. Most of the cases noted began about one year before a fatal termination. In the statistics of Tanchow. out of 1,904 cancers in the male, he referred to but 5, or only 1 in 400. Munn, in 1,286 cases of cancer taken from the reports of the Middlesex Hospital up to 1899, tabulated only 28 cases of cancer of the male genitalia. Fenwick (*Edinburgh Journal*, July, 1899) referred to 50 cases of undoubted primary affection of the prostate as coming under his personal observation. He liked the manner in which Fenwick divided the condition, which he believed to be the correct one, viz., (1) the hard, malignant growth, resembling scirrhus of the breast; (2) the soft, malignant growth, which resembled the encephaloid. Fenwick said the second variety was much rarer than the first, which was in opposition to the usually accepted belief; each of his own cases had been of the hard variety. The speaker concluded by stating that the features which impressed him in the cases cited were: (1) The very advanced stage of the disease before being recognized; (2) the cessation of symptoms on rupture of the capsule; (3) the non-involvement of the bladder in either specimen shown; (4) the absence of metastasis in one case, and the metastasis of the kidney alone in the other.

Dr. L. Bolton Bangs was struck with the statement that primary carcinoma of the prostate was extremely rare—he supposed it was relatively rare. The occurrence every now and then of ordinary prostatic hypertrophy with compensatory symptoms in the bladder, etc., pursuing an unusual course led him to suspect that the diagnosis of this condition was not always made.

Dr. Bransford Lewis referred to an early diagnosis of a case of primary cancer of the prostate occurring in the City Hospital in St. Louis. That patient had no symptoms at all previous to ninety days before his death. He did not even have frequent urinations. One day before entering the hospital he climbed to the top of the custom house, which was followed by complete retention of urine. Upon entering the hospital an attempt to draw the urine failed; various means were employed, but to no avail. Perineal urethrotomy was then done, but it was impossible to enter the bladder, even when strong pressure was used. He then did a suprapubic cystotomy, when the real conditions of things was noted. There was a prostatic carcinoma so large that it filled the outlet of the pelvis and was jammed between the anterior and posterior walls, so that nothing could be gotten through. This man was relieved somewhat by continuous drainage, but died soon after. The pathologist pronounced the growth to be an adeno-carcinoma. So far as clinical evidences were concerned, it was short-lived.

Dr. George Chismore thought that cancer of the prostate was much more common than recorded. He had seen a number of cases, and he had been led to look with a great deal of apprehension upon those cases in which, without ostensible causes, catheterization was extremely painful. He had observed two different forms of the disease—one, in which the scirrhus type prevailed, which pursued a very long and tedious course; the other, in which the cancerous condition was unsuspected almost until the last; all were characterized by unusual pain and difficulty in attempts at catheterization. He referred to the case of a man who was accustomed to use the catheter from his forty-seventh to his seventieth year of age, in whom almost all the symptoms of cancer developed within two weeks preceding his death; this man had rapid ulceration, with the formation of a urethro-rectal fistula.

The Subjective Symptomatology of Renal and Ureteral Disease.—Dr. John P. Bryson, of St. Louis, read this paper. Many clinical observations had been made by him, and from these he inferred (1) that an irritation arising in an otherwise healthy urinary tract in the kidney or its pelvis would create subjective symptomatology referable to the organ itself, and, if passing beyond that, radiate toward the centre of the abdomen along the line of the nerves entering the hilus of the kidney along with its blood-vessels, crossing over, when severe, to the opposite side, and, especially when the right kidney was involved, causing vomiting. (2) Similar irritations affecting the middle third of the ureter caused a subjective symptomatology manifesting itself largely in the distribution of the genito-crural nerve. (3) Similar irritations affecting the lower part of the ureter in the neighborhood of the bladder would manifest themselves chiefly by increased frequency of urination without tenesmus, provided the bladder was otherwise free from disease. In all of these conditions there was a certain amount of tenderness on pressure or pain in that portion of the ureter which was being irritated at the time. Time did not permit him to detail some cases in which, especially in tuberculous inflammations more or less localized, the disease originating in the bladder in the neighborhood of the ureteral orifice travelled up that duct on that side, creating a subjective symptomatology in the reverse order to that mentioned. Just how far down an irritation must travel from the renal pelvis, or how far up the bladder, before affecting a genito-crural nerve, it was not possible to state. We might be aided, however, to a certain extent by anatomical considerations. The chief point in practice was to take advantage, in localizing ureteral disease, of the observation that in apparent irritation at the upper part of the ureter, in the kidney and its pelvis, the manifestations were renal; in the middle portion, genito-crural; in the lower portion, vesical. This might serve as a guide for surgical interference in cases of ureteral disease.

Dr. Arthur T. Cabot, of Boston, referred to cases in which stone in the pelvis of the kidney gave rise to symptoms entirely referable to the neck of the bladder. He cited one case in which the symptoms were, for some time, referred to the neck of the bladder; the patient subsequently went to Paris and was treated by Guyon with injection of nitrate of silver, when a stone passed down through the ureter and was discharged into the bladder, which was accompanied with entire relief of symptoms. He was interested in Dr. Bryson's account of the nervous distribution giving rise to such variations in the pain.

Dr. Edward L. Keyes related the case of an old gentleman who came to New York with a stone in his bladder, which was crushed and removed. This patient was in his "catheter life." He had no cystitis or prostatic disease. He went home and lived a number of years, a strong, vigorous man, about sixty-five years of age, and had no pain except a little renal colic. Suddenly, while in the bloom of life, he was attacked with a sharp paroxysm of kidney colic, for which he was treated by the ordinary methods employed in those days; he died from an ordinary anuria. The autopsy showed one kidney atrophied, with hardly any kidney substance left. The expulsive force from his bladder was good. Vesical spasm caused his retention. The wall of his bladder was smooth and not affected, there being no evidences of cystitis. The other kidney was blocked or plugged by a calculus which had caught in the upper end and stayed there. There was persistent inability to pass urine. This, he thought, was a curious case.

Dr. W. K. Otis related the case of a woman forty-six years of age, who was treated for cystitis for years. She suffered much from irritation and frequency in urination for about fifteen years. The cystoscopic examination showed there was no cystitis. Catheterization of the ureters showed that the left ureter gave out pus; the right ureter was shown to be perfectly normal. The left kidney was cut down upon and was found to be riddled with abscesses, and there was a stone that filled the entire pelvis; the kidney was almost completely destroyed.

Dr. John P. Bryson, in closing the discussion, mentioned the instance of a patient who, when there was the sudden desire to urinate, obtained relief by lying down; in this case there was no vesical tenesmus; this latter symptom in connection with bladder lesion was very important. Before he saw her she had been under the influence of chloroform for four days. He stopped the chloroform and watched the symptoms for a while; she had a constant, unceasing desire to urinate, and a pyuria without any vesical tenesmus. He cystoscoped the patient and found a pus plug coming out of the left ureteral orifice. The bladder was fairly normal. The urethra was then dilated; the left finger was introduced into the bladder, the right finger was placed in the left vesico-vaginal fornix, and he then milked out a mass of material which relieved her symptoms entirely; she soon became perfectly well. He thought it was not an uncommon thing for a lesion to exist at the lower end of the ureter along with renal lesion of a very serious character, a calculous nephritis or a nephro-lithiasis.

Acute Abdominal Symptoms Associated with a Congenital Malformation of a Ureter in a Child.—Dr. Charles L. Scudder, of Boston, read a paper on this subject, illustrating it with numerous drawings. The blind end of a supernumerary ureter was cited, which was the ninth reported, the other eight being found reported in Dr. Bangs' book.

Bacteruria Associated with Congenital Dilatation of a Ureter.—Dr. George K. Swinburne, of New York, reported this case. The persistent residual urine was the particular symptom present. The diverticulum was one and a half inches above and to the left of the ureteral orifice.

Dr. Arthur T. Cabot told of a case in which he had done a suprapubic operation and found a stone in a diverticulum located close to the ureteral orifice. The stone was of good size: the patient gradually died of a pyelonephritis. The autopsy showed another pocket, exactly corresponding to the one on the opposite side and also containing a calculus; it had set up a hydronephrosis behind it.

Dr. George Chismore said he had had the opportunity of making a post-mortem upon a patient in whom, for fifteen years, he had been removing stones by litholapaxy; he first did the suprapubic operation and cleaned out the bladder thoroughly. He had not had occasion to operate upon this patient for more than a year, he having moved away and died while under another man's care. He found in the right ureter a collection of seven stones; in the left ureter, within the bladder wall, were found five stones small in size. He also found a thin stone, spoon-shape, behind the tumor which projected into the bladder wall between the ureters. The ureters were much dilated.

Dr. John P. Bryson stated that the difficulties in making a differential diagnosis between calculus or multiple calculi in the bladder and in the lower end of the ureters must be very great. He had had some curious experiences. In one instance the calculus lay near the end of the right ureter and was fastened there; he was forced to dilate the ureter in order to get it out; he there found an old hernia in the muscular coat, the fibres spreading.

Cases Illustrative of Certain Points of Renal Surgery.—Dr. Francis S. Watson, of Boston, read this paper. The cases reported were as follows:

Case I.—Nephrorrhaphy in the fourth month of pregnancy. The operation was undertaken in the hope of avoiding the necessity of inducing premature delivery, which had already been done in two former pregnancies because of the patient's life being endangered by persistent vomiting associated with frequent attacks of renal colic on the right side, which developed in connection with a movable kidney which followed the second pregnancy seven years previous to her present trouble. On the first occasion both vomiting and renal pain ceased after the premature delivery. But after the second time vomiting alone was relieved, the pain persisting, though in a somewhat less degree, until her present pregnancy, when it became very severe and the vomiting also returned. The patient's life was again seriously threatened. She stated that she thought the vomiting was directly induced by the attacks of pain. She strongly urged that every effort be made to allow the pregnancy to go on to term. The question was, how far the mobility of the kidney was responsible for the pain and vomiting, and whether the chance of relief from a nephropexy was sufficient to justify the risk incurred by its performance, in addition to that attending the induction of premature delivery should the latter be necessitated in case of failure of the former, and, moreover, with the knowledge from two former experiences that she would probably be made safe by emptying the uterus alone, and would be relieved of the vomiting at any rate. Nephropexy was decided upon for these reasons: (1) The strong wish of the patient not to sacrifice the child; (2) the great probability that her pain at any rate depended upon the abnormal mobility of the kidney; (3) the chance that vomiting was in large measure also due to it; (4) because her condition seemed sufficiently good to enable her to support the nephropexy. It was accordingly done, and, while greatly mitigating her pain at once, did not relieve the vomiting, the continuance of which became so threatening to her safety that abortion was done, after which both the vomiting and pain wholly ceased and her convalescence was much more satisfactory than after the two preceding pregnancies. It seemed reasonable to assume that the nephropexy should be credited with the success in that respect, although it failed to fulfil the expectations with regard to the matter for which it was primarily undertaken. The question raised in this case that seemed to the writer of interest was as to the wisdom of attempting to avoid sacrificing the life of the fœtus by doing nephropexy under the conditions presented when a decision was called for.

Case II.—Traumatic rupture of the kidney; nephrotomy; suture of the wound to relieve obstruction to outflow of the urine by plugging the ureteral orifice with blood-clots, and to control hemorrhage eight days after the injury. The case was an example of the development of serious symptoms at a relatively remote period from that of the injury, and showing that an immediately favorable progress of the case did not necessarily preclude the occurrence of grave danger subsequently. The patient was a young man twenty-eight years of age, who had received no less than five injuries to the right lumbar or right abdominal regions between the twelfth year and the present time, the last one being a violent blow during a fight in which he was engaged on the night before he was brought to the Boston City Hospital. There were marked shock, pain, and tenderness of the right kidney, and much blood in the urine. There was no sign of external violence. The pain and shock were of short duration. The hæmaturia persisted. The general condition gradually improved. On the seventh day there was sudden violent renal colic, with cessation of hæmaturia, and the appearance of a tumor in the right hypochondrium and lumbar regions, with great prostration. Twenty-four hours later he rallied somewhat and nephrotomy was performed. The kidney had a lacerated wound an inch and a half long at its upper end, which did not penetrate the fibrous capsule, but extended from the surface of the cortex through to the renal pelvis, which was enormously distended by blood clots and urine, the former occluding the orifice of the ureter. The posterior border of the kidney was incised, the blood-clots were evacuated, the edges of the lacerated wound refreshed, and the incision, together with the wound except for a short space to allow drainage, was sutured with catgut. The hemorrhage was entirely controlled by the sutures. The hæmaturia ceased and the patient made a good recovery, but some months later renal pain returned, and nephrectomy was done with satisfactory results by Dr. Paul Thorndike.

Cases III. and IV.—These were cases illustrating the relief of symptoms simulating renal calculus, no calculus being found, by incision through the convex border of the kidney, and confirming the view that such symptoms were, in many instances, due to sudden enlargements of the kidney within an unyielding capsule. In both of these cases the capsule was thickened and adherent to a greater or less degree.

Cases V. and VI.—These were cases of kidneys fixed in abnormal position by firm adhesions; the kidney in one was hydronephrotic; in the other it was structurally normal. Nephrectomy was done in both cases because of the impossibility of freeing the kidneys from adhesions without tearing the renal substance and the pelvis or ureter, and because, in one case, of the extensive hydronephrosis as well. One patient recovered and was entirely restored to health. The other died of a pneumonia on the thirteenth day following operation. The symptoms in both were attacks of renal pain on the right side with progressive frequency and severity.

Case VII.—This was a case serving as an example of the danger of postponing surgical interference in some cases of movable kidney, which, in this instance, resulted in the almost total destruction of the kidney by intermittent hydronephrosis, which finally became pyonephrosis. Renal calculus was associated with this condition. Nephrolithotomy and temporary drainage resulted in a cure; the wound healed at the end of three weeks and the pus disappeared from the urine after six weeks.

Case VIII.—Resection of one-half of the kidney for tuberculous disease was done, which demonstrated the very marked general improvement that might follow even the incomplete removal of a tuberculous area, and the possible benefits from doing a resection in cases in which the patient's condition did not seem to warrant a nephrectomy.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Seventeenth Annual Meeting, Held at the Arlington Hotel, Washington, D. C., May 1, 2, and 3, 1900.

Second Day—Wednesday, May 2d.

The Construction and Management of Small Cottage Sanatoria for Consumptives.—Dr. Arnold C. Klebs, of Chicago, read a paper on this subject, in which he said that with the opening of the Massachusetts State Hospital for Consumptives a new era had dawned for the treatment of these patients. The advantages which would accrue from the multiplication of similar institutions for the home treatment of tuberculosis could not be overestimated. Every one agreed upon the great educational influence which the sanatorium régime had on the individual, who later became a missionary in the cause of hygiene, by example and by teaching spreading broadcast the principles to which he owed his recovery. Dr. Klebs' paper was largely devoted to a discussion of the proper construction of small cottage sanatoria, and he exhibited the plans for such an institution which he had devised. The plans embraced three cottages, with a capacity limited to twenty-five patients. The cottages were joined by two galleries, so arranged as to admit a plentiful supply of sunlight and air, and the importance of these factors was borne in mind in the construction of the cottages.

Dr. Henry P. Loomis, of New York, said that while the cottage plan of sanatoria was the ideal one, it was also the most expensive, and could not always be carried out on that account.

Dr. C. F. McGahan, of Aiken, S. C., said that after a visit to all the principal sanatoria abroad he was most impressed by that of Walters, at Nordrach, the capacity of which was limited to forty patients. Walters claimed that one man could not attend to more than this number. He visited his patients twice daily and carried out a very thorough system of management.

Dr. E. O. Otis, of Boston, said that the excellent results achieved in the Massachusetts sanatorium at Rutland during the past year had opened the eyes of the people to the fact that tuberculosis could be cured right in their own State, and they had become so much interested in the subject that the construction of a second similar institution was under consideration. The weekly expense of each patient at Rutland was $8.40.

Dr. Carroll E. Edson, of Denver, said that while large sanatoria were expensive, the general plan of treatment pursued in such institutions could be carried out on a small scale in any properly constructed, well-ventilated house. We might not be able to erect a sanatorium like those at Rutland or Liberty, but we could start one, perhaps, in our own back-yard.

Dr. J. Edward Stubbert, of Liberty, said the question of expense was always a very important one in the construction of sanatoria. While the cottage plan was the costliest, it was no doubt the best. Most of these patients did not like to be too close to each other, and were annoyed by the coughing, etc. Dr. Stubbert said that during the past winter the patients at Liberty took up amateur theatricals as a means of amusement, with very gratifying results.

Dr. Edward R. Baldwin said that at Saranac Lake the expense of each patient was between $7 and $8 per week. It should be taken into consideration, however, that Dr. Trudeau received no compensation for his services in supervising the institution, and a salaried man occupying that position would probably increase the cost of each patient to about $8.50 per week. At Saranac the number of cottages had been gradually increased until one hundred patients could be accommodated. A larger number than this Dr. Trudeau considered unwieldy.

Dr. R. C. Newton said that in the lack of sanatorium treatment, or instead of it, bands of incipient cases of tuberculosis might be collected and sent out into the woods and country on tramping trips under an intelligent leader.

Dr. Klebs, in closing, said that the plans he had shown were for an inexpensive sanatorium made up of three properly constructed cottages.

Some Personal Observations on the Effects of Intra-Pleural Injections of Nitrogen Gas in Tuberculosis.—Dr. Henry P. Loomis read a paper on this subject, and gave the following as his conclusions after about eighteen months' test of this treatment for pulmonary tuberculosis: (1) That it would have a permanent place in the treatment of pulmonary tuberculosis. (2) He had never seen any bad results or even unpleasant effects following the injections. (3) He had seen no patients cured by it. In two cases there was an apparent arrest of the disease, and in a number of others there was a disappearance of such constitutional symptoms as cough, expectoration, and fever. (4) The local improvement was not so apparent as the constitutional. (5) A marked gain in weight was found in every case injected. (6) It had never failed to stop pulmonary hemorrhages, even in desperate cases.

Dr. Taylor said he had employed the injections of nitrogen gas in about half a dozen selected cases of pulmonary tuberculosis, with entirely negative results. In two of the cases there was a slight temporary improvement.

Dr. R. H. Babcock, of Chicago, said he had seen a number of cases in which the use of the gas had been followed by a decided improvement in the symptoms. It seemed to give the patients a start in the right direction.

Dr. Charles Denison, of Denver, said that if the sole object of the treatment was to place the affected lung at rest, he thought that could be attained by the simple and equally efficient method of strapping the chest, as described by him in a paper about a year ago.

Dr. Stubbert said he did not believe the injections of nitrogen gas would do good unless absolute compression of the lung was secured. It was useless in cases in which there were adhesions which prevented compression. The operation could best be done under *x*-ray illumination. The speaker said he had seen it successfully used to check hæmoptysis.

Dr. Charles L. Minor, of Asheville, N. C., said he had seen several cases in which the tuberculous process was apparently retarded by the injections of gas.

Stomach Conditions in Early Tuberculosis.—This paper was read by Dr. Boardman Reed, of Philadelphia. The points emphasized might be thus summarized: (1) In early tuberculosis the secretion of hydrochloric acid in the stomach was very frequently excessive, the peptic glands being in a condition of irritability which caused stimulant remedies of the creosote class to disagree and act injuriously. (2) Oils tended to depress the secretory function of the stomach, and in consequence cod-liver oil was likely to help the cases which the creosote class of drugs hurt; but, on the other hand, it hurt the cases in which the gastric secretion was inactive, the very ones in which creosote and its congeners often did good. (3) Therefore it ought to be the rule to ascertain the condition of the secretory function of the stomach before pushing either class of remedies. (4) When analyses of the gastric contents could not be made, it was safer to combine creosote with cod-liver oil, so as to let one neutralize the other in their influence upon the stomach. (5) The motor function was very generally depressed in tuberculosis and must be restored before a cure could be brought about. Drugs availed little in this direction, but diet, exercise, especially in the open air, faradism, and abdominal massage—except when hyperchlorhydria complicated—were all valuable means of effecting the result.

Dr. Howard S. Anders, of Philadelphia, said he was thoroughly in accord with the statement made by Dr. Reed, that in the vast majority of cases of early tuberculosis there was hyperchlorhydria. The percentage of hydrochloric acid present was very variable. The motor function of the stomach he had never found much impaired in these cases.

Subsequent Histories of Patients Apparently Cured under Administration of Anti-Tubercle Serum, as an Auxiliary to Climatic Influences.—This paper was read by Dr. J. Edward Stubbert, of Liberty. At a meeting in May, 1898, he had read a paper before the association entitled "Some Statistics upon Sero-Therapy." The following was the summary of the cases then reported: Number of cases treated, eighty-two; expectoration decreased in eighty-two per cent.; appetite improved in eighty-one per cent.; weight gained in seventy-eight per cent.; physical signs improved in seventy-eight per cent.; temperature decreased in forty-nine per cent.; bacilli disappeared in thirteen per cent.; bacilli decreased in thirty-five per cent ; cough decreased in seventy-nine per cent.; apparent immunity established in twenty-one per cent.; general improvement in seventy-eight per cent. In pursuance of investigation and study upon this subject he now reported a subsequent history of thirty-nine per cent. of the above cases apparently resulting in cure, as well as the present condition of fourteen, the histories of which were not included in the former paper. These cases were divided into three sections: first, those patients who had been discharged for three years; second, those who had been discharged for two years; third, those who had been discharged for one year or less, but in those instances when they had been discharged for less than one year they had been one winter in their old surroundings. All of those patients returned had spent a greater or less length of time in their former environment and work: the speaker had been able to trace definitely the histories of eleven per cent. of those discharged three years, seventeen per cent. of those discharged two years, and $17\frac{3}{7}$ per cent. of those who had been discharged for one winter, and all of those had remained in the same condition as when they were discharged, viz., apparently cured. Those patients remaining, whose histories had not been definitely traced, were all known to the writer by general repute to be in good condition. Thus practically it might be stated that in one hundred per cent. of all cases discharged in the last three years that had received this form of treatment, the patients had remained apparently cured. All of these cases but one were incipient cases; one was a moderately advanced case. The speaker also reported two arrested cases in which the bacilli were present at the time of the discharge, but the diseased area was circumscribed and there was no special activity present. One of these patients since returning home had lost the bacilli and was apparently well, while the second one continued at hard work, and held her weight, but continued to expectorate about once in ten days or two weeks. He also reported one case of pulmonary tuberculosis complicated by tuberculous kerato-iritis, in which the ocular as well as the pulmonary symptoms had cleared up very markedly under serum and climatic treatment.

Dr. Klebs referred to the unreliability of statistics in general, and thought that Dr. Stubbert had given too much credit to the anti-tubercle serum and too little to the excellent régime which was carried out in the treatment of these patients at Liberty.

The Phlebitis of Advanced Phthisis, with Report of Cases of Phthisis following Abscess of the Hand.—Dr. R. G. Curtin, of Philadelphia, read this paper.

Dr. S. Babcock said he had seen three cases of phlebitis in tuberculosis.

Dr. Thomas D. Coleman, of Augusta, Ga., also referred to a case which had recently come under his observation.

Dr. Anders spoke of the obscure origin of these venous conditions, of which he had seen two examples secondary to chronic phthisis. One might regard them as cases of thrombo-phlebitis, or phlebitis from within. In the last two cases reported by Dr. Curtin, in which a phlebitis resulted from an injury to the hand, which was immediately followed by abscess, there might have been an inflammation of the vein, extending from without inward, with subsequent thrombosis and softening and the detachment of emboli.

Dr. Norman Bridge, of Los Angeles, Cal., reported the case of a young man with pulmonary tuberculosis who developed a phlebitis of both lower extremities; after giving rise to rather severe symptoms, the swelling in both limbs disappeared, and the patient made a good recovery. Dr. Bridge said he thought it was impossible to say that this complication was, strictly speaking, tuberculous. This, so far as he knew, had never been proven.

Dr. Babcock said he thought the phlebitis in these cases was due to infection, either mixed or otherwise.

Splenic-Myelogenous Leukæmia with Pulmonary Tuberculosis: Report of a Case.—This paper was by Drs. Henry L. Elster and William A. Groat, of Syracuse. They reported a case of splenic-myelogenous leukæmia with pulmonary tuberculosis. The writers reviewed the literature, and gave a full bibliography showing that the association of pulmonary tuberculosis with any form of leukæmia was exceedingly rare. There were a few cases on record of lymphatic leukæmia complicated with tuberculosis. A thorough study of the cases which were supposed to have been of the splenic-myelogenous variety showed that there were only two, and one of these might be considered to be of the splenic-lymphatic myelogenous variety with tuberculosis. The case reported was probably the first of splenic-myelogenous leukæmia with pulmonary tuberculosis in which the diagnosis had been confirmed by a differential count of the leucocytes and the demonstration of tubercle bacilli in the sputum. The patient, who was referred to Dr. Elster for diagnosis, was a baker, forty years old; his family history showed a strong tuberculous taint. His present illness began a number of months before the advent of continuous symptoms, when the patient complained of great fulness in the abdomen and progressive increase in its size. He became depressed, and his general condition was also below par. In the spring of 1899 all of his symptoms increased, and he grew gradually weaker. His color changed and became characteristic of leukæmia. In November, 1899, he commenced to cough, and had all of the symptoms of progressive pulmonary tuberculosis. Tubercle bacilli were found in the sputum; the sputum was also blood-streaked. The patient lost weight regularly; the temperature was usually slightly above normal, averaging from 100° to 102° F.; the pulse was uniformly accelerated. Physical examination failed to show involvement of the lymphatics. The spleen almost filled the abdomen; the liver was also enlarged; the lungs showed positive physical signs of infiltrating tubercle, disorganization, and cavity formation. The blood examination was characteristic of splenic-myelogenous leukæmia. The red corpuscles varied from 3,320,000 to 2,922,000. The differential counts showed an enormous percentage of myelocytes. The average of these was twenty-six per cent. At one time the writers found thirty-eight per cent. There was a marked relative reduction in the number of lymphocytes, which varied in the counts from 4.1 per cent. to 7.5 per cent. The eosinophiles were increased. Many of these were myelocytes and dwarf cells. There were large numbers of normoblasts, or nucleated red corpuscles. The highest count of leucocytes was 320,000; lowest, 121,500. They found a gradual and steady decrease in the total number of leucocytes, but an increase in the percentage of polymorphonuclear neutrophiles, a decrease in the number of myelocytes, and an increase in the number of lymphocytes as the tuberculous process advanced. The blood at all times retained the characteristics of splenic-myelogenous leukæmia. The paper contained besides a full table giving the results of many blood counts, diagrams which showed the physical signs, and water-colors reproducing the picture of the blood as it was found on microscopical examination. The writers dilated on the interesting changes found in the blood of leukæmia with added tuberculosis, and also considered the literature of this subject as well as the effect generally of added infection on leukæmic blood. The urine showed a marked increase in the excretion of uric acid. The changes found in the lung in leukæmia were considered in connection with a study of the literature of the subject. The case reported demonstrated very clearly the effect which the added tuberculous infection had upon the blood, reducing materially the number of leucocytes. The physical signs with associated laryngeal tuberculosis, the enlargement of the liver and spleen, the presence of tubercle bacilli in the sputum, and the changes in the cellular elements of the blood, with the convincing differential counts, made the diagnosis of splenic-myelogenous leukæmia with pulmonary tuberculosis positive.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, April 16, 1900.

Frederick Holme Wiggin, M.D., President.

The Prevention of Intracranial and Intravenous Complications in Suppurative Diseases of the Ears.—Dr. J. H. Woodward read a paper with this title. He said that in spite of free drainage through the drum membrane the disease process might spread into the cranial cavity. To prevent this the conditions giving rise to it must be removed. In the majority of cases the objective symptoms would be a reliable guide. There were six important indications for the mastoid operation, viz., (1) bulging of Shrapnell's membrane, or the upper posterior quadrant of the membrana tympani, and bulging of the inner extremity of the membrane; (2) persistent tenderness over the mastoid process; (3) swelling of the soft parts over the mastoid process; (4) granulations and fistulæ in the external auditory canal; (5) persistent and relapsing fistulæ behind the auricle; (6) persistent, and especially offensive, otorrhœa. Retention of pus in the ear could not be regarded too seriously, and whenever incision of the drum membrane failed to secure efficient drainage it was better to open the mastoid antrum at once than run the risks incident to delay. Persistent mastoid tenderness or swelling of the soft parts should be looked upon as an indication for operation. Fistulæ which alternately closed and opened were especially liable to be followed by sinus thrombosis.

Dr. Francis J. Quinlan said that all suppuration of the middle ear should be regarded with grave misgivings. When there was a perforation in Shrapnell's membrane there was almost always carious bone present. No life insurance company of this city today would accept any one having a chronic suppuration of the middle ear above the short process. Any condition attended by pain over the antrum, pain over the tip or over the middle plate of the mastoid should be a reason for doing a mastoid operation. With a little care and attention the antrum could not only be entered but thrown open to inspection. It was most important that all of the cells should be laid open. A practitioner of ordinary intelligence should be prepared to open this cavity and clean it out.

What are the Ultimate Results in Treating Cancer of the Uterus? What is the Best Plan of Treatment?—Prof. Howard A. Kelly, of the Johns Hopkins University, Baltimore, read this paper. He said that from the standpoint of the frequency of this disease cancer of the uterus was of the first importance, because Welch had shown that out of 31,482 cases of primary cancer, 29.5 per cent., or approximately one-third, were instances of cancer of the uterus. In every case of cancer of the uterus the entire organ should be extirpated—an old dictum, but one which he believed required reiteration in this country even at the present time. There was a temptation, particularly in the earlier stages of the disease, to do an amputation of the cervix or to remove only the body of the uterus. Speaking on a basis of one hundred and seventy-six cases of his own, studied most minutely, he found the exceptions regarding the limitation of the disease so numerous that they might, for practical purposes, be reckoned as the rule. In many cases of cancer of the cervix he had found the disease also in the body, and in one case it had skipped the body and had developed in the tubes. With the uterus one should remove the Fallopian tubes in all cases of cancer of the body. The next great danger was in the vaginal vault. Cervical cancer often extended down the vagina under the mucosa without, at first, producing any alteration of color. The disease should be given a wide berth, therefore, at the vaginal vault, cutting at least from 2 to 2.5 cm. away from it. In many cases of cancer of the uterus attended by pain it would be found that the pain was not due to the cancer *per se*, but to an occlusion of the cervical canal by the growth, and the consequent imprisonment of the secretions. In such cases, by boring through the carcinomatous mass and establishing free drainage of the uterine cavity, the pain would be completely relieved. The disease often involved the bladder before it had extended very far in any other direction. In such a case the whole base of the bladder could be readily cut out and left attached to the cervix. Almost all cases of involvement of the bowel were associated with considerable involvement laterally also. The mode of extension of the disease laterally was a subject upon which surgeons differed widely, yet the method of treatment must hinge on this point. He had removed many glands which macroscopically appeared to be diseased, yet microscopical examination had failed to find, in all but a few instances, any evidence of cancerous involvement of these glands. The operator should concentrate his whole efforts on giving the cervix a wide berth, and if he did this he need give himself no concern about the tissues beyond. In all but five per cent. of cases the disease extended laterally by continuity, and not by "jumps." On the question of the risk of inoculating the fresh tissues with cancer during operation, the speaker said that implantations of the disease in the vagina below the site of operation were rare accidents. The experiments made on animals showed that it was difficult to inoculate cancer unless aseptically done, and hence it did not seem probable that implantation would occur when drainage was used.

Advisability of Operation.—An opinion which had gained some ground in the profession was, that the radical operation was hardly to be recommended because the disease almost always recurred quickly. In refutation of this assertion, Dr. Kelly said that out of sixty-one cases of squamous carcinoma of the cervix, twenty per cent. of the patients were living, and out of twelve cases sixteen per cent. of the patients were well. Of thirty cases of adeno-carcinoma of the body, sixty-three per cent. of the patients remained well. The fact that seventeen out of thirty-four patients had remained well for periods varying from three to six years seemed to him a sufficient argument in favor of operating in this class of cases.

Mode of Operating.—The old plan of "skinning out" the uterus was the method most apt to be followed by recurrence, and should, therefore, be abandoned. It was true that it was possible to distinguish the ureters in an abdominal operation without the introduction of bougies into them, yet it could not be denied that without such an artificial guide the operation was made somewhat more tedious and dangerous. The disease must be given a wide berth by ligating far out in the parametrium. Any operative procedure based on these principles would give vastly better results than those hitherto achieved. He had followed three modes of attack in his endeavors to carry out these principles. One of these operations consisted in tying off the ovarian vessels, round ligament, and uterine artery on both sides, and then cutting in through the vagina and taking out the uterus through the vagina. Dr. X. O. Werder, of Pittsburg, had greatly modified the operation. The peritoneum was opened both anteriorly and posteriorly, and then a wide dissection of the vagina was done low down. After the uterus had been separated, the detached peritoneum was sewed over the top of the uterus so that the uterus was practically extruded from the peritoneal cavity. After closure of the abdominal wound the vagina was inverted and the parts were removed.

His Own Method.—Dr. Kelly then described his own method, which consisted in (1) the removal of all the tissues down to the point where the infiltration was deepest, and (2) the concentration of all the energy of the operator on the most complete removal of this last segment. A thorough curettage was first done, and then the vagina was divided on all sides one inch below the diseased area. The vesico-uterine peritoneal fold was widely opened, as was also the posterior cul-de-sac. The uterus was then brought out through the anterior opening. The peritoneum posteriorly was well protected by gauze packing. The uterus was next bisected from fundus to cervix with scalpel and scissors; this was attended with very little hemorrhage. The uterus was next caught by the cervix with two pair of forceps, and was split again and removed. The next step was to begin the enucleation on the side which was the less diseased. Up to this point the operation was very simple. These preliminary steps secured the maximum of room and mobility. This operation was, of course, done through the vagina. It was a question in his mind whether the ligature or the cautery was better. Much credit was due to Dr.

John Byrne for his persistent advocacy of the use of the actual cautery in advanced cases of carcinoma of the uterus.

Dr. Henry C. Coe said that the old method of skinning out the uterus had certainly given him most unsatisfactory results. In the majority of cases there had been a recurrence within two years. He had had occasion to read a paper on this subject a few weeks ago, in which he had taken the ground that the operation of the future would probably be a radical abdominal hysterectomy. Serious as the operation was, this seemed to be the most scientific method of dealing with the disease by any cutting operation. It enabled one not only to deal with the diseased organ itself, but with the glands and any suspicious tissue. In his experience the great difficulty had been to decide at the operation what tissue was inflammatory and what tissue was involved in the malignant process. He had always been a stanch upholder of Dr. Byrne's method of treating malignant disease of the uterus by means of the cautery. Such a method seemed to him very rational, and the ultimate results in the hands of Dr. Byrne had certainly been very brilliant. He did not feel sure that cancer of the uterus always extended into the broad ligaments by continuity. One saw at times cases in which there was a small nodule of malignant adenoma of the body of the uterus, yet in spite of a radical removal by abdominal hysterectomy there would be early recurrence in the scar. Such a case was difficult to explain. He could recall one very severe case which he had considered most unfavorable at the time of the operation, yet this patient had lived five years without any recurrence.

Dr. Egbert H. Grandin spoke of his personal results in the treatment of cancer of the uterus. He had analyzed the histories of nearly three thousand women seen consecutively. The first point was that cancer of the uterus, in his experience, had been relatively uncommon. There had been forty-eight cases of cancer of the uterus. Thirty of these had presented an advanced type of the disease, *i.e.*, the base of the bladder, the rectum, and the broad ligaments had been implicated. In such cases he had not been bold enough to attempt any major operation. These women had all suffered for a long time from hemorrhages, and had not reported for examination at an early enough period to make a radical operation of much value. He had tested the various routine methods, such as curettage, cautery, and caustic applications. He was not quite sure but that in these advanced cases of carcinoma the less done the better. Eighteen cases had been suitable for operation. Total hysterectomy had been the operation of choice in the cases in which the disease had involved the body of the uterus. Seven of these twelve cases had been traced, and there had been no recurrence. In one case the operation dated back six years, and in the others from six months to four years and a half. In six cases in which the portio vaginalis had been involved the operation selected had been vaginal hysterectomy, either by clamp or ligature. He had traced four of these cases, and there had been recurrence in all but one, that one being a recent operation. The recurrence had taken place in the vagina at periods varying from eighteen months to two years. From his experience he was inclined to believe that cancer of the uterus was susceptible of cure if seen early enough and promptly treated by a radical operation. Vaginal hysterectomy, whether by clamp or ligature, he thought should be rejected in cases of cancer of the uterus, for the reason that it was not possible to do as thorough a resection of the broad ligaments by this route as from above. In any event it was desirable to remove at the same time as much of the vagina as possible, as this was the site of recurrence. In any case of cancer of the uterus, whether of the body or of the portio vaginalis, a partial operation should not be thought of. Probably in the future a combination of methods, such as the knife and the cautery, would best enable us to certify against recurrence.

Dr. W. R. Pryor said that he did not think the vaginal operation met properly any of the requirements laid down by the reader of the paper of the evening. He did not look favorably upon Dr. Kelly's method of performing morcellement by the vaginal route in cases of cancer of the cervix. The surgeon should do the most radical operation possible, provided it did not carry with it too high a rate of mortality. Vaginal hysterectomy for cancer was, in his opinion, a palliative operation merely, and in this connection it should not be forgotten that the mortality from it was between five and ten per cent. Vaginal hysterectomy was suitable only for a few selected cases. His own preference certainly was for the operation through the abdomen, which necessitated no preliminary procedure for marking out the anatomical relations, such as Dr. Kelly's clever one of introducing bougies into ureters. As every drop of blood was precious to these patients, the internal iliac arteries should be ligated. This ligation could be done with perfect safety.

Dr. Phineas H. Ingalls, of Hartford, Conn., said that the majority of cases seen by him had first come under the observation of practitioners who believed that irregular hemorrhages occurring in women between the ages of thirty-five and fifty years were merely an indication of the approach of the menopause; hence the disease was far advanced before coming under his care. He would like to know in how many of the cases treated by Dr. Kelly, in which recurrence had not taken place for five or six years, palpation of the broad ligament before operation had indicated freedom from disease. In his experience, operations performed for cancer of the body had done far better than those done for cancer of the cervix. He had been impressed with the fact that a partial operation, as, for example, by the cautery, had rather aggravated the disease and hastened the fatal termination more than if the patients had been let alone.

Dr. Hermann J. Boldt said that cancer of the uterus must be looked upon as a local disease in the initial stages; hence, if the diagnosis was made and the proper treatment instituted at this time, a cure should result. In his opinion, there was no other method equal to the cautery for the treatment of that spot which seemed to be most intimately connected with the organism. He had personally had but little experience with the method, but the results obtained by Byrne and Mackenrodt, and others, left no doubt on this point. He had treated one hundred and eleven cases of cancer of the uterus, with a direct mortality of 5.4 per cent. and a mortality from recurrence of 34.2 per cent. Those patients living with recurrence constituted 2.7 per cent., those living and free from recurrence 24.3 per cent. No report had been obtained in 30.6 per cent. After the first year's experience he had never performed the "shelling out" operation. The danger of injuring the ureters was very great.

Dr. George Tucker Harrison subscribed most heartily to all that Dr. Kelly had said, for he had preached the true gospel of this disease. It was a demonstrated fact that cancer of the uterus was a local disease, and it was certainly susceptible of cure. He did not consider that statistics of cancer of the uterus were available until a period of five years had elapsed. Taking this as the standard, at least fifteen or twenty per cent. of the patients had been cured, yet the remaining eighty per cent., or some of these, should have been cured, and would have been if the diagnosis had been made early enough and appropriate treatment instituted. He had been disappointed with his own results by the vaginal route.

Dr. Joseph E. Janvrin said that about four years ago he had read before this association a paper in which he had reported sixteen cases of cancer of the uterus beginning, so far as could be judged, in the cervix. He had operated upon these cases by vaginal hysterectomy—simply skinning out the uterus. Of the sixteen cases, twelve at that time dated back three years or more, and one for twelve years. At that date four patients had been living and in perfect health. The remaining four cases dated back at that time, one four months, two five months, and one twenty-two months. Two of these patients he knew were living and well at the present time; two had died within a year after the operation. This gave a percentage of 37.5 per cent. These cases had been selected as exemplifying the results when the disease began in the cervix and was, in the majority of cases, confined to this part. In every instance the diseased condition of the cervix had been well marked. He had not tabulated his other cases operated upon prior to four years ago, but from recollection the ultimate results had been fully up to the percentage just given. Out of the thirty cases he was sure over one-third had no recurrence of the disease. In four of the sixteen cases the disease extended down upon the mucous membrane of the vagina, yet three of these had resulted in a cure. His experience had been that when the disease began on the cervix it was more apt to invade, probably by attrition, the vaginal mucous membrane rather than to extend down under the mucous membrane. He thought that vaginal hysterectomy should be confined to cases in which the disease was limited to the cervix, or to the cervix and mucous membrane only of the upper part of the vagina, or those in which the disease having involved these points had also begun to develop upon the mucous lining of the uterus itself. To this class might be added cases of adenoma and carcinoma uteri in their early stages. In all cases in which there was a suspicion of extension of the disease beyond these limits, whether into the parametrium, the folds of the broad ligament, or the ovaries, the combined abdomino-vaginal operation or the radical operation by the abdomen itself was by all means the most appropriate if we resort to any radical operation whatever. As a rule, he had not performed either abdominal or vaginal hysterectomy in advanced cases. He had long been of the opinion that the cases which were operable could be successfully treated by the abdominal route.

Dr. J. Riddle Goffe said that only in recent years had accurate and reliable statistics been presented concerning cancer, and the profession and the public had been startled by the rapid increase of cancer in England. Some had refused to accept these statistics, maintaining that the increase was apparent and not real. Others, speaking with much authority, insisted that the disease was not only rapidly increasing, but that it was developing more and more frequently among younger subjects. The figures that had been presented were sadly disappointing, and made him hesitate to attempt anything. His own experience led him to think that the vaginal operation was the only justifiable one in cancer of the uterus, because of the danger of inoculating fresh tissues with cancer in other methods of operating. In his opinion, there seemed to be two serious objections to the operation presented here this evening by Dr. Kelly. The first objection was to the method of inverting the uterus, for the turning of a carcinomatous cervix upward into the peritoneal cavity seemed to be an excellent way to encourage inoculation of the peritoneal cavity. Again, he was not in favor of quadrisecting the uterus, for the less it was interfered with the less likelihood of spreading the disease. He would favor taking out the whole vagina, if necessary, for the dissection was very easily performed. The diseased tissue should be shut up in a little sac of vagina.

Dr. E. E. Tull said that he had a record of twenty cases of cancer of the uterus upon which he had operated in hospital practice since 1890. Four patients were living, and two of them had been operated on in 1890. The operation had been by the vaginal route, and in all of them the diagnosis had been made positive by a microscopical examination. From observation and experience it seemed to him that the vaginal operation was far from being an easy one. He would operate upon a fairly advanced case first by the application of the cautery, and then, entering the abdomen, would remove the disease as thoroughly as possible.

Dr. H. N. Vineberg said that although he had probably seen about twelve thousand cases of diseases of women in dispensary practice, the number of cases of cancer of the uterus had been exceedingly small, probably not more than twelve cases. The majority of these women had borne many children, and had suffered extensive laceration of the cervix, a point of interest because of the view held by some that such lacerations were a prominent cause of cancer. The cervix was situated in the midst of much connective tissue rich in lymphatics. These lymphatics acted as a barrier to the dissemination of the disease upward. Only in those cases in which the disease was limited to the body had his results been at all encouraging. He would venture to suggest a modification of Dr. Kelly's method, viz., the making of a longitudinal incision in the anterior vaginal wall. Through this the uterus could be anteverted, and there would then be no need of entering the peritoneal cavity posteriorly.

Dr. Ralph Waldo said that when the disease had lasted more than six months it was probable that the tissues had been so much invaded that recurrence would take place., His personal preference was for operating from below, and using ligatures.

Dr. John Byrne, of Brooklyn, said that in 1892 he had undertaken an analysis of the published statistics on cancer of the uterus up to date. The trouble had been in the past that many in the profession had been disposed to minimize the danger of hysterectomy, pointing to the exceptionally good statistics of a few specially skilful operators. In two hundred and thirty-five cases treated by a number of the leading operators in Germany, France, and elsewhere, he had found sixty-three, or twenty-seven per cent., in which relapses were noted, while nothing was said about the fate of one hundred and seventy-two cases. Such important gaps in the records made the task of collecting honest and trustworthy statistics most disheartening. Olshausen had reported in 1892 one hundred and sixty-one cases of hysterectomy for cancer, with only forty-two patients living at the end of two years. Of the one hundred and fifty-five who had survived the operation, only nineteen had been free from recurrence. Such statistics as these were worthy of the most thoughtful consideration. Of late years his own work had consisted in the free use of the cautery, and a thorough roasting of the cavity. Exceptionally was the actual cauterization carried to the fundus. In circumscribed cancer of the cervix the use of the cautery and a thorough roasting of the cavity were free from danger, and afforded the very best chances for a cure. He had many cases on his books in which the patients had lived eight or ten years, or even longer, free from recurrence. The effect of the electro-cautery knife on the surrounding structures probably explained the absence of fever and pain after the operation, the almost complete immunity of the scar tissue from involvement in the event of recurrence, and the comparative rarity of recurrence. The improved electric apparatus of the present day left no excuse for further apathy on this important subject.

Dr. Kelly made a few closing remarks.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, April 9, 1900.

Robert F. Weir, M.D., Chairman.

Difficulties of Intubation.—Dr. Rogers presented a young girl who illustrated some of the difficulties of intubation. She was intubated for diphtheria in December, 1896; tracheotomy was done in February, 1897; in May she was re-intubated. She was then in Willard Parker Hospital for a year, during which time her stenosis remained unchanged. In 1897 she was transferred to Gouverneur Hospital. A small tube was then introduced, but the patient coughed it up and was on the point of being asphyxiated, when a tracheotomy was done with a penknife. In January, 1898, there was no improvement, and a laryngotomy was done. Nothing was found but a mass of thickened tissue. A suture was introduced through the thyroid cartilage to keep the swollen tissues away from the median line. Infection of the wound followed, and in April she was discharged, being considered a hopeless case. There were much excoriation and dermatitis about the tracheotomy tube, and a great deal of dense tissue around the larynx. A No. 4 or 5 tube was introduced, and in October of the same year a larger tube was placed in. In November, 1898, the tube was taken out, and she had remained cured ever since. The interesting point was that from December, 1896, to October, 1898, she was unable to breathe through her larynx; then, by wearing a big tube in the larynx, she became cured. She was unable to phonate until this year. She now breathed with some dyspnœa at night.

Dr. Rogers also presented the case of a boy who, in March, coughed out the tube and nearly strangled, a tracheotomy being performed to prevent asphyxia. The attempt was made to replace the intubation tube, but it was again coughed up. In October he was admitted to Gouverneur Hospital, and it was found that even a uterine probe could not be passed. The attempt was made at dilatation with urethral sounds. A No. 4 or 5 tube was then introduced and worn for nine days; then, a No. 5 or 7 tube was placed in and left for five weeks, when he was considered cured.

Dr. Rogers presented the third case of a girl who was intubated at the Willard Parker Hospital in May, 1896, for diphtheria; in July the tube was coughed up, and she stopped breathing, making it necessary to perform a tracheotomy; in October a laryngotomy was performed. The swollen tissue was excised; there was no cicatricial tissue, only œdematous tissue; there was no granulation tissue. The child was no better; she could not breathe without the tube. Laryngotomy was again performed in October, 1897. Until last July, a period covering nearly three years, intermittent dilatation was done, but the patient did not breathe through the larynx. In July the tracheotomy tube was removed and a large-sized intubation tube—11 to 13 tube—was placed in and worn for five weeks, when it was taken out. A cure followed. He closed by stating that every one of these patients did well by the insertion of as large a tube as could be crowded into the larynx, to be left there for six weeks, or even longer.

Pylorectomy; Gastro-Enterostomy.—Dr. Robert F. Weir presented this case. The patient, a woman forty years of age, gave a history of gastric disturbance but not of severe type. Eight or ten months ago she noticed a swelling in the upper part of her stomach; it increased in size, with some distress in digestion, with vomiting, but there was no hæmatemesis. The tumor was as large as an orange and fairly movable. An exploratory incision was made to determine if any adhesions existed or if there was any glandular involvement. The diagnosis of carcinoma of the stomach was made, there being a growth of considerable extent in the cavity of the stomach. Along the greater curvature of the stomach, running for a distance of four or five inches, a mass could be felt in the walls of this organ, both anteriorly and posteriorly. A pylorectomy was decided upon and done, seven inches being removed. This area was clamped. The stomach wound was closed by means of sutures which passed through the entire thickness of the mucous membrane, and two extra layers of sutures turned the stomach in three-quarters of an inch. A gastroenterostomy was then done by means of a Murphy's button—the duodenum being connected to the posterior wall of the stomach. Recovery was uneventful; there were no bad symptoms. The stomach was washed out from the beginning, and fluids were administered within the second or third day. She now ate almost any kind of good food.

Pathology, Diagnosis, and Treatment of Diphtheria.—The feature of the evening was a discussion on this subject.

Dr. J. Blake White opened the discussion. He treated of the throat conditions resembling diphtheria. There were three distinct exudations: (1) Grayish, aphthous patches seen in states of debility and in a deranged state of digestion; (2) a local non-contagious condition about the glottis, which was accompanied by stridulous breathing, and described under the term "croup"; (3) the specific, contagious, infectious disease, which was accompanied by lymph exudation, by great prostration, and other symptoms, and often paralytic complications—diphtheria. In making a differential diagnosis bacteriological evidence of the disease was of great importance, but should always be considered in connection with the clinical history. He cited the instance of a little girl in whom the clinical diagnosis was diphtheria; the cultures obtained said there was no diphtheria. She was treated for diphtheria, and a subsequent bacteriological examination showed the presence of the Klebs-Loeffler bacilli. The indications for treatment in diphtheria were naturally those that were present in any condition of toxæmia, *i.e.*, to sustain, then aid the efforts of nature in the struggle to eliminate the principles under which the patient suffered. Nature fought the disease, and often a blind man with a club came along; if he struck the disease, he killed it; if he struck nature the patient was a sufferer. The speaker, in referring to the rational methods of treatment, said that among the vast host of remedies advocated there was no one that was entitled to superior confidence. The immunizing effect of antitoxin was compared to that following the inoculations of smallpox, but he claimed that they were in no way identical. In France the antitoxin treatment was discredited; also in Moscow. The *British Medical Journal* stated that in Paris, with the use of the antitoxin treatment, there was an increase of diphtheria. The relative value of intubation was compared with tracheotomy. Intubation should be practised early to give greater chance of life. If the obstruction extended below the furthest reach of the O'Dwyer tube the patient should be looked upon with superadded anxiety. In conclusion he remarked that the rational treatment consisted in the study of each symptom and the idiosyncrasy of each case.

The Heart and Circulation in Diphtheria.—Dr. Henry Dwight Chapin continued the discussion, confining his remarks to the various phenomena seen in connection with the heart in diphtheria. This organ naturally attracted much attention in the treatment of this disease. The heavy mortality from diphtheria in severe types was accompanied by failure of the heart, and death ensued from this cause. Rapid failure of the heart was especially seen in the septic type of diphtheria. Here, the throat was covered with a false membrane, including the tonsils, the uvula, the palate, and in addition there was marked involvement of the glands about the neck. The nose was almost invariably blocked up. This type was exceedingly depressing to the heart. At the Willard Parker Hospital it was found that the septic type of the disease acted as a powerful depressor of the heart; of course, here were present the mixed infection, the Klebs-Loeffler bacilli, the streptococci, and other germs, which combined their toxins with the original toxins. In these instances when the heart began to fail it rarely recovered itself; the pulsation was rapid and feeble, and the patient developed the type of great prostration, with pallor and finally stupor and death. The speaker referred to the grave significance of vomiting; if vomiting ensued with a weak pulse death usually followed; this vomiting might precede or follow failure of the heart. This was not the vomiting that accompanied over-feeding of the patient. Another phenomenon referred to was the distinct slowing of the pulse, which was regarded as of grave significance; this slowing of the pulse might come on before or after great rapidity. The following cases were cited to show this retardation of the pulse:

Case I.—E. F——, eight years of age, died on the fifth day. The day before death the pulse was 42 and remained slow; it previously had been 115 to 120.

Case II.—L. M.——, about four years old; on the fourth day the pulse ranged from 128 to 66; next day, 120 to 138. Death followed in three days.

Case III.—G. S——, about six years of age, was in stupor with a pulse of 60; it was regular. The following day it was 38 and irregular. Death occurred in three days with a pulse of 104.

Case IV.—B. C——, aged five years, had a very rapid heart, which gradually slowed and in a few days was 28. The patient lived two days thus.

Case V.—A. H——, aged thirteen years, had a pulse of 90; in two days it was 40, remaining so for three days, when it became 60 to 70. The patient recovered.

When the pulse dropped in this way recovery was rare. The care of these cases consisted in insisting upon the recumbent position. Dr. Chapin stated that there seemed to be a direct ratio between the amount and character of the local inflammation and exudation and the severity of the constitutional symptoms, especially the heart. If there was not much membrane, and no swollen lymphatic glands were present, no matter if the pulse was rapid and irregular, the case was not so serious, especially if there were no symptoms of prostration. He believed in the study of the heart in diphtheria, which was the only disease in which we must interpret the physical signs by the rational signs. He had had a mild case of diphtheria, with a rapid and irregular pulse; the patient improved by getting up and running about the ward. Whenever we found that the character of the pulse was poor, with evidences of prostration, pallor, vomiting, and stupor, the condition of the heart must give grave solicitude; but when there were the same physical signs without prostration, the significance was not so grave. The treatment consisted of whiskey, strychnine, and nitroglycerin. In cases of slow pulse strychnine in large doses apparently had no effect whatever; it was given hypodermatically. Nothing seemed to steady the heart in these grave cases. One therapeutic agent used at the Willard Parker Hospital was morphine in certain cases. In non-narcotic doses it was a powerful heart stimulant. Children were hard to keep quiet; heart failure sometimes followed when a child simply sat up in bed; the children should be kept quiet, and it could be done with morphine administered hypodermatically. This was most efficient. A child of one or two years of age could stand gr. $\frac{1}{16}$ to $\frac{1}{14}$ of morphine hypodermatically.

The Treatment of Diphtheria as Carried Out in the Willard Parker Hospital.—Dr. John Winters Brannan continued the discussion, confining his remarks to the above subject. The treatment there did not differ from that employed in other hospitals or in private practice except in matters of detail. Unless there was some opposition antitoxin was given in all cases; 1,500 to 3,000 or 4,000 units of the strongest serum obtainable was administered, the dose being regulated by the severity of the case. If no improvement followed within twenty-four hours the injection was repeated, and, in some cases, even given a third time. No cases were admitted to the wards until the clinical diagnosis had been verified by bacteriological examination. The naso-pharynx was cleansed by means of a fountain syringe; that, he believed, was the key-note to success. The child was placed on a table and swathed in sheets; outside of this was placed a rubber blanket. With the patient upon one side the nozzle of the syringe was introduced into one nostril, then into the other, then into the mouth and naso-pharynx, and all the parts were thoroughly flushed with decinormal saline solution. The fountain syringe was elevated three or four feet above the table. If the fauces were encroached upon, water at a temperature of 120° to 130° F. was used. Irrigation was practised every one, two, or three hours; if any nasal hemorrhage occurred it might have to be abandoned for a time. This irrigation prevented further absorption by removing the false membrane, and by clearing away the discharge; no attempts were made to do this by the aid of chemical agents. The speaker laid particular stress upon the preparation of the patient before the treatment was begun; the patient should be immobilized first. The further treatment was chiefly systematic. All patient were placed upon stimulating diet and kept in bed until convalescent. Ninety feet of floor space was allowed for each bed. The temperature of the room was kept at about 68° or 70° F. Tracheotomy was rarely necessary, being performed but ten or twelve times in a year. In some cases gavage was used, the tube being introduced through the nostril. For the cardiac weakness whiskey and strychnine were given, the latter being given with a free hand, a young child sometimes receiving gr. $\frac{1}{10}$ in twenty-four hours; he had never seen the slightest toxic effect from it. Broncho-pneumonia and other complications received the usual treatment. Paralytic sequelæ were seldom seen; they were treated by tonics, massage, and faradism. Recently the use of the suprarenal gland had been begun; it was spread directly upon the part; it had also been given internally in powder in five-grain doses every two hours. No marked effect had been noticed from its use in the treatment of diphtheria.

Cocaine in operations upon the lower extremities may be used as a partial anæsthetic by injecting 1–2 cgm. into the lumbar subarachnoid space. Quincke, Sichard, Bier, Seldowitsch, and Tuffier have employed the method. Tuffier has operated with success in ankylosis of the knee, pelvic suppuration, and vaginal hysterectomy.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, March 14, 1900.

EUGENE HODENPYL, M.D., PRESIDENT.

Thrombosis of the Pulmonary Artery; Sudden Death.—DR. J. H. LARKIN presented specimens from a man thirty-five years of age, who had given a history of syphilis and of repeated attacks of gonorrhœa. The man had entered St. Francis' Hospital about two weeks ago complaining of difficult and painful urination. Examination showed a stricture at a depth of four inches, and another in the membranous urethra. There was also some enlargement of the prostate. The next day perineal section had been done. The patient had done well for four days, and then on attempting to irrigate the bladder with hot saline solution the man suddenly became cyanotic, complained of intense pain in the chest and of dyspnœa, and in a moment was dead. At the autopsy, having in mind the clinical diagnosis, the lungs and heart were exposed *in situ*. On opening the pulmonary artery a thrombus of large size had been found. The portion extending into the right ventricle was rounded, showing that this part had slipped down into the ventricle after having formed higher up.

Fat Embolism of the Pulmonary Artery; Sudden Death.—Dr. Larkin exhibited specimens and photographs of this case. The patient, a man aged thirty-six years, had fallen from his bicycle and injured the right hip. Examination had shown fracture of the greater trochanter of the femur and impaction of the neck. For the first few days temporary wooden splints had been used, and then a plaster spica bandage had been applied. A day or two after the man had suddenly experienced severe pain in the chest, and this had been associated with nausea and feeble heart action. He had recovered from this attack of syncope, and had done well until about one week later, when there had been another attack similar to the first one except that it had terminated fatally. The autopsy had been performed by Dr. Norris and himself. The viscera had appeared normal. Having in mind fat embolism, portions of the viscera were taken, and stained with osmic acid. In all the branches of the pulmonary artery, both the smaller capillaries and the medium-sized vessels, were found accumulations ot fat globules and thrombi. It was noted at the time that the lungs were not so œdematous as had been observed in other cases of fat embolism. The microscopical appearances seemed to leave little doubt regarding the correctness of the diagnosis of fat embolism. The fractured femur was also exhibited. At the time of the autopsy the bone had been found riddled with hemorrhages.

DR. NORRIS said that fat embolism of the pulmonary artery was very common after fractures. One observer had found, in a large series of autopsies, that there had been some fat embolism in ten per cent. of the cases. The first attack had been quite mild in the case reported, and the man had soon recovered from it. The fact that this had come on twenty-four hours after changing the dressing made it probable that the moving of the parts had been the immediate cause of the embolism. It was difficult to explain the second attack. Respiration ceased two or three minutes before the heart stopped beating, which would point rather to an affection of the blood-vessels supplying the respiratory centre.

Cystic Degeneration of the Kidneys with Cysts of the Liver.—DR. L. A. CONNER presented specimens from a woman who had died at the New York Hospital last December. She was admitted on December 26, 1899. She was forty-four years of age. Her family and earlier personal history was unimportant. She had felt "tired" for several months. For the past six weeks she had been very weak. There was some dyspnœa on exertion. The urine had a bad odor. There were no œdema, no lumbar pain, and no hæmaturia. On admission, her temperature was 97.8° F.; respiration, 32; pulse, 106. Physical examination revealed a tumor mass in the region of the left kidney and little else besides feeble heart action. The urine had a specific gravity of 1.011; it was acid, turbid, and contained 1 gm. of albumin to the litre, much pus, few red cells, and no tubercle bacilli. The patient grew steadily weaker, became stuporous, and died three days later.

At the autopsy, the heart showed moderate hypertrophy of the left ventricle—its weight was 320 gm. The heart muscle was rather soft and light colored. The valves were competent. The coronary arteries showed a somewhat anomalous distribution. The left kidney measured 19 × 8 × 6 cm., and weighed 686 gm.; the right kidney measured 15.5 × 9.5 × 7.5 cm., and weighed 472 gm. The kidneys preserved in general their usual shape, but owing to the many projecting cysts their surfaces presented somewhat the appearance of a bunch of grapes. On section both organs were seen to be composed chiefly of a multitude of cysts, which varied in diameter from 1 mm. to 2.5 cm. They were most abundant in the peripheral parts. The usual topography of the kidneys was entirely lost, and in only a few places could anything resembling kidney tissue be recognized. Several of the large cyst cavities in each kidney contained thick grumous pus. In the remaining cysts material of two fairly distinct types was seen: (1) A number of large cysts contained thick, brown, gelatinous material, which became very firm by preservation in formalin. (2) Most of the smaller cysts and some of the large ones contained a thin, whitish, transparent, gelatinous fluid, which seemed to be little changed by the formalin. The pelves of the kidneys were small, and seemed compressed by the cystic kidney tissue. The ureters and renal vessels appeared normal. The bladder contained purulent urine, with mucous membrane. The liver was somewhat irregular in outline. The right lobe was prolonged downward, and was somewhat constricted at one point. It weighed 1,770 gm. Scattered over the surface of the liver everywhere and projecting slightly above the surface were seen many small cysts from 2 to 10 mm. in diameter. On section of the organ these cysts were seen scattered throughout, being separated by normal-looking liver tissue. The cysts as compared to the liver tissue made up a comparatively small part of the volume of the organ. A part of the anterior margin of the right lobe was lighter in color, tougher, and evidently contained much more fibrous tissue than did the rest of the liver. In this part the cysts were especially numerous. The left ovary was 5 cm. in diameter, and consisted chiefly of a number of good-sized clear cysts. Microscopical examination of the kidneys showed the cysts to be lined by a single layer of cuboidal epithelial cells, and to bear a very close relation to the uriniferous tubules, and sometimes to the Malpighian bodies. Between the cysts in many places areas of much-damaged renal tissue could be seen. In the liver, in the same way, the cysts could be seen in process of development from the small gall ducts.

Dr. Conner said that Ritchie,[1] of Edinburgh, after a thorough study of the subject, had drawn the following very reasonable conclusions: (1) That in cystic kidney there was an irritative lesion leading to proliferation of epithelium and also to connective-tissue changes. There was evidence of it in simple cysts, in those which occurred in contracting kidneys, but to a much greater degree in the large polycystic kidney. (2) That in the large polycystic kidney, as in cystic disease of the mamma, the disease arose in consequence of irritation propagated through the nervous system; (4) that this disease of the kidney had no direct relation to congenital cystic kidney, which was due to an error in development; (5) that the cysts were formed from the pre-existing tubules and Malpighian bodies of the kidney, and that they were not a new formation arising out of persistent embryonic rudiments; (6) that this cystic disease was related to and should be studied along with the adenomata; (7) that cystic kidney was similar in character and in origin to cystic liver. Continuing, the speaker said that a number of other writers had concluded that this condition had nothing to do with congenital cystic kidney, and that it should be classed along with the adenomata. It had been suggested that they should be called multilocular adeno-cystomata. Ritchie had tabulated eighty-eight cases, in twenty-one of which it had been associated with cystic liver, in two with cystic ovary, in one with cystic uterus, and in one with cystic thyroid. In all but two cases both kidneys had been involved. Hypertrophy of the heart had been noted in twenty-nine out of thirty-nine cases. The average age was forty-five years, the youngest patient being twenty-three and the oldest eighty-eight years. As to sex, there were slightly more males than females. In three cases the symptoms had existed for over fifteen years; in seventeen for over one year. Thirty out of seventy-eight had given some renal symptoms, such as pain, hæmaturia, and œdema. Of the seventy-two cases, thirty-eight patients died with symptoms of uræmic coma, and eight of cerebral hemorrhage. The microscope had shown in the kidney islands of greatly damaged renal tissue between the cysts, and the cysts themselves bore close relation to the uriniferous tubules and sometimes to the Malpighian bodies. In the liver, the close relation to the small gall ducts was evident.

---

[1] Reports of Laboratory of the Royal College of Physicians, Edinburgh, vol. iv., 1894.

Dr. E. Hodenpyl said he was very much astonished at the citations made by the last speaker, for it seemed to him that it had been quite generally accepted that such kidneys as these were of congenital origin. He had seen the condition a number of times in the newly born, and the specimen just presented reminded him forcibly of a similar one that he had shown to this society a year or two ago. He saw no reason for calling these cysts tumors. From the fact that children were born with these it seemed reasonable to look upon them as congenital.

Dr. James Ewing said he had been surprised at the statements quoted from Ritchie, and he would like to know more regarding the grounds upon which these cysts were declared to be tumors. He would like to know what was the character of the lining of these cysts. The kidneys just presented seemed to exhibit much more of the renal tissue than in the cases he had seen in the newly born.

Dr. Conner replied that cases of congenital cystic kidney resulted fatally after a comparatively short time, and, so far as he knew, the condition had not been traced from early infancy into adult life. Ritchie and others had found many evidences of tumor formation, and had given their reasoning in detail. The cysts in this case had been lined with cuboidal epithelium.

A Case of Perforated Ulcer of the Duodenum.—Dr. A. J. Lartigau presented a specimen of perforated duodenal ulcer. The specimen was from a man sixty-four years of age, who had entered the Roosevelt Hospital on January 17th complaining of pain in the right iliac fossa. One week previously he had been taken ill with pain in the region of the umbilicus. On admission, the diagnosis had been made of general peritonitis, probably from perforation of the appendix. When the peritoneal cavity was opened a large quantity of thin fetid pus had escaped, and the intestine and appendix in that region had been found normal. Further search had revealed the presence of a perforation of the bowel, and of adhesions to the liver. The operation had not been pursued further, and the man had died eight days afterward. The autopsy had been made five hours after death, and the anatomical diagnosis had been purulent peritonitis, chronic diffuse nephritis, and miliary tuberculosis of the lungs, spleen, and ileum. The duodenum was adherent to the under surface of the right lobe of the liver. The duodenal ulcer was unusually large, measuring 3 by 2 cm. As a rule, the pancreas was the protecting barrier, but in this instance the liver had formed the protecting wall. The microscopical appearance of the ulcer was similar to that of the ordinary round ulcer of the stomach.

Dr. J. H. Larkin presented a specimen of perforated duodenal ulcer taken from a man twenty-eight years old, who had been ill three days before coming to hospital. His condition at that time had been very bad, but an operation had been immediately undertaken. An extensive peritonitis had been found, and the peritoneal cavity contained much fetid pus. The appendix was normal. The perforation had been found at the site of a small ulcer in the posterior wall of the duodenum.

Dr. Lartigau remarked that while these ulcers were usually circular, the one he had presented was oval. Most of the duodenal ulcers closely hugged the pylorus, as in both these specimens.

Microscopical Demonstration of "Vaccine Bodies."—Dr. A. W. Williams gave this demonstration. She said that the principal point of interest in regard to the so-called "vaccine bodies" was that their nature had not yet been determined. Most observers, among them L. and E. Pfeiffer, Guarnieri, von Wasielewski, von Sicherer, and Kourloff, considered them microorganisms, placing them among the rhizopoda in the group Sarcodina of the protozoa, and basing their belief upon the facts that in the fresh tissue they showed amœboid movements, that some possessed a more refractive central spot (nucleus) and showed evidences of division by fission, that they had been found in no other disease, and that they could be accounted for in no other way. On the other hand, Ferroni and Massari, Salmon, Hückel, and others said that these appearances were due to products of a degeneration, either intra-cellular, proceeding, as some said, from the nucleus of the epithelial cells, others from the epithelial cell body—the centrosome perhaps; or extra-cellular, from the leucocytes, the epithelial cells then taking up the degenerated particles. Such degeneration, they stated, was probably specific, and might be produced by an unknown microorganism. The specimens under the microscope were a section from a rabbit's cornea, hardened forty-eight hours after inoculation with vaccine virus, and one from an isolated vaccine vesicle on the skin of a calf six days after inoculation. The section from the cornea was hardened in bichloride of mercury and stained by Heidenhain's method. The portion under the microscope showed the edge of the area of inoculation. Immediately about the point of inoculation the epithelial cells had fallen off, leaving only the lower layers of epithelium. The vaccine bodies lying, one or two generally, sometimes more, in the body of the epithelial cell, were stained a more or less homogeneous brown-black; the bodies of the epithelial cells were a light yellow, and their nuclei were an irregular faint gray. The specimen of calf-skin was hardened in absolute alcohol and stained with hæmatoxylin (Delafield's) and eosin. In the field under the microscope was a sebaceous gland in which the bodies showed more plainly on account of the large size of the epithelial cells. The vaccine bodies were here stained a more or less homogeneous purple, the nuclei of the epithelial cells a darker irregular purple, and their bodies a light pink. The nuclei of the leucocytes which were present in moderate numbers about the gland, and occasionally within it between the epithelial cells, were stained also a dark purple.

A Case of Trichinosis.—Dr. Harlow Brooks reported this case from the fourth medical division of Bellevue Hospital, in the service of Dr. Lambert. After eating sausage a man had begun to complain of malaise and muscular soreness. Microscopical examination of several sections from his muscles had showed a myositis, but no trichinæ. Subsequently a large piece of muscle had been excised under cocaine anæsthesia from the junction of the belly of the biceps muscle with its tendon. From this specimen one trichina had been found about to become encapsulated. The fæces had been carefully examined, but no trichinæ were found. There had been 18,000 leucocytes and ten per cent. of eosinophiles at the time of his admission to hospital on February 2d. On February 12th he had had forty-four per cent. of eosinophiles and a proportionate leucocytosis. The percentage of eosinophiles had steadily increased up to a maximum of eighty-three per cent., and then had slowly declined. At the present time the percentage of eosinophiles was fifteen per cent. It had seemed to him that these eosinophiles differed somewhat from the cells ordinarily called by this name. They were possibly a transition form.

Dr. Lartigau said that he had recently had occasion to examine specimens of blood from various cases of a small epidemic of trichinosis investigated by Dr. George Blumer, of Albany, N. Y. The percentage of eosinophiles in none of these cases had been so high as that just reported. As recovery had taken place the eosinophilia had declined; at the end of two months, Dr. Blumer found these cells still increased in number although much diminished. In many but not all cases, a decrease in the small mononuclears was observed. It was worthy of note that some of the severest cases did not necessarily correspond with the degree of eosinophilia, some of the mild cases showing a greater increase than the clinically more severe cases.

Dr. Ewing said that the case reported by Dr. Brooks gave the highest percentage of eosinophiles on record. In this connection he would refer to the possible aid to diagnosis afforded by the increase in the percentage of eosinophiles. A marked increase in these cells might furnish grounds for suspecting trichinosis, but nothing more than this except when it was associated with an exudative myositis. When this combination was present, one was justified in making a diagnosis of trichinosis. He had carefully examined the eosinophile granules in this case, and had found that many of them were smaller than the usual type, but reacted alike with staining-agents. He had been unable to find any evidence that they were transition forms between eosinophiles and neutrophile granules. If there was a transition here, it was probably between the eosinophile and basophile granules. The case was exceedingly interesting because of the influence which a parasite like the trichina seemed to have upon the eosinophile cells.

Dr. Lartigau remarked that notwithstanding the fact that the eosinophilia might be attributed to a number of different causes, he regarded a marked increase in the eosinophiles as extremely suggestive of trichinosis. He knew of several unpublished sporadic cases in which the diagnosis had been made wholly by the differential blood count, and subsequently verified by the finding of the trichinæ.

A Case of Chylous Urine and Filaria Sanguinis Hominis.—Dr. M. Nicoll, Jr., reported this case, and presented the patient, a young man aged nineteen years, a native of Santa Cruz. Six months ago, without previous symptoms, he had begun to pass creamy urine. After passing this daily for two months, he had noted that the urine was pinkish, and then that there was a momentary retention, relieved by the passage of a small clot of blood. For the past four months he had had in the left groin varicose glands, which gave rise to an appearance resembling a hernia. The urine was now pink and creamy, and contained fat cells. He had been unable to detect the filaria in the urine, though they were probably present. Dr. Nicoll also exhibited under the microscope the embryonal filaria—the variety found in the blood.

A Case of Solitary Tubercle of the Heart.—Dr. E. Dunham reported this case, which occurred in a person aged twenty-one years, in the service of Dr. John W. Brannan at Bellevue Hospital. There was a solitary tubercle about the size of a pea on the inner surface of the wall of the left auricle, just beneath the endocardium. There were a miliary tuberculosis in the lungs, several large tubercles in the brain, and a solitary tubercle in one of the kidneys. It was rather difficult to explain the occurrence of the solitary tubercle immediately underneath the endocardium in the auricle. A number of sections had been made and examined, and in every one it had been possible to demonstrate from one to six tubercle bacilli, all within giant cells.

Dr. Hodenpyl remarked that there were on record a number of similar cases of solitary tubercle of the heart.

A Case of Aberrant Suprarenal Body with Pachymeningitis Hæmorrhagica Interna.—Dr. F. C. Wood reported this case; also a case of aneurism of the aorta with unusual lesions of the lung, and a case of tuberculosis with multiple sarcomatosis.

Notes on the Preparation of Hæmatoxylin Staining-Solutions, and on the Technique of Staining.—Dr. George C. Freeborn read a paper on this subject, based on personal observation and study in the laboratory.

Dr. Brooks asked if Dr. Freeborn found that the acid in the acid eosin injured the clearness of the hæmatoxylin stain.

Dr. Freeborn replied that if the precipitated eosin was washed until the wash-water became tinged, one could be sure that all of the acid had been removed. He had never known it to interfere with the hæmatoxylin stain at all.

Dr. Brooks asked if the sections could be left for a long time in the eosin oil without their over-staining.

Dr. Freeborn replied that he had left them in as long as ten days, and had not been able to observe any detriment from so doing.

Dr. Ewing said that for the last six months he had tried all the purified eosins he could find in the market, yet he had not been able to make a good blood preparation with any of them. In order to get a good selective stain for blood he was sure it was necessary to improve on the ordinary eosins now on the market.

Dr. Freeborn said that the eosin employed by him had been procured from Grubler, and was known as "water-soluble eosin." The acid was added until a precipitate no longer formed. He had not tried the effect of using an excess of the acid.

Persistent Vomiting.—Iced towels to the epigastrium, changed every minute.—Mitchell.

Otorrhœa.—Injections of a two-per-cent. solution of formalin.—Cipriani.

Progress of Medical Science.

Journal of the American Medical Ass'n, May 12, 1900.

Notification and State Supervision of the Tuberculous.—Joseph Matteson says that while he shares in the general recognition of the value of instruction of the people in the danger of the dissemination of tuberculosis by the sputum of the consumptive, and in the method of disposal or disinfection by which this danger may be minimized, he believes that in spite of the agitation for State preventive measures there exists in the mass of the medical profession a strong if quiet opposition to any radical steps in State interference with the tuberculous, and that it is based on (1) an underlying belief that there is a variance between the infectiousness of tuberculosis predicated on scientific experiment and deduction, and the actual, every-day facts of common observation; (2) on the instinctive recoil of reason and humanity at the difficulties and hardships of the progressive measures which are the logical sequences of the first step; (3) on the evidence we have that tuberculosis in man is to be decreased by increasing vital resistance, discouraging marriages of tuberculous persons, and improving general and individual sanitary environment and living.

The Use of Adrenal Substance in the Treatment of Asthma.—Solomon Solis-Cohen reports a case of distressing asthma which failed to yield to all treatment until adrenal substance was used. Burroughs & Wellcome's tablets, gr. v. each, were prescribed once, then twice, then three times, daily, and finally the patient for a time took gr. xc. daily. A striking improvement shortly became manifest. The constant dyspnœa first appeared, then the paroxysmal nocturnal attacks became less frequent and less severe. Recovery was not rapid but was continuous. The author believes that in cases which are really spasmodic, that is, due to contraction of the bronchial muscles, the remedy is without good effect and is perhaps capable of bad influence. But it is of use when the paroxysm is but one other manifestation of a congenital fault of structure or of metabolism, affecting the vasomotor system, and thus permitting the cardio-vascular balance, and especially the tonicity of the blood-vessels to be readily overturned by exciting causes which would have but slight effect on other individuals.

The Tenements and Tuberculosis.—S. A. Knopf believes that the conditions most conducive to the propagation of tuberculosis, and especially of pulmonary consumption, are those that prevail in the old-fashioned tenement-houses as they still exist by the thousand in this and other large cities. Not only is there a greater number of consumptives in these tenements than in the same area elsewhere, but the proportion is actually greater per number of inhabitants. The author urges the building of model tenements, in which with plenty of light and air, perfect ventilation in all rooms, complete sanitary arrangements, and the absence of filth, dirt, and sickening odors, consumptives will have a chance of being cured, and the further spread of the disease will be checked. Invalids should also be instructed as to the precautions to be taken in regard to disinfection of the sputum.

Instrument for Use in Phototherapy.—J. W. Kime has devised and is using, in the treatment of cases by means of concentrated light, a reflector which produces a light equal in intensity to twenty times that of direct sunlight and covering an area of twenty-eight square inches. Concentrated light is useful in the treatment of diseases of parasitic origin, strong light being very destructive to bacteria. In tuberculosis of the lungs in its earlier stages, it has some germicidal influence on the bacilli; moreover, the blood, every drop of which passes a number of times through the area bathed in the powerful light during each treatment, is without doubt beneficially influenced by the chemical action of the light upon it. In the treatment of chronic joint affection, it has over the apparatus in which high temperatures alone play a part, the additional advantage of the beneficial action of the powerful light.

The Influence of High Altitude on Albuminuria.—Edward C. Hill says that in his experience true renal albuminuria is comparatively rare in Colorado, this state of affairs being probably chiefly due to atmospheric dryness and rarity, both of which favor the eliminative action of the lungs and skin, and thus relieve the kidneys in a corresponding degree. Acute nephritis, though not common, is exceptionally severe. Amyloid disease is less frequent under predisposing circumstances than text-books would lead us to infer. Chronic parenchymatous nephritis appears to terminate fatally in about the same time as at lower altitudes. The chronic interstitial type of the disease is influenced favorably by the tonic, invigorating qualities of the climate. Renal tuberculosis is comparatively common. Serious eclampsia is less common than at lower levels.

Hair and its Anomalies.—Henry Alfred Robbins writes of the importance attributed to long and flowing locks in ancient times, of hirsuties, of sudden whitening of the hair under the influence of shock, terror, or grief, and of the opposite condition of white hair suddenly turning black. In regard to alopecia, he mentions the many varying theories held in regard to its causation. The latest opinions appear to be that it is due to the action of micro-organisms. R. Sabouraud by his experiments has given convincing proof that the microbacillus is the constant microbian expression of seborrhœic infection, causing baldness.

Traumatic Perforation of the Membrana Tympani.—By Francis R. Packard.

Etiological Studies on Neuroses of Peripheral Origin.—By H. Gradle.

New York Medical Journal, May 12, 1900.

The Technique of Lumbar Puncture.—In discussing the special point as to the preferable site for puncture, L. A. Connor states that the needle should find ready access to the sub-arachnoid space, that the tapping should be made at the point least likely to admit of damage to the nervous structures of the canal, and that the fluid should be as rich in sediment as possible. As regards the first requirement, it may be said that this is sufficiently well met by entrance through any of the lumbar spaces or through the lumbo-sacral space. Possible injury to the cord can be excluded by entering at some point below the third lumbar vertebra. In adults it is perfectly safe to puncture between the second and third vertebræ, but in small children there is some chance that the cord may be touched. The last requirement, that of obtaining fluid richest in sediment, is best fulfilled by tapping in the lumbo-sacral space. If the puncture is made for purposes of diagnosis, then it seems best to enter the lumbo-sacral space and to have the patient, if a child, in the sitting position. With adults, and especially with those who are delirious or comatose, or who are greatly prostrated, the difficulties of operating in the erect position are so great as to render it impracticable. Puncture in the upright position should then, in general, be confined to small children.

General Remarks on the Pathology and Treatment of Stricture of the Urethra.—C. G. Cumston gives in the two articles the second of which appears in the present issue, a general review of the subject, though nothing especially new is presented. To render the genito-urinary apparatus antiseptic, he advises reliance first upon urotropin, then tincture of eucalyptus and salol in large doses. For local use, he prefers iodoform, citrate of silver, and cyanide of mercury. The orifice of the urethra must be carefully disinfected before instrumentation, and for this purpose he advises soap and water freely, then alcohol, and afterward an antiseptic solution.

The Treatment of Hay Fever by Suprarenal Gland.—B. Douglas commends both the local and internal use of this remedy. A six-per-cent. solution may be sprayed into the nose every two hours until the symptoms are controlled. Internally, gr. v. of the saccharated extract are given every two hours until some giddiness or palpitation is observed, or until the vasomotor paralysis in the nose is brought under control. Then the dose should be diminished, though the remedy should be continued until the hay-fever season is safely passed. Douglas regards the remedy as almost a specific for the disease.

Another Case of Typhoid Infection without Intestinal Lesions, with Possible Widal Reaction.—W. Ophüls reports the case of a man of twenty-four years, who died in spite of all remedial measures employed. Widal reaction was positive, but no changes visible to the naked eye were found in the intestine, and Peyer's patches were distinctly normal. Reference is made to other similar cases already on record, and a bibliography of this special topic of typhoid literature closes the paper.

The Kyphotone or Modified Plaster Jacket Stool for the Correction of Humpback.—By R. T. Taylor.

Philadelphia Medical Journal, May 12, 1900.

Remarks to the General Practitioner Regarding the Pessary.—Frank C. Hammond says that before a pessary is inserted into the vagina one must be certain that a displacement exists. This fact being ascertained, the indications and contraindications for the employment of a pessary may be stated to be as follows: (1) All inflammation must be allayed. If there be a metritis, parametritis, perimetritis, vaginitis, salpingitis, or ovaritis, the presence of a pessary would be so painful as to contraindicate its employment. Inflammation may be overcome by local tamponade, and the consistent use of the hot douche. (2) All adhesions must be "broken up" to permit the fundus to be replaced to its normal position. (3) If a tumor is the cause of the displacement the downward force will be greater than any pessary can counteract, hence the neoplasm must be removed. (4) By laceration, subinvolution, or other cause, the pelvic floor may be so relaxed that it will fail to give a pessary the necessary support. This is a very important point, as too often patients wearing a pessary are seen with the pelvic floor so badly lacerated that it fails to support the instrument, hence they receive no benefits from its employment. The pessary, when so strongly condemned, often has been used in those cases which distinctly contraindicate its employment.

Relation of Diseases of the Nose and Throat to Life Expectancy.—E. Fletcher Ingals says that very few life insurance companies require their physicians to ask any questions regarding affections of the nose and throat, and he thinks that less than three out of a hundred persons examined for life insurance are subjected to any examination of the air passages. He says that usually examinations of the nose and throat would not aid the life-insurance examiner, but in a limited number of applicants a thorough examination of these parts would enable him to reject persons otherwise acceptable, who within one or two years will develop diseases that very greatly shorten their expectancy. Such examinations should therefore, he holds, be made whenever the hereditary or personal history, the general appearance, or a quick pulse leads the examiner to suspect the beginning of pulmonary or cardiac disease.

Mütter Lectures of the College of Physicians of Philadelphia.—By John B. Roberts.

Intestinal Indigestion and its Consequences.—By William Henry Porter.

Scarlatina Miliaris.—By J. P. Crozer Griffith.

The Lancet, May 5, 1900.

Remarks on Vasectomy Relative to Enlarged Prostate and Bladder Atony.—R. Harrison concludes: (1) That vasectomy has been shown to be specially effectual in the earlier stages of prostatic hypertrophy in producing shrinkage of the gland and the restoration of the natural process of micturition; (2) that in cases in which there is evidence to show that the prostate has in the course of degeneration assumed the form and structure of a fibrous growth the conditions are such, provided the symptoms of obstruction warrant the adoption of other measures than catheterism, as to render some form of prostatectomy preferable to either vasectomy or castration; (3) that when as a consequence of sudden or protracted prostatic obstruction secondary changes have taken place in the bladder itself, in the form of sacs, pouches, or trabeculation, the possibility of restoring its natural function by any means is extremely unlikely. Under such circumstances the induction of shrinkage of the enlarged gland will do good in affording a readier access for the catheter and in removing spasm, pain, or hemorrhage connected with this or other similar process.

The Causes and Treatment of Movable Kidney.—C. M. Moullin calls attention to the fact that the kidneys are normally movable organs. He confines his remarks to those cases in which the kidney fails to re-ascend on tranquil expiration when the patient is standing upright and has driven the kidney as low down as he can by forced inspiration. Causes of nephroptosis include tearing or stretching of the bands of connective tissue which run through the fat surrounding the kidney, and the relative displacement of neighboring organs which, packed in around the kidneys, keep them in proper position. They are situated in a relatively unprotected position in the abdomen, and any sudden pressure, violent movement, or lowering of intra-abdominal pressure can displace them. The choice in treatment lies between wearing an abdominal belt and nephrorrhaphy.

Three Cases of Surgical Interest.—The cases reported by T. F. Gardner are as follows: (1) Amputation for scirrhus of the breast in a woman over eighty-two years of age. The lump was first noticed two years previously. The patient did well, and there had been no recurrence in nearly two years. (2) Ruptured pyosalpinx complicated by fibroid tumor of the uterus, abdominal section, hysterectomy; recovery. (3) Trephining for threatened cerebral abscess; symptoms of meningitis; arrest and recovery.

The Effect of Alcohol on the Human Brain.—V. Horsley traces the effect of alcohol upon the finer nerve elements, and does not believe in the view so often advanced that small doses of alcohol such as people take at meals in the form of wines, etc., are harmless. He believes that from a scientific standpoint total abstinence must be the only course in view of the teaching of both truth and common sense.

Colonial Practitioners and the Public.—Presidential address at the annual meeting of the New Zealand branch of the British Medical Association, by W. Thomas.

Then and Now; or the Influence of Modern Surgery upon Medical Practice.—Hunterian oration by F. J. Smith.

Epidemiology of the Plague.—By F. Pearse.

British Medical Journal, May 5, 1900.

Secondary Suture of the Brachial Plexus. — William Thornburn reports upon a case of complete rupture of the brachial plexus, in which for the first time suture was effected a long time after the injury. Seven months after an accident by machinery a girl aged sixteen years presented paralysis of the arm, which was much wasted, and there was absolute anæsthesia. An hysterical monoplegia was the only condition which could confuse. In operating a long incision was made in the posterior triangle of the neck parallel to and just in front of the trapezius; the clavicle was divided and the cervical vessels were held back with retractors. An irregular cicatricial mass represented the plexus, which was dissected out as a tense cord two inches long and three-quarters of an inch thick. After suturing the ends wound healing took place by first intention. Feeble though recognizable motion of all muscles returned with muscular sense and localization.

Treatment of Lupus by the X-Rays.—R. E. Scholefield presents, with special plate showing lupus of the nose in various stages of the cure, an account of how the rays were applied. The results were such as to make the author wonder whether the rays from the tube might not have the same effect as the photo-chemical rays of the solar spectrum employed by Finsen. He suggests that if dermal tuberculosis may thus be cured by concentrated sun- or *x*-rays, why not pulmonary?

The So-Called "Stave of Thumb," or Bennett's Fracture.—G. T. Beatson refers to Bennett's statement that when fracture occurs in the metacarpal bone of the right thumb, this is not "just above the middle," but at the base of the bone. He relates a case seen sixteen days after the accident, when crepitus was still thought to be detected. All supposed sprains of the right thumb should be subjected to *x*-ray investigation, as the fracture is liable to be overlooked.

Fracture of the Carpal Scaphoid. Sir William Stokes says that without the *x*-ray no surgeon can form a true estimate of many osseous lesions. He gives, with special plate illustration, an instance of the comparatively rare lesion of carpal scaphoid fracture sustained in falling twenty-one feet through an elevator shaft. In Dublin only two cases have been noted. The diagnosis could not have been made without the aid of the Roentgen rays.

A Case of Fracture Dislocation of the Spine.—Ashley W. Mackintosh reports a case in which there was complete destruction of the cord in the upper lumbar region. A synopsis of the case is given, with drawings illustrating the lesions and areas of total anæsthesia.

An Example of the Use of the X-Rays in the Examination of Enlarged Metatarso-Phalangeal Joints.—By G. H. Rodman.

The Therapeutic Value of the X-Rays in Medicine.—By Edouard Schiff.

Deutsche medicinische Wochenschrift, April 26, 1900.

The Pathology of Bronchial Asthma.—A. Fraenkel discusses the view held by Curschmann, that most instances of bronchial asthma have underlying the condition a particular form of catarrhal affection known as "bronchiolitis exudativa," and which Curschmann believes is a disease *sui generis*. He also goes into the question of the presence of Curschmann's spirals in asthmatic catarrh. Two fatal cases have proven correct his former belief that the anatomical findings in the lumen of the bronchi are not always the same. There exists, however, a bond of union between them all in the abundant epithelial desquamation.

Clinical Observations upon Excretion of Ammonia by the Urine.—L. Michaelis says that the previously recognized causative factors in the increase of ammonia in the urine under certain pathological conditions can be placed in four categories, which he goes on to describe. He then enumerates a number of clinical conditions in which he has found a relatively large ammonia loss in the urine.

A Contribution to Physical Therapy.—By Professor Goldscheider.

On the Technique of Abdominal and Pleural Puncture.—By H. Hellendall.

On the Treatment of Obesity (Concluded).—By W. Ebstein.

Berliner klinische Wochenschrift, April 23, 1900.

The Treatment of Nævus and Associated Congenital Vascular Formations.—E. Holländer warmly advocates the method of hot-air cauterization. Instead of the frequent and painful cautery punctures, the operation can be done at one sitting. There is no hemorrhage, so that the blood in the diseased area is not abstracted from the body. The cicatrix is a good one, and from its slight extent is hardly perceptible. Finally the method is applicable to all surfaces, even those in cavities. It is contraindicated especially at subcutaneous sites in which a total capillary substitution has occurred, and when extirpation offers a more speedy result. The technique of the procedure is described.

The Nutrition and Diseases of Nurslings.—A. Baginsky gives a general review of the vast progress made during the present century in our conceptions of the matter of infant feeding, and discusses the relative nutritive values of mother's and cow's milk. He shows the relation of improved feeding to general hygiene, and believes that it is possible largely to eradicate, by care in this respect, many of the affections of the mouth, skin, ear, etc., which arise from neglect in feeding and in hygienic management.

Weather, Duration of Sunshine, and Infectious Diseases.—J. Ruhemann gives some meteorological statistics for Berlin, showing that during the period of most sunshine the amount of contagious disease is the least.

The Plague in the Light of Latest Researches.—By P. Frosch.

French Journals.

Researches upon the Semeiological Value of the Toe Reflexes.—H. Verger and J. Abadie discuss the Babinski phenomenon in its varied relations and also the antagonistic reflex of Schäfer. They study the toe reflex in the normal state and in pathological conditions, and conclude that the sign is of delicate execution and open to many sources of error; it is frequently seen in lesions of the pyramidal tracts, but is too variable to constitute a symptom of the first order. It cannot be compared to the epileptoid trepidation of the foot or patella. The antagonistic reflex of Schäfer has no semeiological value as a sign of cerebral lesion. Schäfer's manœuvre produces an effect of its own independent of cutaneous excitation. This effect consists in flexure of the toes in the normal as well as in the pathological state. In cases of reflex hyperexcitability the effects of excitation of the skin are felt before those from pinching the tendon, and Schäfer's manœuvre can cause only extension of the toes; but there is no question of antagonistic reflex.—*Le Progrès Médical*, April 28, 1900.

Early Diagnosis of Madness in the Biting Dog.—V. Babes refers to his previous writings upon accumulated embryonal cells in the region of the central canal and the possibility of making a rapid diagnosis of rabies by examination of the bulb of a biting dog. Out of a large number of examinations of bulbs from dogs dead from all causes, sent to the author by the veterinary school, he has always been able to pick out those whose death was due to rabies. Out of four hundred and eighty-seven cases he has never declared a dog mad which was not shown to be so. He discusses Van Gehuchten's views and method, and calls upon antirabic institutes to test the two methods of rapid diagnosis and compare them.—*La Presse Medicale*, April 25, 1900.

Pulmonary Gangrene after Gastro-Entero-Anastomosis for Cancer.—J. J. Peyrot and G. Milian report the case of a woman aged fifty-seven years operated on by Souligoux according to his own method for gastro-entero-anostomosis. On the tenth day, after moderate fever, slight signs of lung implication, pleurisy with slight effusion, fetid breath, etc., there were sudden tearing pain in the right chest, dyspnœa, cyanosis, and rapidly following death. At the autopsy gangrene was found, supposed to be due to septic embolism from the gastric ulceration. This is looked upon as one of the causes of the high death rate after stomach operations.—*La Presse Médicale*, April 25, 1900.

Migratory Abscess becoming Autonomic.—H. Morestin speaks of certain abscesses in Pott's disease which become isolated from the primary lesion, or shut off in such a way as to be readily cured. The prognosis in this case is very different from the majority in which connection with the bony necrosis still persists. Two typical examples are cited. One variety of abscess may continue to increase, the other to grow smaller with atrophying walls and hardening contents.—*Gazette des Hôpitaux*, April 19, 1900.

Treatment and Prophylaxis of Gonorrhœa.—Claudio Fermi thinks we should possess some short, efficacious, painless treatment capable of warding off complications. He recommends a bulb syringe filled with 100 or 200 c.c. of permanganate solution 1 : 200, nitrate of silver 1 : 500, protargol 1 : 500, or ichthyol 1 : 200, to be carried in a metallic box and the solution to be squirted into the canal and sucked out again at frequent intervals during the day.—*Gazette des Hôpitaux*, May 1, 1900.

Tetanus.—Ch. Dopter gives a clinical and therapeutic study with symptomatology, prophylaxis, orrhotherapeutic and other forms of treatment. Only the cases observed from the beginning are suitable for intracerebral orrhotherapy. Splanchnic tetanus is excluded by reason of its fatal outcome and subacute motor tetanus, which carries off its victim in two or three days.—*Gazette des Hôpitaux*, April 28, 1900.

Annals of Surgery, May, 1900.

Report of a Case of Recovery after Ligation of the First Part of the Right Subclavian Artery for Aneurism of the Third Portion.—A. E. Halsted reports this case, occurring in a man aged sixty-three years. He believes that it is the second case of recovery on record. He regards the following points as worthy of consideration: (1) The aneurism involved the entire third portion of the subclavian and encroached slightly upon the second portion, so that the only rational method of treatment was ligation of the first part. (2) The subclavian vein was found above the artery throughout its whole course. Owing to this position of the vein, it was torn while efforts were made to retract it downward so as to reach the artery external to the internal jugular. As a result of this accident, a considerable amount of time was consumed before the hemorrhage could be controlled by lateral ligation of the vein; and (3) the anomalous origin of the right subclavian and the unusual depth of this vessel were for a time very confusing. He would strongly recommend preliminary resection of the clavicle and a portion of the sternum in all cases. In his opinion, it makes very little difference whether the portion of the clavicle which is resected is restored or not. In the case just reported the patient had an almost perfect clavicle at the end of six weeks, although the inner third, together with the upper end of the sternum, had been removed. The ligatures employed in this case were of formaldehyde catgut. The suggestion of Souchon, of applying two or three non-contiguous absorbable ligatures, should be followed in all cases. The ordinary surgeon's knot is all that is required. The ligatures should be drawn sufficiently tight to occlude the vessel, which can be determined by the cessation of pulsation in the aneurism, and not tight enough to rupture the arterial wall.

Complete External Dislocation at the Elbow.—R. Winslow regards this case as belonging to th "sub-epicondylar" variety, in which the elbow is flexed to nearly or quite a right angle and the forearm pronated; the radius is placed somewhat anterior to the ulna, and the great sigmoid cavity is placed just below the external epicondyle. Reduction in this case under anæsthesia could not be accomplished, so twenty days after the injury causing the dislocation a crucial incision was made on the back of the joint and the parts were thoroughly exposed, the muscles separated from the external condyle and from the olecranon process, and a further attempt was made at reduction, which failed entirely until the triceps muscle was cut quite across, when the bones were made to resume their natural relations. The triceps was sutured and the extensive wound closed except a small opening left for drainage on account of the free oozing which occurred. The triceps tendon was found displaced to the outer side, and attached normally to the olecranon process; the other muscles were also more or less out of their normal relations, but not torn. The ulnar nerve was found stretched, and was carefully held out of the way with a hook, but it was not injured; subsequently the little finger and the inner side of the ring-finger remained anæsthetic for some time. Of course, all the ligaments of the joint were entirely ruptured. The radius retained its normal relation to the ulna, and the functions of pronation and supination were unimpaired. Four weeks later the limb was in a useful position with a considerable range of motion, but some œdema of the parts.

Post-Diphtheritic Stenosis of the Larynx (Retained Intubation Instrument and Retained Tracheal Cannulæ.—The late J. O'Dwyer stated as the most common causes of obstruction under the conditions implied in the title, an œdematous, chronically inflamed condition of the subglottic region, less commonly cicatricial tissue, and exceptionally granulations from erosion by the tube. He also mentioned the possibility of a post-diphtheritic paralysis of the laryngeal abductor muscles, but regarded this as extremely improbable. In the present paper J. Rogers, Jr., states that the commonest cause of post-diphtheritic stenosis necessitating long-continued intubation is a hypertrophy of the subglottic tissues accompanied by a chronic inflammation. The intubation is in no way the cause of this, as it occurs irrespective of the operation. Less often there is an ulceration, with subsequently the formation of a greater or less amount of cicatricial tissue and contraction. This likewise is not the result of the intubation except in rare and practically unavoidable instances. But it certainly may follow a tracheotomy, and in a larynx already chronically stenosed, it makes the condition worse but not necessarily more difficult to cure. Exuberant granulations within the larynx apparently do not occur with intubation, no matter how prolonged. The remedy for these conditions is the use of a tube as large as can be crowded into the larynx.

Two Cases of Œsophageal Diverticulum, with Remarks.—M. B. Richardson describes the cases, on both of which he successfully operated. The number of cases now on record is fifty-six. When excision of the pouch is impracticable or impossible, recourse should be had to gastrostomy to prevent starvation and to prolong life. These pouches are to be regarded as protrusions of the mucosa through the muscular coat. The primal cause is undoubtedly pressure together with the presence of scar tissue or tissue weakened by unknown causes. A constriction of the œsophagus is not necessary for their formation, for in all the cases hitherto reported no stricture has been found.

Dislocation of the Shoulder Complicated by Fracture through the Anatomical Neck of the Humerus.—By C. B. Brigham.

Report of a Case of Superficial Bilateral Gangrene with Asymmetrical Lesions.—By G. F. Wilson.

Report of a Case of Actinomycosis Hominis of the Lungs.—By J. B. Bullitt.

The Edinburgh Medical Journal, May, 1900.

Some Practical Observations on the Early Diagnosis of Cancer of the Stomach.—Carstairs Douglas gives detailed directions as to the diagnosis of this condition. Palpation is the most reliable method of clinical examination, the great point in the method termed "dipping" being to take the abdominal walls by surprise and bring the finger tips against any subjacent hard structure before the muscles have time to contract. Chemical examination of the stomach contents should be made in doubtful cases; in the large majority of cases of cancer of the stomach, free hydrochloric acid is absent a couple of hours after a test meal, while in many cases it is found that lactic acid has taken its place. When there is grave suspicion of malignancy but a positive diagnosis is not possible, a surgeon should make an exploratory incision. Even if no tumor is present, in some inexplicable way the simple making of an incision produces "some change of government," and the patient finds that his symptoms are relieved.

On the Mechanism of the Intestinal Movements, and on Reversal of the Intestine.—I. L. Bunch says that there are three forms of intestinal movement: first, regular pendulum movements, which take place at the rate of about twelve a minute and travel along the wall of the intestine at from 2 to 5 cm. per second; second, the peristaltic wave, which travels only from above down and is independent of connection with the central nervous system; the third form is best seen in animals recently killed. It travels rapidly, about ninety times as fast as the peristaltic wave, both in an upward and a downward direction, but it is seen only when the intestine is in a very excitable condition. This form of wave explains the antiperistalsis which is present in certain varieties of intestinal lesion. The author studies the mechanism of these various movements and reports various experiments upon animals.

Observation on the Excretion of Nitrogen in Rheumatoid Arthritis.—William Bain reports a case of marked rheumatoid arthritis, in which an analysis of the urine made for seven days gave the following averages: Total quantity of urine, 1,235 c.c.; urea, 18.856 gm.; uric acid, 0.266 gm.; phosphoric anhydride, 0.986 gm.; alloxur bases, 0.033 gm.; ammonia, 0.397 gm.; lactic acid, absent. There was therefore a diminution in the excretion of uric acid and phosphoric anhydride. It is stated that in healthy individuals the excretion of uric acid varies from 0.3 gm. to 1.2 gm. Although the author has examined the urine of a moderately large number of healthy people he has never met with an excretion below 0.4 gm. The normal relationship between the uric acid and alloxur bases was not disturbed.

Optic Neuritis in Children.—Leslie Buchanan says that during the few past years he has seen several cases in which a child, showing no evidence of present bad health, suffers from atrophy of the optic nerves; or again, in which a child with but slight signs of disease has moderately acute optic neuritis. It was noticed that almost all such cases showed more or less marked enlargement of the cervical glands. Unless another distinct cause can be found, if either atrophy or inflammation of both optic nerves be seen in a child or young person, the presence in the neck of enlarged glands, even of very moderate size, is an indication that there may have been, or may be, a meningitis or a tuberculous growth in the brain.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

REPRESENTATIVE COUNCILLORS AND THE MIDWIVES BILL—DR. HORTON-SMITH ON TYPHOID—RESISTANCE OF BACTERIA TO COLD—SIR WILLIAM MAC CORMAC AND MR. TREVES—MAJOR BABTIE, V.C.

LONDON, April 27, 1900.

THE somewhat lively discussion about the midwives bill continues to occupy our attention. The relation of the corporations, societies, medical council, and our representatives on it is exciting acrimonious remarks. Last week I told you how Dr. Glover had found himself at variance with a rather active committee who had challenged him to appeal to the constituents, but of course he refuses to consider himself a delegate. Prof. Victor Horsley has now been cornered by the same committee. It is common enough to hear these men spoken of as busybodies or as lacking followers. That is no rare fate for reformers—or for obstructives either. In this matter it is impossible to doubt that a large number of practitioners consider their interests have been betrayed, and it is far from improbable that an election at this time would displace both these representatives. I should regret this, for both are earnest men, anxious to serve the profession, but are removed from the anxieties and arduous life of the masses, and apparently neither of them can in thought put himself in the position of a struggling general practitioner. Both, too, have friends among the managers of the Obstetrical Society and hesitate to brand them as dealers in sham diplomas.

The matter was before the parliamentary bills committee of the British Medical Association, when it was decided to send a deputation to Sir John Gorst, who has charge of the bill, to urge amendments. The association, if its members were consulted, would repudiate the bill, but the council and its committee have admitted the principle and will not find it easy to avoid the consequences of their error in assuming that they represent the body of members who decline to follow them.

"There is not the smallest difficulty in distinguishing the typhoid bacillus from what may be called the classical bacillus coli communis." So said Dr. Horton-Smith in the first of his Goulstonian lectures on the 20th ult. But I should qualify this statement, and indeed the lecturer proceeded to say that we must recognize the fact that the term bacillus coli refers not to a single microbe, but to a whole group, some of which very closely resemble the typhoid bacillus. Then he went on to describe the various tests by which the differentiation can be established. Some of these are long and tedious, and at any time additional microbes may be discovered—possibly still more closely resembling the typhoid. Therefore I repeat I would qualify the Goulstonian lecturer's statement, and with special emphasis I would add that it can be so easy only to the skilled bacteriologist in a properly equipped laboratory. It may be granted, as the lecturer holds, that in all cases the bacilli pass into the blood, for they are very widely distributed to the viscera. But they are not found in great numbers in the blood during life. Perhaps the blood is a bad medium for their growth and soon acquires the power of rapidly destroying them, so that only those which reach a viscus escape. If the blood for any reason failed to acquire this power, the bacilli would develop in it and be found in large numbers after death. The failure would indeed lead to a fatal termination. As the bacilli gain entrance to the blood and circulate to the organs and are to be found in the excretions, typhoid is no longer to be looked upon as a local intestinal disease. Dr. Horton-Smith is inclined to regard it rather as a modified form of septicæmia, inasmuch as in all cases the bacilli pass into the blood, thence to the various organs, producing symptoms of poisoning. But the septicæmia is modified, as there is almost always a definite, local, primary disease from which secondary dissemination of the bacilli takes place. Looked at in this way we see why the severity of a case has no relation to the extent of the intestinal lesion. There may perhaps be some objections to this view, but at least, I think, it seems about time to discard the term enteric, for though usually the starting-point of the disease is a lesion of the intestines, the microbes speedily pass into the blood. Moreover, in some cases they gain access to the blood without any obvious intestinal lesion. The infectiousness of the fæces has been long enough recognized and is often regarded as the sole source of danger. But it now appears that the urine may be equally dangerous, and expectoration, if present in a case, is to be suspected. There is not much evidence about the sweat, but it would seem that any secretion might convey the microbe. The great point, however, is the extreme danger of urinary infection. Three years ago Dr. Horton-Smith was able to report that sometimes the microbe could be found in the urine. Now he can definitely state that it is present in one out of every four cases. As a rule it is late in the disease that it appears, perhaps after convalescence has set in. The danger, therefore, is increased at the very time it is too often thought to have passed by. Not uncommonly the microbes are present in such extraordinary numbers that 1 c.c. may contain 500,000,000. They are much more easily detected than in the fæces, as they are almost always in pure culture. They may set up cystitis, but this is not necessarily so, and there may be no clinical symptoms. It seems that the urine in these cases is a favorable medium for their growth. In other cases it is not. Thus, while in one a few stray bacilli in the bladder speedily produce enormous numbers, in other cases they perish. The bacilli can be rapidly cleared out of the urine by a few doses of urotropin, mostly within twenty-four hours, but it is well to continue the drug for a week. It would seem then desirable to give the drug in all cases in order to prevent infection through the urine—much more difficult to avoid than in the fæces.

Writing so much about bacteria reminds me that Dr. A. Macfadyen and Mr. S. Rowland lately communicated to the Royal Society some experiments on the influence of the temperature of liquid air on these organisms. The microbes experimented on include the typhoid, diphtheria, anthrax, and several others. The intense cold had no effect on their vitality. After being exposed to about −190 C. for a week no impairment of their vitality could be detected. Cultures grew as well as before. It is wonderful that such organisms were not injured by the mechanical strain that must have ensued, to say nothing of the temperature.

Sir W. MacCormac and Mr. Treves are both back in London. A dinner is to be given them to-morrow. Sir William has been interviewed by a Reuter's agent and talked about the wounds of the different rifles, the x-rays, the great value of hospital trains, and the slight loss in killed compared with battles of the past. On these points he could speak, but on the effectiveness of artillery fire I doubt if military men will accept his authority. As to the adjective admirable applied to the provisions of the government, few of his countrymen will think it appropriate to the War Office, even if he throws in his own engagement to help.

Major W. Babtie, R.A.M.C., is awarded the Victoria Cross for his gallant conduct at Colenso, of which you must know the particulars.

Rhythmical Tongue Traction in a Case of Asphyxia of Bulbar Origin.—J. V. Laborde quotes a case reported by G. Schneider. A patient suffering from typhoid fever suddenly showed alarming symptoms of bulbar origin. The face was cyanosed; the conjunctivæ were injected, and the pupils enlarged to the maximum and immobile. There was intense trismus; the respiration was hoarse, the neck swollen, the jugulars were dilated and pulsating. Loss of consciousness was almost complete. Rhythmical tractions of the tongue restored normal conditions. As soon as the patient became conscious he seized the forceps and drew his tongue forward with desperate energy, and continued to make rhythmical tractions for two hours, until the occasional crises of asphyxia entirely disappeared. This he did by instinct and absolutely refused to give up the forceps until respiration was entirely free.—*Bulletin de l'Académie de Médecine*, March 20, 1900.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 12, 1900:

	Cases.	Deaths.
Tuberculosis	241	179
Typhoid fever	21	13
Scarlet fever	166	12
Measles	559	14
Diphtheria	288	44
Laryngeal diphtheria (croup)	9	7
Cerebro-spinal meningitis	0	1
Chicken-pox	11	0

Locating the Antagonism.—Dr. Virtue writes to *The Plexus* as advice to physicians choosing a location, that they "shall call on every reputable physician in the locality as an act of courtesy, and in this way to find out who will antagonize them in the new field." In other words, "Will you kindly allow us to come in?"

Michael Angelo's Physique and Health.—Michael Angelo is described as having been of middle height and broad across the shoulders. He was not fat and his features were marked, his forehead being square. His nose had been broken in early life by a blow from a fellow-student, which had caused permanent disfigurement. In some of his portraits this is represented; others give him a good nose of Roman type. He had been weakly in youth and probably dyspeptic, for through life he was very careful in his diet. He was accustomed to say: "However rich I may have been, I have always lived as a poor man." In spite of this care, however, he suffered late in life from gravel and stone. It is on record that he had much trouble with cramp in his legs. His father had attained the age of ninety-two years, end he himself was only a year short of ninety when he died, having retained his faculties to the last.—Hutchinson's *Archives of Surgery*.

Alcohol and Hard Work.—In the current number of a small serial, entitled *The Medical Temperance Review*, is a short paper on the above subject by Dr. Sims Woodhead. The writer points out that the greatest amount of work can be done only by completely abstaining from alcohol, or, in other words, that alcohol hinders us from accomplishing the maximum amount of work of which our bodies and minds are capable. Now there may be another way of regarding this which perhaps might be urged by our moderate drinkers. We were not created to be beasts of burden as regards our bodies, nor yet to exercise our brains until our nerves became shattered. So that the administration of a little alcohol to those who believe we should be working every moment of our lives might be of the greatest service in restraining an output of energy which must undoubtedly be pathological. Numbers of youths at our universities break down at a critical period of their lives from sheer overwork, which they are not sufficiently discouraged to attempt by their responsible teachers. In the same number is a short statement on this subject by the late Sir Andrew Clark, who, curiously enough, was himself a moderate drinker. He instances an experiment by Dr. Parkes, of Netley, who set two gangs of men to work; one gang was liberally supplied with beer, the other gang being deprived of all alcohol. By the end of the day the beer gang was left hopelessly behind. Now, the only inference we can draw from this experiment is that men in a state of intoxication or semi-intoxication are incapable of hard work. No one denies that to place gallons of beer beside workingmen is on a par with placing, say, a quart of Fowler's solution beside a choreic patient. What we desire is to have the effect of alcohol tested with the same scrupulous regard to dosage and conditions as in the case of toxin, antitoxin, digitalis, or any other similar agent.

Isolation for Consumptives.—When we demand isolation for cases of tuberculosis, we are, I think, fanatics; that is, we are driving hard one set of arguments with a blind eye to contingent and conflicting considerations derived from the other circumstances which we ignore or to which we are insensible. This is to be "logical," as the French call it. Would it have been for the public good to have isolated Henry Bennet or Andrew Clark in the midst of a beneficial career, or now on early suspicions to carry off young people to desert islands, or to banish a bread-winner on the rather remote chance of consequences which we are learning successfully to neutralize?—DR. CHALMERS, in *London Practitioner.*

Disappearance of Beri-Beri from the Japanese Navy.—Dr. Tatsusabaro Yabe, head of the medical department of the Japanese navy, relates in the *Archives de Médecine Navale* how kakke or beri-beri has to all intents and purposes disappeared from his branch of the service. Before 1884 the proportion of men affected during the summer was rarely below twenty-five per cent., and sometimes it reached forty per cent. M. Kanebiro Takaki then suggested an improvement in the food (which was composed mainly of rice) by the addition of pearl barley, with the result that from 1885 to 1895 there were only three fatal cases of beri-beri, all of which occurred during the war with China, when the supply of rice failed.

Typhoid Fever in South Africa.—The terrible ravages of typhoid among both troops and civilians in South Africa is a matter for very serious consideration by the government in the Soudan, and in Cuba the same state of matters existed. Typhoid seems to be the great scourge of our modern armies. The great desideratum is not to allow it to get a chance so far as is humanly possible. Once a case or two occurs, it seems impracticable to arrest its spread where such crowds are huddled together. Boiling and filtering, the only remedies for infected water, are neglected, it is to be feared to an unwarrantable extent. According to a correspondent in the *British Medical Journal*, the type of fever differs from that found in England. Rash is usually absent; the temperature is more of the continuous type, while diarrhœa is generally in abeyance until about the third week, and is then of a mild character. Notwithstanding, the necropsy shows the typical lesions. The fever is often extremely prolonged and may assume an intermittent character.—*Medical Magazine.*

Smoking among the Young.—The medical officer for the city of Perth, Scotland, in his annual report refers to the prevalence of smoking among the young of his neighborhood, and calls attention to the harmfulness of the habit in the following words: "Excessive smoking, while not so common a cause of serious disease as excessive drinking, is still a sufficiently powerful factor to cause disturbances in the various systems of the body. While adults may enjoy the benefits of the moderate use of tobacco without harm, smoking to the slightest extent is productive only of injury to young people by checking their physical and mental growth. Societies taking an interest in the welfare of children have given recommendations to parents how good would result if deterrent measurse were employed, and some people suggest that the fault lies at the door of the adult members by providing children with the bad example. The thought of curing the evil habit among children by asking men to refrain from smoking requires no comment. Deterrent measures have, I fear, little effect, and while I give credit that the vast majority of parents are opposed to their children's smoking, and use what means they can to prevent it, yet the evil is done when out of their sight. Legislatures have in some other countries adopted means to stay the evil, but in Britain nothing of this nature has as yet been attempted. Municipal authorities have no legal powers, but there is one way in which I believe the practice of cigarette smoking among the youth could be greatly decreased, and it is a very simple one—viz., a recommendation to all those having a license to sell tobacco to restrict the sale of cigarettes unless in such quantities as to put them beyond the reach of children. Thus, if only sold in packets, for threepence (six cents) as a minimum, it is my belief we would have a means of seeing less cigarette smoking, because it is not in the nature of children to spend such a sum on any article."

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended May 12, 1900:

		Cases.	Deaths.
SMALLPOX—UNITED STATES.			
Alabama, Mobile	April 26th to May 5th	4	
District of Columbia, Washington	April 26th to May 5th	1	1

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue

New York, May 19, 1900.

CONCERNING THE PLAGUE.

FROM almost every part of the world the news is being constantly sent that plague has broken out or is on the increase. In the East generally, and especially along the shores of the Red Sea, the disease is spreading with alarming rapidity. In Egypt there has been a recrudescence. In Manila its inroads are assuming alarming proportions. It is raging in New Caledonia. In Buenos Ayres there has been an epidemic since the middle of March. In India the deaths from plague average about five thousand a week, and it is computed that since the first outbreak five years ago the enormous total of two hundred and fifty thousand persons have perished by its agency. The pest has made its appearance on shipboard off Cape Town. There have been one or two cases in San Francisco, and lastly, according to latest accounts, it seems to have gained a foothold in Australia. In Sydney, within the past three months, there is said to have been nearly two hundred cases, with a mortality of more than fifty, while Melbourne, Brisbane, Perth, and Auckland are experiencing visitations of the disease. The persistency of its stay in Sydney, and its continued dissemination throughout Australia, are the most sinister features in connection with the plague so far as civilized countries are concerned.

There is no doubt that individuals of the white race are less prone to contract plague than are Asiatics, but that they enjoy an immunity has now been altogether disproved. Nor unfortunately, with the experience of Australia before our eyes, does it appear that good sanitation is an absolutely sure safeguard against a plague invasion. When several cases occurred in Oporto, the filthy condition of that city was regarded as the cause, and the assertion was confidently made that in the more or less cleanly towns of Europe outside the Iberian peninsula it would be impossible for the plague to last or spread. This comforting belief has received a decidedly rough shock, for the sanitary condition of Sydney is quite equal to that of the average European town and infinitely better than that of Oporto. Yet from the latter city the plague was apparently quickly driven out, while in the former and more healthy place it is every day increasing. The truth is, so little is known about the plague that it is an act of unwisdom to dogmatize concerning it in the slightest degree.

The fact that rats are an important, if not the most important, factor in disseminating the plague is gradually being appreciated. Another point to which notice has been drawn of late is the peculiar difficulty of correctly diagnosing the disease. Professor Simpson, referring to this phase of the subject in *The Lancet*, April 14th, says: "The difficulty of diagnosis of plague arises from the several types and forms which it assumes, and unless the medical man is on the alert for plague and is fully conversant with the types the disease may easily at its commencement escape attention. . . . A disease which may be mistaken for yellow fever, gastro-enteritis, typhus fever, diphtheria, influenza, syphilis, malaria, and parotitis is one in which diagnosis from clinical symptoms is by no means easy." The glandular or bubonic, the most frequent form of the disease, is comparatively easy to diagnose, its characteristic feature being, as its name denotes, the appearance of a bubo occurring in most cases in the region of the thigh or groin, often under the arm, or in children on the neck. In a few instances, however, the buboes appear on different parts of the body.

The department of health of Berlin has recently issued a circular of instructions in regard to the plague, dealing especially with its clinical symptoms, which has been reprinted in Public Health Reports, April 20th. This circular places the number of forms under which the plague presents itself as three—glandular, skin, or lung plague. In regard to skin plague it says: "Plague pustules and plague carbuncles are not frequent as compared with plague buboes. They begin with a spot about the size of a flea-bite or a pea on some part of the skin. From this very painful spot there develops a blister filled with cloudy matter. It then either retains the character of a pustule or the surrounding tissue becomes hard and thick, later developing into a deep carbuncle and then into a burning swelling. Inflamed lymph vessels may convey the infection to the nearest layer of glands, in which then a bubo may grow. A bubo may also make its appearance in the neighborhood of a carbuncle." Pneumonic plague is the most difficult of diagnosis. In some epidemics it is the most common form and generally closely resembles an ordinary violent catarrhal or croupous pneumonia, while on occasions it is extremely similar to other inflammations of the lungs. The Berlin circular says: "In all forms of plague the early appearance of heart weakness is noted, together with irritation of the stomach and abdomen, extreme sensitiveness to pressure in the region of the epigastrium and the cæcum, violent nausea, and later also the expulsion of black fecal matter. A slight degree of swelling of the abdomen is the rule; soft swelling of the spleen and traces of nucleo-albumin and serum-albumin in the urine, bloody vomit or blood in urine are less frequent. A diphtheric affection of the tonsils is often found in the early stages."

It is needless to say that not only has no specific been as yet discovered in the treatment of the plague, but that ordinary curative measures have but little effect on its course. The therapeutic value of anti-plague serum has been by no means decisively proven.

British physicians who have investigated Yersin's cases place but little faith in his statistics claiming favorable results. The following is the report of the British plague commission treating of Haffkine's antiplague inoculation:

"1. Inoculation sensibly diminishes the incidence of plague attacks on the inoculated population, but the protection which is afforded against attacks is not absolute. On the one hand plague has attacked persons who have undergone inoculation as many as four times in the course of two years previous to their attack. On the other hand, as many as eight per cent. of the inoculated population may suffer from plague. Many varying influences have been at work in determining the rate of attack in different places, and it is impossible to give a numerical expression for the measure of protection against attack which inoculation confers.

"2. Inoculation diminishes the death rate among the inoculated population. This is due not only to the fact that the rate of attack is diminished, but also to the fact that the fatality of the attacks is diminished. Here again no numerical expression for the amount by which the death rate is diminished can be given.

"3. Inoculation does not appear to confer any great degree of protection within the first few days after the inoculation has been performed. This fact, we may note in passing, has an important bearing on the risk of infection which would be incurred by recently inoculated persons if they were left behind in surroundings so plague-infected as to render their evacuation by the uninoculated desirable.

"4. Inoculation confers a protection which certainly lasts some considerable number of weeks. It is possible that the protection lasts for a number of months. The maximum duration of protection can only be determined by further observation.

"5. The varying strength of the vaccine employed has apparently had a great effect upon the results which have been obtained from inoculation. There appears to be a definite quantum of vaccinating material which gives the maximum amount of protection, and provided that this quantum can be injected in one dose, and provided also that the protection turns out to be a lasting one, re-inoculation might with advantage be dispensed with. The best results from inoculation will only be obtained after an accurate measure of standardization has been devised."

This somewhat non-committing report, although certainly a not enthusiastic eulogy of Haffkine's serum, nevertheless points to the fact that under certain conditions its use is valuable. Now that plague is prevalent in the Philippines and in other parts of Asia with which this country is in constant communication, it is essential that every precaution should be taken to keep out the disease. Rigid quarantine and a wholesale destruction of rats are measures of the first importance, while second only to these is the need that physicians, and especially port health officers and members of the boards of health, should be able to diagnose accurately cases of plague. Professor Simpson makes the following recommendation to the government of England, which should be equally applicable to that of the United States, viz., that under the auspices of the government there should be instituted a course of instruction on plague, to be attended in batches by the medical officers of the country.

THE HOSPITAL TREATMENT OF PULMONARY TUBERCULOSIS.

Other things being equal, it may be admitted that certainly not less good results should be obtained in the treatment of pulmonary tuberculosis at home than in institutions. If, however, nursing, care, food, sanitary conditions, and the like are open at all to suspicion at home, the chances for the patient are much better in a well-equipped hospital. How successful may be the results under the latter condition is illustrated by Schaper (*Berliner klinische Wochenschrift*, 1900, No. 12, p. 253), who presents in tabular form the statistics of the Charité Hospital in Berlin for ten years, from 1889 to 1899. In the year 1889-90 recovery or improvement took place in 45.7 per cent. and death in 54.2 per cent. of the cases of pulmonary tuberculosis, and in the year 1898-99 recovery or improvement in 54.8 per cent. and death in 34.3 per cent. of the cases. These satisfactory results are attributed, among other things, to early diagnosis, to better care, the more effective medication, and the relation between the hospital and the sanatorium. In the Institute for Infectious Diseases, which was opened in 1892-93, recovery or improvement took place in sixty-one per cent. and death in twenty-three per cent. of the cases of tuberculosis received during the first year, and recovery or improvement in sixty-one per cent. and death in twenty-nine per cent. in 1898-99. The conclusion to be drawn from these experiences is that with further improvement in hygienic conditions still better results may be possible and should be secured. In addition, special institutions will have to be organized for the care and treatment of incurable cases of tuberculosis.

News of the Week.

The Spitting Nuisance.—At a recent meeting of the board of health, the section of the sanitary code relating to spitting in public places was made more stringent than before, the prohibition being extended to cover the station platforms and stairs of the elevated railroads, as well as the floors of cars, ferryboats, and public buildings. Notices of this prohibition must be kept posted wherever the prohibition applies; and janitors of buildings, conductors of cars, and employees of ferry-boats and on station platforms are directed to call the attention of all violators of the ordinance to those notices. A rule has also been established that in every cigar manufactory and printing-establishment where ten or more persons are employed, receptacles for spitting, in the proportion of one receptacle for every two persons, must be provided, and all such receptacles must be cleaned and disinfected at least once during each working-day. All these rules are excellent, and the only objection any one can have to them is that not the slightest attempt is ever made to enforce them. Inoffensive citizens shrink from calling down curses upon their heads by insisting upon the arrest or ejection from a public vehicle of a spitter, and the conductors are themselves too much attached to the habit of expectoration to reprehend it in others. *The Times* of this city says very justly that "either the spitting provision of the code is foolishness and should be repealed, or it is as much the duty of the health department staff to enforce it as to seize diluted milk or immature veal." And it suggests that the "physicians, sanitary engineers, inspectors, and detailed policemen of the sanitary squad, constituting the administrative staff of the health department, set the example not only of respecting the law, but of enforcing it in the cases of those who do not. As salaried employees of the city, whose especial business it is to do whatever will promote or protect the public health, it is quite within their duties to aid in enforcing the provisions of the sanitary code."

Navy Department, Bureau of Medicine and Surgery, Washington, D. C., May 12, 1900.—Changes in the medical corps of the United States navy for the week ending May 12, 1900. May 7th.—Surgeon G. P. Lumsdon ordered to the *Kentucky* May 15, 1900. Assistant Surgeon G. F. Freeman detached from the Naval Hospital, Washington, D. C., May 10th, and ordered to the *Essex*. Assistant Surgeon C. H. DeLancy detached from the *Essex* when relieved, and ordered to the Naval Hospital, Washington, D. C. May 10th.—Passed Assistant Surgeon S. G. Evans ordered to the *Kentucky* May 15, 1900. Passed Assistant Surgeon W. C. Braisted detached from the *Detroit* when put out of commission, and ordered home and to be ready for orders to sea.

The Medical Course at the University of Havana.—A committee, consisting of Drs. Casuso, Menocal, Nuñez, and Vildózola, which was appointed some time ago by General Wood to revise the course of medical studies at the University of Havana, has recently made its report. According to this report, published in the *Archivos de la Policlinica* of April 29th, it is recommended that the old system of instruction be abandoned and that the course pursued in English and American colleges be followed. The course is to cover four years, and candidates for admission must be at least eighteen years old, and must possess the degree of Bachelor in Letters and Science of the Cuban colleges, or a foreign equivalent recognized in Cuba. Much opposition developed to the report because it recommended the Anglo-Saxon system. The supporters of the Latin system protested, but when it was shown that the French faculties had made a reorganization on the same basis they accepted the change. The candidate for the degree of M.D., after having completed the course and been admitted to examination, must present a thesis which will be submitted to a jury of five who will determine whether or not it is "admissible." If the decision is favorable, the candidate will be obliged to sustain the thesis in public. The course begins in September each year, and clinical study is an essential to graduation.

Philadelphia Hospital.—Dr. H. B. Allyn, formerly registrar, and Dr. D. Riesman, formerly assistant pathologist, have been elected physicians to the Philadelphia Hospital, in succession to Drs. Samuel Wolfe and F. A. Packard, resigned.

Philadelphia County Medical Society.—At a stated meeting held May 9th, Dr. William S. Thayer, of Baltimore, presented a communication entitled "Recent Additions to our Knowledge concerning the Life-History of the Malarial Parasites."

Dr. Jameson, of Transvaal fame, who has been very ill, presumably with typhoid fever, is reported to have entirely recovered. He is said to be going into politics, and is mentioned as a candidate for one of the seats in the Cape parliament, representing Kimberley, in succession to Dr. Frederic Rutherford Harris.

Medical and Chirurgical Faculty of Maryland.—The next annual meeting of this society will be held the last Tuesday, Wednesday, and Thursday in April, 1901. The following are the officers for the ensuing year: *President*, Dr. Samuel Theobald; *Vice-Presidents*, Drs. Samuel T. Earle, Jr., and J. B. R. Purnell; *Secretary*, Dr. J. Williams Lord; *Treasurer*, Dr. Thomas A. Ashby.

Again the Fasting-Cure.—A disciple in Philadelphia of a medical man who recommends starvation for the treatment of various diseases, having himself recovered from digestive disturbances under such treatment, has been recommending a similar course to others. To the fact that the method is not infallible the death of one of the patients has brought a rude awakening. In this instance, however, death was not attributed to the system, but to "a cancer or severely ulcerated condition of the patient's stomach." The patient had fasted for fifteen days, and is said to have shown marked improvement. We fear the results in this case are like those occasionally reported by surgeons in which death ensues, although the operation is successful.

Philadelphia Pediatric Society.—At a stated meeting held May 8th, Dr. D. J. Milton Miller read a paper entitled "Brief Notes of a Case of Acute Leukæmia in a Child Eight Months Old." A thorough examination of the blood could not be made, but the number of leucocytes was greatly increased, while the number of red corpuscles was diminished and the spleen was enlarged. Dr. S. C. Peter reported a case of facial diplegia due to middle-ear disease. The patient was a girl fourteen years old, in whom in connection with bilateral otitis media complicating scarlet fever, first the facial nerve on one side and then that on the other side was paralyzed. Dr. Alfred Hand, Jr., reported a case of intussusception in a four-months-old infant relieved by injection. Some days after reduction had been effected symptoms of recurrence made their appearance, but these subsided spontaneously. It was thought that the use of paregoric exercised a useful therapeutic influence.

The New York State Medical Association.—The sixteenth annual meeting of the Fifth District Branch will be held in Wurzler's building, 315 Washington Street (near City Hall Square), Brooklyn, on Tuesday, May 22, 1900, under the presidency of Dr. J. C. Bierwirth, of Brooklyn. The secretary of the branch is Dr. E. H. Squibb, of Brooklyn. The president's address will be on "The Necessity and Benefits of More Completely Organizing the Medical Profession." The afternoon session will be devoted to a discussion on "Diabetes Mellitus," to be participated in by Drs. Heinrich Stern, Egbert le Fevre, Henry Dwight Chapin, Charles P. Gildersleeve, L. A. W. Alleman, Samuel Sherwell, and Jonathan Wright.

The Plague.—Honolulu is once more a free port, as the quarantine was lifted on April 30th. The official declaration that the plague is at an end is confirmed in the lay mind by the fact that rats are returning to Honolulu, as it is a popular belief that the animals never return to plague-infected places.—From India it is reported that the epidemic in all the infected places is showing a general decline, but in Hong Kong it is now increasing. Fifteen thousand Mohammedan weavers met in Benares on Sunday last and signed a protest addressed to the Indian government against the plague rules, declaring that these were contrary to the laws of Mohammed.—The plague is also reported to have reappeared at Alexandria and several other places in Egypt.

Famine and Cholera in India.—A recent despatch from Lord Curzon to the Secretary of State for India in London states that the famine conditions have materially improved in Madras and Mysore in consequence of the recent rains. In the remainder of the affected tracts the distress is increasing in intensity, owing to the want of fodder and water and the increasing heat. The number of persons now in receipt of relief is 5,617,000.—Regarding cholera, the Bombay correspondent of The London *Times* says that the disease continues to rage in the famine camps. There were four hundred deaths in three days at Mandivee. So numerous are the cases at Godra that it is impossible to collect the bodies, and they lie for days in the sun. The people have fled and cannot be induced to return. A similar state of things prevails at Broach.

The St. John's Guild.—Mrs. Augustus B. Juilliard, who last year presented the second floating hospital to St. John's Guild, has laid the foundation for a permanent fund by a gift to the guild of $50,000, the interest of which is to be used toward defraying the expenses of operating the floating hospital, the *Helen C. Juilliard*. Mrs. Frederick Elliott Lewis will build a cottage hospital on the Seaside Hospital grounds at New Dorp, S. I., in memory of her little son, Frederick Chandler Lewis. The building, which will be known as the "Lewis Memorial Cottage of St. John's Guild," is to be detached from the other buildings of the group and will be for the care and treatment of very sick infants. It will contain two wards for eight babies each, a diet kitchen, laboratory, bath, and irrigating-rooms. The hospital will be completed in time for use this season.

Practitioners' Society of New York.—The following officers were elected for the ensuing year: *President*, Dr. A. Alexander Smith; *Secretary*, Dr. Walter B. James.

The Medical Society of the State of North Carolina will hold its forty-seventh annual meeting at Tarboro on May 22d, 23d, and 24th, under the presidency of Dr. George W. Long, of Graham. The secretary is Dr. George W. Pressby, of Charlotte.

Dr. Georges Apostoli, of Paris, who was for many years an ardent advocate of the treatment of uterine fibroids by means of electrolysis, died recently at the age of fifty-three years. He was a voluminous writer on electro-therapeutics and was editor of a journal devoted to this subject.

The Stickler Memorial Library.—Ground was broken on Saturday last for the Stickler Memorial Library, which Mr. and Mrs. Joseph W. Stickler, of Orange, N. J., are to erect in memory of their son, the late Dr. J. W. Stickler, who died suddenly in New York about a year ago.

The Yale Medical School.—The Yale University authorities are negotiating for the purchase of a site for a new medical school adjacent to the New Haven Hospital. The land will cost about $75,000. The building now used as a medical school is not large enough nor suitable in other ways for the work of the medical department of Yale, nor is it convenient to the hospital.

The American Medical Editors' Association will meet in annual session at Atlantic City on June 4, 1900, the day preceding the meeting of the American Medical Association. The president of the association is Dr. I. N. Love, of St. Louis, and the secretary Dr. Dillon Brown, of New York. It is reported that the annual sermon by Dr. George M. Gould will be omitted this year in deference to the wishes of the president of the association.

The Dental Society of the State of New York held its annual meeting at Albany last week. The following officers were elected for the coming year: *President*, Dr. John J. Hart, of New York; *Vice-President*, Dr. R. H. Holheinz, of Rochester; *Recording Secretary*, Dr. W. L. White, of Phelps; *Treasurer*, Dr. G. W. Stainton, of Buffalo; *Corresponding Secretary*, Dr. Henry D. Hatch, of New York. Drs. William Jarvie, of Brooklyn, and F. C. Walker, of New York, were recommended to the board of regents as dental examiners from the second district, and Drs. S. B. Palmer, of Syracuse, and A. Detter, of Utica, from the fifth district.

Artificial Immunity against Tuberculosis.—Dr. Tatsusaburo Yabé of the Japanese navy states, in the introduction of an article on "Immunity against Tuberculosis," published in the *Sei-I-Kwai Medical Journal* of March 31, 1900, that he has discovered a means of effecting this desirable result. In the course of his studies in the Pasteur Institute of Paris, he has proved, he says, that Koch's tuberculin is a false toxin possessing no immunizing properties whatever. He has himself discovered in tubercle bacilli a substance possessing bactericidal properties and another which confers antitoxic immunity. By means of progressively increasing doses of one of these substances or of a mixture of the two injected into healthy guinea-pigs he was able to obtain immunity in them against injections of pure cultures of tubercle bacilli; and the same injections in the case of tuberculous guinea-pigs effected a cure, the bacilli disappearing before the tubercles. He asserts, therefore, that it is possible both to confer immunity against the disease in case of the well and to obtain a cure in those already tuberculous.

St. Luke's Hospital.—The Rev. George F. Clover, for many years assistant pastor and superintendent at St. Luke's Hospital, has been appointed full superintendent in place of the Rev. Dr. George S. Baker, whose resignation was recently accepted by the board of managers.

The Michigan State Medical Society.—The thirty-fifth annual meeting of this society will be held at the Grand Hotel, Mackinac Island, July 11th and 12th. The annual meeting of the Upper Peninsula Medical Society will immediately precede that of the State society, and a joint session of the two will be held to commemorate the achievements of Dr. Beaumont, whose celebrated investigations in gastric digestion, conducted upon Alexis Saint Martin at Mackinac in 1825, the former society will memorialize by an address and the erection of a tablet. The address on medicine will be delivered by Dr. Albert E. Carrier; that on surgery by Dr. Oliver A. LaCrone; and that on gynæcology by Dr. Eugene Boise. The subjects for set discussion will be: in the medical section, "Diseases of the Stomach" and "Tuberculosis"; in the surgical section, "Appendicitis," "Hysterectomy," and "Eclampsia." The president of the society is Dr. Austin W. Alvord, of Battle Creek, and the secretary Dr. Collins H. Johnston, of Grand Rapids.

Camden (N. J.) District Medical Society.—At the annual meeting held May 9th, the following officers were elected for the ensuing year: *President*, Dr. J. T. Leavitt; *Vice-President*, Dr. W. R. Powell; *Secretary*, Dr. P. M. Mecray; *Treasurer*, Dr. E. R. Ramsdell; *Historian*, Dr. H. H. Sherk; *Reporter*, Dr. J. G. Doron; *Standing Committee*, Drs. J. S. Baer, J. E. Hurff, J. W. Marcy, W. A. Jennings, and W. A. Wescott; *Censors*, Drs. Alexander Marcy and Blake; *Trustee*, Dr. O. B. Gross.

Pathological Society of Philadelphia.—At a stated meeting held May 10th, Drs. W. C. Posey and E. A. Shumway exhibited specimens from a case of alveolar sarcoma of the choroid. Drs. A. O. J. Kelly and S. Flexner presented a specimen probably of carcinoma of the ileum close to the ileo-cæcal valve without metastasis or evident glandular involvement. Abdominal symptoms had not been marked during life, but constipation, which had been present, was followed by symptoms of intestinal obstruction, with marked retroperistalsis. An operation was undertaken, but without a successful result.

Army Surgeons and Bicycles.—All the members of the German army medical service are required by a recent regulation to learn to ride the bicycle.

Morphinism among Physicians.—The editor of *The Quarterly Journal of Inebriety* returns to this question in a brief note in a recent issue of that journal, quoting the travelling agent of a large drug house, as follows: "Within ten years my orders from physicians for morphine have rapidly increased. I have a number of regular customers who order from two to five thousand one-fourth-grain and one-half-grain tablets of morphine for hypodermic use every month. Some of these physicians buy for their patients, others clearly use morphine themselves. Many of these doctors have a large practice, and are not known to be morphine-takers. Other physicians buy very largely of deodorized tincture of opium and opium pills. In a small village of five thousand, where seven doctors practise, one physician bought over five gallons of tincture of opium every year. In another town where the practice was limited, large quantities of opium pills and preparations of codeine were sold to two physicians. Other narcotics, such as chloral hydrate, hyoscyamine, and cannabis indica, are called for in large quantities beyond the natural demand of practice."

Obituary Notes.—Dr. Jacob Rickabaugh, the oldest practising physician in Chester County, died in Tredyffrin Township, Pa., on May 6th, at the age of eighty-five years. He was graduated from Jefferson Medical College in 1842, and until within a week of his death was actively engaged in the practice of his profession. He was also largely engaged in agriculture, being one of the most extensive land-owners in eastern Chester County. He also took an active interest in political affairs.

Contribution to the Study of Dentigerous Cysts of the Superior Maxilla and their Relations with the Maxillary Sinus.—P. Jacques and G. Michel make the following classification: (1) Cysts of external origin which develop about the roots of the incisors, canines, and sometimes the premolars. These have a great tendency to develop toward the canine fossa, separating the two tables of the maxilla. As a rule, it is the external table which yields, as it is the thinner; thus the anterior wall of the antrum is bulged outward. Finally it gives to the finger the characteristic crackling feel. (2) Cysts of sinus origin. As a rule, these simply pouch inward the wall of the sinus without actually breaking through, so that there is no communication between the cavity of the cyst and that of the antrum. Sometimes, however, such a communication does actually exist. In the former of the two conditions extraction of the tooth involved will provide proper drainage, but in the latter it is necessary to perform the classical operation for opening and draining the antrum.—*Revue Hebdomadaire de Laryngologie, etc.*, March 24, 1900.

REMARKS ON SOME OF THE CONDITIONS SIMULATING APPENDICITIS AND PERI-APPENDICULAR INFLAMMATION.[1]

By E. G. JANEWAY, M.D.,

NEW YORK.

So much has been written and spoken of appendicitis in its surgical and medical aspects that interest in this small portion of our anatomy has never flagged for any considerable period. It has seemed to me that no better place than a meeting of this society, in which there are members who have had a very large experience with this disease, can be found before which to present for consideration the subject of conditions which simulate appendicitis and peri-appendicular inflammation. The conditions which I shall mention in this paper are those which have either been presented to me for consideration and advice in consultation and hospital practice, or about which I have had information from physicians. I prefer to make this paper, as far as I am concerned, one which has been drawn from observation in my field of work, and hope that it will be supplemented by the observations of those who have had a very large experience in these conditions.

A doubt whether, or the belief that, appendicitis existed has arisen in the case of neuralgia affecting the lower abdominal nerves on the right side in a number of cases. As a rule, a close scrutiny has enabled the observer to come to a right conclusion. Yet I have knowledge of two cases in which an operation was performed, the appendix found normal, and not removed. In one of these there had been several antecedent attacks. It is probable that to-day the appendix would have been removed at the time, and not allowed to remain as a source of future apprehension. The cases in this category relate to those neuralgias whose origin was rather obscure, or, better, so obscure that it could not be referred to an abnormal condition of any special organ. There are, however, those other neuralgic pains reflected over the lower right abdomen when there is disease of an inflammatory nature above, more especially pneumonia and pleurisy of the right lung. I have been consulted several times in cases of this nature, in some of which the idea of operation for a supposed appendicitis had been entertained. Moreover, as at times, if a physician is called late, a pleurisy may have supervened on an appendicitis whose inflammatory process has taken an upward direction, a right decision as to the true origin and nature of the disease processes may be the occasion of considerable study. Ordinarily a careful survey of the history and study of the existing conditions leads to a correct diagnosis.

Another source of difficulty in the diagnosis is afforded by conditions of the right kidney. Those which have come under my own observation have been renal colic, when somewhat protracted, and especially if associated with fever. Still greater trouble has been occasioned by those cases in which a retention of urine constituting hydronephrosis was developed, as thus a swelling in the right side and some tension of the abdominal muscles have occurred. Of course, the members of this society are all aware of the coexistence of fever in certain cases of renal colic, but owing to the teaching of certain text-books not a few physicians are uninformed of this possibility. Moreover, we all know that in certain cases of appendicitis, owing to the character and direction of the pain, the opposite error of considering appendicitis renal colic has been made. Yet so firmly have I known the dread of appendicitis to influence intelligent medical opinion, that in cases in which the patient was thin, and without difficulty manipulated, and thus the assurance was obtained that no exudate or swelling existed in or about the appendix, an exploratory operation has been proposed to make assurance doubly sure. The condition of the urine at the time or later has clinched the diagnosis.

Intermittent hydronephrosis independent of calculus has also come under my observation as a source of possible diagnostic error. Moreover, hydronephrosis with a displaced right kidney existed in one case about which I was consulted. Movable kidney has to my knowledge at times been mistaken for a peri-appendicular inflammation.

Cholecystitis has, in several cases of which I have had knowledge, been operated upon with the belief that the condition was one of peri-appendicular inflammation. An operation was necessary for relief of this condition. The only evil likely to be entailed is that with healing, owing to the low site of the incision, considerable dragging pain may be experienced. For this I was consulted in one case.

Conditions in the intestinal tract at times also have occasioned the belief that appendicitis existed or that a peritonitis was occasioned by perforation of the appendix. In this latter category are the perforations of ulcers, duodenal, etc., which have been comparatively latent in their course. Gastro-intestinal catarrh with colic coming from some irritant, either undigested food or toxic agent in the food, has also been mistaken for appendicitis. Tuberculous ulcers, with tuberculous peritonitis over and about the cæcum may give rise to very great difficulty in decision, and have been the occasion for exploratory incision for diagnosis. So also cancer of the cæcum may occasion a condition which may simulate peri-appendicular inflammation. The strangest illustration of this was the case of a man, whom I had been requested to see in order to determine whether an indurated mass was of this or another nature. The hour was fixed for consultation at three o'clock on a certain day. I was summoned several hours earlier, because the patient had suddenly gone into collapse. When I arrived there was no difficulty in determining that perforation had occurred and that there was free gas in the peritoneal cavity. The patient's condition forbade operation. The history of an illness lasting months made the diagnosis of carcinoma very probable. An autopsy showed colloid carcinoma of the cæcum, in which there was a deep ulcer which had perforated. Fecal impaction may at times also simulate peri-appendicular inflammation, though in my experience the opposite error may be made of considering the exudate impaction and the obstruction due to the accompanying local peritonitis as dependent upon some other cause. There is, however, a class of cases not very frequent in which there exists an ulceration or narrowing, non-malignant, of the hepatic flexure of the colon, which is apt to be attended from time to time by accumulation of fæces in the cæcum and ascending colon, and also, as the patients are thin, by movable right kidney. As these patients have occasional fever also, these combined events may give rise to considerable trouble in diagnosis to one who has not had previous experience with the individual patient.

---

[1] Read at a meeting of the Practitioners' Society, held April 6, 1900.

In a paper read before the Medical Association of the State of New York attention was drawn to the fact that the pain and tenderness occurring in certain cases of typhoid fever either during the primary attack, or in a relapse, had led physicians, to my knowledge, either to propose or to perform the operation for removal of the appendix. This has happened in the early stage of the disease, when the fever under the circumstances has been believed to denote the gravity of the supposed appendix inflammation. That the appendix may at times be affected in typhoid fever is also known. A careful survey of the case, including the history of the method of incipiency of the attack and a study of the condition of the spleen, of the bowels, of presence or absence of roseola, of the blood for Widal's reaction, and a count of the leucocytes will, together with a careful physical study of the right iliac region, as a rule, enable the physician to make a correct diagnosis.

The general aches and pains connected with follicular tonsillitis had led to the removal of the appendix in a case which I saw afterward for a complication. The pains in this case were to a considerable degree complained of in the right iliac region. As an offset for this I might state that it has happened on two occasions that I have been consulted regarding peritonitis from perforation of the vermiform appendix when the disease had been ushered in with follicular tonsillitis.

Abscess of the ovary has been mistaken for inflammation of the appendix. The neighborhood of these parts readily explains the possibility of a mistaken conception as to the cause of a local peritonitis. So also difficulty may arise in deciding whether a given inflammation in a woman is due to appendicitis or to salpingitis. Retained menstrual fluid gave rise in one case to a sapræmia causing chill, fever, and some pain on the right side of the abdomen, which came under my observation to decide between a possible typhoid or appendicitis. The case was that of a young woman sixteen years of age, who had been unwell two weeks before, but had felt poorly since that time. There was some sense of soreness deep in the right side of the abdomen, more in the pelvis than over the usual appendix site; there was no exudate nor distinct swelling to be appreciated at the ordinary site of the appendix nor back of the cæcum; the leucocyte count was not increased. On the next day a free discharge of an offensive serous fluid from the vagina was followed by a disappearance of all the symptoms.

At times retro-peritoneal abscesses will simulate appendicitis or rather the abscess connected with it.

At times patients become hypochondriacal as regards the appendix, and under these circumstances going to a physician may receive the advice to have the appendix removed at once, as happened in a case which came under my observation this week.

These cases sufficiently illustrate the need of careful thought lest we fall into the error of considering every case with pain and tenderness in the right iliac fossa as appendicitis.

A CONTRIBUTION TO THE TREATMENT OF RUPTURE OF THE PARTURIENT WOMB—WITH A CRITICAL REVIEW OF THE VAGINAL OPERATION.[1]

By A. V. WENDEL, M.D.,
NEWARK, N. J.,
SURGEON TO THE ALEXIAN HOSPITAL.

In accordance with the rule of this society requiring an annual thesis upon one of the surgical emergencies, some recent experiences have induced the writer to select rupture of the parturient womb for this evening's discussion. Rupture of the uterus is justly regarded as one of the most formidable and fatal accidents to which the pregnant woman is liable. In this country, and particularly in our own section, we meet with it most frequently in the poorer classes who are generally attended by midwives. This very fact causes the writer to bring an obstetric emergency before this, a surgical society, because the midwife sends either for the family physician or the nearest practitioner. The practice of operative midwifery is therefore commonly performed by the general practitioner, and since rupture of the uterus constitutes a surgical complication of the first magnitude, the outcome of which depends in no small measure upon the judgment and technical knowledge commanded by him who attempts to relieve the woman, a discussion of the practical points involved and of the appropriate measures to be adopted must be my apology.

Rupture of the uterus is considered by the text-books a rare accident, but, as Freund says, one may not encounter a case in a decade while another may meet two cases in the same day, as happened to him. There can be no question, however, that rupture of the uterus is far more frequent than is generally supposed; a larger number of those occurring in private practice, if fatal from hemorrrhage, are reported as post-partum hemorrhages, and others merely as septic peritonitis when death results from infection. This statement, as Fritsch naïvely remarks, may easily be proven by inquiring carefully into the histories of fatal obstetric cases. Whether the average given by Anufrieff of eighteen ruptures to four thousand labors, or Bandl's of one in twelve hundred, or Garrigues' of one in five thousand deliveries, is correct shall be left to your own fancy. The writer has examined the annual statistical reports of New Jersey for the past three years, without obtaining any information concerning this matter.

The accoucheur is aware of the causal importance of contracted pelvis, fœtal malposition, and maldevelopment and cicatricial obstruction of the maternal soft parts, but cases are being constantly reported in which women have borne a number of children in as many normal labors, yet suddenly and without warning rupture of the uterus occurred either during and not seldom even before the occurrence of the next labor.

The predisposition to rupture manifested in such a manner has been explained by the giving way of scars formed after the separation of sloughs from the corpus or cervix uteri following previous accouchements; atrophic spots in the uterine wall leading either to circumscribed thinning or sacculation; general uterine atrophy; placenta prævia, and chronic interstitial metritis. Indeed, nowhere in nature do we find the defensive dispositions better exhibited than by the frequent abortions resulting from chronic metritis, for if these pregnancies went to term ruptures would no doubt be very much more frequent, owing to the diseased state and consequent diminished elasticity and cohesion of the myometrium.

---

[1] Read before the New Jersey Surgical Society, December 5. 1899.

It must be remembered, however, that, as Sänger says, these conditions merely lessen the resistance to rupture; mechanical factors are absolutely necessary to cause rupture, and in the majority of instances they are the sole factors. During normal labor the lower segment and cervical portion of the uterus are sufficiently dilated to permit fœtal extrusion, but if there should be obstruction of any kind to the progression of the child, the upper segment continues to retract until the fœtus is born into the distended and excessively thinned lower segment and neck of the womb. Unless the woman is delivered by art from her perilous position, rupture of the uterus will certainly occur. Considering that sixty per cent. of women (often the flower of child-bearing women) and ninety-two per cent. of the children are lost even under the best treatment, we should ever have the possibility of its occurrence in mind and be prepared to act with decision when signs of threatened rupture occur.

The recognition of the predisposition to and causes of rupture can be compassed only by methodical anamnesis, pelvimetric and physical examination during pregnancy and during labor. Rupture will also become rarer the more strictly the law is enforced which requires the midwife to summon a physician as soon as she notices difficulty or danger to the patient during the progress of labor. There can also be no doubt that the mortality after uterine rupture will be lowered the more asepsis in obstetric practice becomes generalized, because sepsis still constitutes the most formidable obstacle to reduction of the mortality rate, and Kroner's statistics show that an infected patient has but little prospect of recovering even if submitted to operation. Nevertheless no case should be considered hopeless, however desperate it may appear, since cases are reported which appeared hopeless, yet prompt intervention gave brilliant results.

"The worst cases are allowed to die; if more cases were operated upon more lives would be saved, but the whole death rate after operation would be raised."[1]

There still remain unsettled so very many questions in the pathology and treatment of ruptured uterus, that every case, whether fatal or not, should be reported with the minutest care, because every case presents so much that is interesting that the time is amply repaid if it is examined in all its details and compared with that which is known in order to increase our knowledge of its nature and draw more correct conclusions as to treatment. With this object in view the writer begs to report his own experiences, which are limited to the three following cases:

Case I.—Primipara; pelvic contraction with massive bony development; complete rupture of the uterus; Porro operation; recovery.

Pelvic diameters: bisiliac 23 cm., bispinous 21 cm., bitrochanteric 25 cm., Baudeloque 15.2 cm., oblique conjugate 9.5 cm., true conjugate 7.5 cm.

Mrs. S——, aged thirty-one years, weight one hundred and fifty pounds, robust German peasant. Her last menstruation occurred January 9, 1897. Pregnancy passed without unusual incidents. Labor began October 22, 1897, at 5 A.M.; the membranes broke at 6 A.M. She was examined by her attending physician some hours later and he noted that the head had not engaged, also that the partially dilated cervix was somewhat swollen. Drs. Ost and Bailey saw the case at 9 A.M. on the 23d. They found that the pains were not so powerful as previously; the contraction ring was near the navel; the abdominal walls were sensitive to pressure; the fœtal dorsum was in front and to the right; the cervix was swollen but completely dilated, the presenting part above the brim. The child was living.

Drs. Ost and Bailey realized the grave danger of impending rupture; perforation and extraction by the cranioclast was decided upon, and immediately begun under deep anæsthesia. Notwithstanding the removal of the entire vault by the craniotomy forceps, they were unable to deliver the base on account of its massiveness and large size. Laparotomy now appeared to them the proper method of delivery. The writer saw the case with these gentlemen at 10 A.M. At this time the patient's general condition was good; pulse, 108; no fever. The uterus was noticeably movable, but its contour was not decidedly altered. There was some emphysematous crackling detected over the hypogastric region extending laterally into both iliac regions. The contraction ring was obliquely upward from right to left just below the umbilicus. The catheter brought away 60 c.c. of clear urine. There was slight but continuous bleeding from the uterus. There was no injury of the vagina or portio vaginalis. The greater portion of the calvarium had been removed; the head was very movable. On passing the hand into the uterus a large irregular rent could be felt in the lower segment, severing in a transverse manner nearly three-fifths of the cervix from the body. The hand was not passed beyond the uterus. There was no apparent prolapse of omentum or intestine. Since laparotomy would be the operation of necessity, no attempt was made to determine whether the peritoneal cavity had been opened or not, for fear of carrying infection into the parametrium. The wound in the uterine wall gaped nearly 5 cm. on the left side. Twenty minutes later the abdomen was opened in the middle line. The uterine serosa presented many emphysematous blebs over its entire aspect; extensive suggillation of the pelvic subserosum could be seen, which crepitated on pressure. About 300 c.c. of blood lay posterior to the uterus, but no active hemorrhage was apparent. By passing the hand down into Douglas' pouch a rent could be felt in the posterior wall of the uterus involving about 4 cm. of its investment.

The blood was quickly removed from the belly; sterilized towels were packed behind the uterus to protect the intestines; the uterus was incised in the middle line and the fœtus extracted. The placenta, which was adherent to the rear and upper wall, was not removed. The vesico-uterine plica was next incised, the bladder separated by blunt dissection, and two fixation needles pushed through the uterus a little below the level of the lower angle of the tear; an elastic ligature was applied and the uterus amputated from its remaining attachments. Fixation of the stump in the lower angle of the wound, drying of the peritoneum, and closure of the belly completed the operation. Recovery was uneventful. The decerebrated fœtus measured 48 cm., and weighed 4,760 gm. No measurements of the head could be made. The photograph of the uterus was taken after the specimen had been eleven months in alcohol, which caused much shrinkage, the result being that the upper limit of the tear appears in thicker tissue than was really the case. Inspection of Fig. 1 shows the tear beginning at *c*, extending downward about 4 cm., corresponding to the peritoneal tear; then the uterine lesion continues irregularly from *c* to *b* to *a*, that is, to a point a little anterior to the insertion of the base of the broad ligament; this portion of the tear was entirely subperitoneal.

Remarks: Beyond doubt this was a typical spontaneous rupture according to the teachings of Bandl. The weakening of the uterine contractions prior to any operative attempts shows that rupture had probably already begun; the rule being for the contraction to become more and more violent until the uterine fibres give way, although Fritsch[1] claims that the differentiation of rupture threatened from the beginning is by no means easy, because as soon as the innermost layers of muscular fibres have separated rupture has already become actual, and any additional increase of intra-uterine tension, such as the passage of the hand into the uterus, the insertion of forceps blades, or pressure on the uterine fundus, will result in the more or less complete and extensive breach of the uterine wall, the degree of laceration depending on the amount of uterine energy. The diagnosis of this case was relatively easy, and the question whether the peritoneum had been opened or not could probably have been determined by simply passing the hand through the tear. But should this be done as a routine measure? For the following reasons I would reply with an emphatic negative: When there has been instrumentation, there is also infection of the genital tract corresponding to the extent of the field traversed during the manipulations. You can easily prove this statement for yourselves by the culture tube and microscope, if you entertain any doubt concerning the accuracy of this statement. We also know that pathogenic organisms may actually lie at the edge of a wound, and notwithstanding primary union will occur if the infectious material is not carried into the wound by overzealous handling. You have all seen proof of this while attending the cut fingers of the dirty-handed factory boy. To pass the hand into the belly in suspicious cases is to risk carrying infection into tissues infiltrated with blood and therefore peculiarly susceptible to progressive infections, and the question of preventing the spread of infection is now the most difficult one. Ludwig[1] asserts that the peritoneum will not infrequently adapt itself to the examining fingers so gently as to deceive one and give the impression that the peritoneum has been perforated when in reality it has not. Another objection to this method of examination is the probability of the admission of air to the pelvic connective tissue. If this complication has not resulted from the circumstances attending the rupture, we ought not to induce such a state. Indeed ante-uterine emphysema or an emphysematous crackling of the abdominal walls should be sought for, not only because it favors the invasion and spread of pathogenic micro-organisms, but also because its presence is an almost pathognomonic sign of uterine rupture; the only exception being its occurrence from decomposition of the fœtus in utero. The presence of subperitoneal emphysema is also an indication for early and radical operation, as will be seen from the following notes taken from a paper of Dischler's[2]: McClintock's case was fatal several hours after delivery; Winckel's first case, forty-six hours post partum; both patients probably died from the entrance of air into the venous system. Paulli's case was fatal eight and one-half hours post partum; Jolly's, eleven and three-quarter hours after delivery; Winckel's second case, twelve days after labor; Löhlein's first case, eight hours, his second case, ten days post partum; Bayer's, two days after birth. All these patients died of sepsis. On the other hand, in the cases of Leopold, Frank, and Halbertsma, recovery took place after the Porro operation; of Knauer,[1] after abdominal panhysterectomy; but Dischler reports a personal case in which recovery resulted after gauze packing. Dischler after a careful study of this condition arrives at the conclusion that subperitoneal emphysema is a valuable sign of uterine rupture, and that an emphysematous state of the pelvic connective tissue is a serious menace to the woman's life for the reasons which have already been stated, and that radical methods of surgery—notwithstanding the recovery in his own case by the gauze treatment—are indicated whenever it is encountered with uterine rupture.

[1] "Die Behandlung der Uterusruptur" Verhand. d. Deutsch. Gesell. f. Gyn., vi., p. 8.

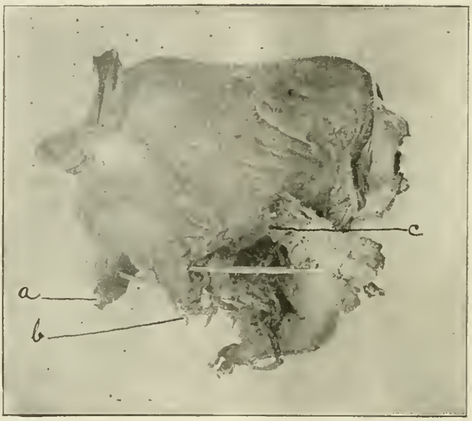

FIG. 1.

Irregularity of the uterine quadrant is regarded as a good sign of uterine rupture but was not present in this case, as there was no large collection of blood in the form of hæmatoma, and the fœtus did not leave the uterine cavity. The contraction ring was well marked and characteristic. Mobility of the uterus was readily demonstrated. The Cæsarean section was absolutely indicated here on account of the large head and the resistance of the fœtal base. Supravaginal amputation of the uterus was added because the uterus was so extensively injured, and because of the certainty of rupture in subsequent labor if conservation had been attempted, since the pelvic contraction would remain.

CASE II.—Vpara; complete rupture of the uterus with partial escape of the fœtus into the abdomen; pelvic obstruction by dermoid ovarian tumor; intrapartal vaginal ovariotomy and vaginal Cæsarean section; recovery.

Pelvic diameters: bisiliac 28 cm., bispinous 26.2 cm., bitrochanteric 30.5 cm., Baudeloque 20.3 cm., oblique conjugate 14 cm., true conjugate 11.7 cm.

Mrs. K——, Jewess, aged forty-three years, weighing one hundred and fifteen pounds, and wiry; she was married when seventeen years old. Her first, second, and third confinements were natural and averaged nine hours in duration. Her fourth confinement was in 1892; it lasted thirty-four hours, was followed by fever and much pelvic distress, but the midwife had not considered matters serious enough to call a physician, although the patient was confined to bed for five weeks. Since then and until the last conception occurred, she has complained of dragging pains, dyspareunia, and vaginal discharge. Her last menstruation was November 30, 1897. During the last four months of the present gestation she had to wear an abdominal binder to obtain relief from the distress caused by anteversion of the gravid uterus. The present labor began at 2 A.M., September 9, 1898. A midwife was in attendance. The membranes broke at 11 A.M., and the pains continued strong until 4 A.M., September 11th, when the patient complained of feeling weak; the midwife noticed that the contractions also became feebler and were separated by longer intervals. She thereupon ad-

[2] "Ueber subperitoneales Emphysem nach Ruptura uteri." Archiv f. Gynäk., Bd. 56, S. 199.

[1] Wiener klin. Wochenschrift, 1897, S. 254.

ministered several doses of ergot, which increased the pains, although she noticed no descent of what she presumed to be the presenting part. Dr. H. B. Epstein was summoned and arrived at 7 A.M. He found the patient weak, with a temperature of 101° F.; pulse, 100 but feeble; the abdomen was very sensitive but soft because the abdominal walls were very thin and flabby. By gentle palpation he found the uterus contracted, reaching about 3 cm. above the umbilicus. The fœtal extremities were palpable in the peritoneal cavity, but no fœtal movements or heart-sounds were discernible. Indagation showed the vagina obstructed in the upper part by a hard, fixed tumor springing apparently from the rear. The obstruction was so complete that the finger could not reach the cervix. The doctor made the diagnosis of complete rupture of the uterus with partial escape of the fœtus into the abdominal cavity; he advised operation, and requested the writer to see the case with him. We agreed on immediate abdominal section, but on presenting the decision to the husband and some of the relatives who were present, they would permit only such operative intervention as could be done without cutting the abdominal wall or removing the uterus. We therefore concluded to attack the growth from the vagina and then deliver by the natural passages. Preparations were made for operation, and additional assistance was summoned. The catheter brought away about 80 c.c. of clear urine. The patient was anæsthetized with ether, placed in the lithotomy position, and the bladder and vagina were thoroughly irrigated. The labia and vaginal walls were retracted to expose the neoplasm. An incision was made in the median line about 12 cm. in length, which bled profusely; the adhesions were so dense and tough that the scissors were brought into requisition and applied freely until the pedicle was reached. Owing to the largeness of the tumor it became necessary to open it; much malodorous material and hair having been removed, the edges of the cyst wall were rolled in and sutured to prevent soiling of the field, and then dissection was continued with the scissors and fingers until the pedicle was isolated. During this time 1,200 c.c. of decinormal salt solution were introduced into the veins of the arm. A curved clamp was applied to the pedicle and the tumor cut away. The slender pedicle was tied off and allowed to retract. Many small vessels also required ligature. Bloody serum, clots, and meconium escaped from Douglas' pouch, which had been thoroughly opened during the dissection. The bleeding was now entirely controlled, and we turned our attention to the delivery of the fœtus. As a result of the low form of chronic inflammation around the tumor the cervix had become converted by induration into a hard, unyielding mass; all attempts at dilatation failed. Delivery was attempted by passing the hand into the belly through the Douglas incision to ascertain the feasibility of delivering by version through this channel, but it could be felt that the fœtus was grasped so tightly about the neck that traction would enlarge the uterine wound, and besides there was not room enough to permit the manœuvre successfully. The fœtus had escaped through a rent in the posterior wall of the uterus, nothing but the head remaining in utero. The only alternative remaining was vaginal Cæsarean section. The vaginal fornix was incised in front in the median line, the bladder separated to the replica, and several bleeding vessels were ligated. With heavy scissors the anterior lip of the uterus was split in the middle line to a distance of 5 cm. from the os externum. The rear wall, which consisted of a bridge of tissue intervening between the external os and the transverse tear in the lower segment (some 6 cm.), was also split; there was not much bleeding from the cervix on account of the induration, but above hemorrhage was decidedly free. The Taylor blades were now quickly applied and the child was extracted with ease, the placenta following. The uterus contracted firmly and all bleeding (above the ordinary) ceased. The vagina was now thoroughly sponged, then the peritoneal cavity cleansed with gauze. Another 1,000 c.c. of decinormal salt solution had been transfused during this period. The rupture proved to be a large, ragged transverse tear in the lower segment, so we attempted to draw it together with sutures. Slender Péan retractors were inserted in such a way as to retract the uterine and vaginal walls, the uterine flaps also being drawn divergent by means of slender volsella. Only two sutures could be placed, but they sufficed to appose the ruptured surfaces. The Cæsarean wounds were then closed by a few interrupted catgut sutures excepting the lower portions, which were left open for the purpose of uterine drainage. Three sutures closed the anterior wound of the fornix. The incision in Douglas' pouch was not closed. Gauze was passed into the peritoneal cavity, and the vagina filled loosely with gauze to absorb the products of drainage from the peritoneum.

The operation lasted two and three-quarter hours, the patient leaving the table with a pulse of 156 and a temperature of 97° F. By warmth and stimulation the pulse soon fell to 100, but in the evening of September 11th it went up to 140 and the temperature to 102.5° F. The abdomen was distended and much pain was complained of. Salines and the ice-bag were ordered, and by the 15th the temperature and pulse rate had fallen to the normal. The gauze had been changed daily. Five weeks from the operation the patient was allowed up. She was examined on the 9th of March, 1899. It was found that the induration had almost entirely disappeared; the uterus was retroflexed and adherent; the deep antero-posterior scars could be felt, but otherwise her condition was good, and she felt no distress.

The fœtus measured 32 cm. and weighed 2,600 gm. The suboccipito-bregmatic diameter was 8 cm.; biparietal, 8.2 cm.; occipito-mental, 13 cm.

Remarks: Several factors contributed to the occurrence of rupture: uterine anteversion, the fixed ovarian dermoid, and the chronic induration of the cervix and neighboring soft parts. The uterine anteversion was certainly a fortunate coincidence, because the fœtus was directed against the rear wall of the uterus, and the injury therefore was comparatively innocent as compared with ruptures occurring in the anterior wall of the uterus. The anamnesis indicates that the tumor must have caused the delay and subsequent complaints in the fourth labor. Pelvic obstruction by ovarian tumor is not a frequent cause of uterine rupture during labor. McKerron[1] collected one hundred and eighty-three instances of prolapsed ovarian tumors complicating pregnancy, but only three resulted in uterine rupture. The patients all died. Kerswill[2] reported three instances, two of which were fatal. Hintze's[3] case resulted in recovery after laparotomy, but was complicated by pneumonia and pelvic abscess. Subperitoneal emphysema could not be detected, neither was undue mobility present. This case demonstrated in a surprising manner how tightly the fœtal neck can be incarcerated by the uterine wound. The tumor so completely blocked the vagina that the cervix could not be indagated, thus leaving us entirely in the dark concerning the state of the cervix until the tumor had been removed. Given a case as related, is it justifiable as a rule to submit the patient to intrapartal vaginal ovariotomy? The answer should be, no. The shock resulting from two and three-quarter hours of anæsthesia, manipulation, and loss of blood is much greater than that of a twenty-minute abdominal section. The general rule should be applied here as in other surgical emergencies; that is, to relieve the individual of immediate peril. The deep shock attending uterine rupture is a bar to lengthy operations, although this case demonstrated in a superior manner how much more the patient can endure when her intestines are not exposed. If I were to meet the same condition as in Case II. minus uterine rupture, I would follow the advice of Löhlein[1] and perform intrapartal ovariotomy. The contents of the tumor were so thick that a trocar could not have emptied it. Abdominal section, extraction of the fœtus, cleansing of the peritoneum, supravaginal amputation, and provision for drainage was the plan settled upon before submitting the same for approbation to the relatives, and notwithstanding the successful issue of this case and much reflection, this plan appears the best, leaving the tumor unmolested until the patient is better able to stand its removal.

CASE III.—IVpara. Incomplete rupture of the uterus involving the bladder; escape of the fœtus into the right broad ligament; vaginal panhysterectomy, abdominal section for uncontrollable hemorrhage; recovery; pelvic measurements normal.

Mrs. G——, thirty-five years old, weight one hundred and thirty-five pounds, American. She was submitted to vaginal section in 1896 for a mural teleangiectatic myoma developing in the right side of the uterus, involving the corpus and upper part of the cervix and bulging into the right broad ligament. The right uterine and ovarian arteries required ligation on account of the very free hemorrhage. For this purpose chromicized catgut was employed. The uterine cavity was not opened during the removal of the tumor, but the bed of the neoplasm could not be accurately sutured. A physical examination conducted on August 21, 1897, showed the patient's pelvic organs in a very satisfactory condition. She menstruated the last time in April; her gestation passed without abnormal manifestations. Her previous labors averaged twelve hours in duration. Labor began at 5 P.M., December 19, 1898. Dr. H. F. Cook examined her at 8:30 P.M., and found the uterus sinistroverted, the contractions strong, the os dilating, membranes unbroken, but the head not engaged in the superior strait on account of the malposition. The fœtal heart was audible on the left. He placed the patient on the opposite side and matters appeared to progress favorably. The maternal pulse was 75 per minute; no fever. At 9:30 P.M., during a contraction the patient complained of fluttering at the heart, extreme weakness and pain in the right side; marked facial pallor and drawn features appeared. The pulse became very weak and rapid. Vaginal examination showed the cervix dilated to about three inches; the amniotic sack was unbroken, but instead of the head the foot presented. The doctor's left hand plainly felt the contracting uterus through the thin abdominal walls, and the fœtus in the right iliac region. Realizing at once the true state of affairs he broke through the membranes, seized the feet, and delivered a deeply asphyxiated male child. Much blood began to flow from the uterus. The placenta was removed by the hand. The doctor passed his hand carefully into the uterus and felt an irregular gaping tear extending from the middle of the right side to the right cornu. As the patient complained of an urgent desire to urinate, the catheter was passed and brought away a small amount of very bloody urine. The uterus and vagina were tightly packed with sterile gauze and a tight binder applied around the abdomen. It was now 10 P.M.; the pulse was 126, the temperature 98° F. There was no external bleeding, and after partaking of some hot tea the patient felt better. The placenta and membranes were now examined and exhibited but one opening, corresponding to the opening made by Dr. Cook. The amnion must, therefore, have enveloped the fœtus during its extrusion into the broad ligament. At 11 P.M. the pulse was 136 per minute, the temperature 98° F.; at 11:30 P.M., pulse 142, temperature 98° F. The doctor concluded that hemorrhage was going on in the parametrium or peritoneal cavity, and prepared for immediate operation. A little later the narcotized patient was placed in the lithotomy position. As the writer commenced the operation, 1,800 c.c. of artificial serum were thrown into the median basilic vein. After the gauze was removed from the vagina and uterus, and the field cleansed, the fornix was incised around the cervix; the bladder was detached with some difficulty because the rent in it communicated with the enormous cavity in the broad ligament, and also because the connective tissue of the paravesical space was so infiltrated and distorted by liquid and clotting blood as to render the landmarks very obscure. The hemorrhage from the incision was readily checked by strong downward traction on the uterus by the volsellum attached to the cervix; indeed, after separation of the posterior attachments the uterus could be developed with amazing ease. The left broad ligament was tied off with six ligatures of catgut; on the right side the broad ligament was so disorganized, and the peritoneal layers were so distended and distorted by the larger clots, that I concluded to morcellate the uterus in order not to include the ureter in the ligature. After this was done it was seen that no semblance of a broad ligament remained; the uterus was attached merely by peritoneum and a few shreds on the right side, and the blood was welling out from the side of the pelvis. The stump was cut away, and we tried to pick up the bleeding vessels with clamps, but without success. After losing twenty minutes in futile attempts because the oozing and clotting blood obscured the field, the abdomen was opened in the middle line with the patient in the Trendelenburg position. The wound retracted to the right; the ovarian and uterine and many smaller vessels were tied without further trouble. Clots were turned out, gauze was placed in the crater of the broad ligament, the end of the gauze led into the vagina, and finally the belly wall was closed with suture. The operation lasted fifty-seven minutes. The pulse numbered 180 beats per minute when the patient left the table. Altogether 3,000 c.c. of salt solution had been thrown into her venous system. She rallied nicely from the shock. The vesical wound closed on the eighth day. Convalescence was smooth. The child measured 37 cm., and weighed 2,300 gm. Biparietal diameter 9.5 cm., sub-occipito-bregmatic 7.9 cm., occipito-mental 13.4 cm.

Remarks: Unfortunately, the portion of the uterus containing the tear was cast away by an attendant before I had time to place it in safety, so that we are left to conjecture the condition of the uterus. However, it seems most likely that the weak scar in the uterus permitted a sacculation which gave way during a uterine contraction. The moral learned is, to remove the uterus whenever accurate suture of the wound is not possible during conservative myomectomy. An important and serious feature of this case was the vesical laceration, because of the great risk of urinary infiltration of the parametrium and consequent sepsis. Bonnaire[1] reported five cases, all of which were fatal. The first three cases were treated by vesical drainage and conservative surgery, and the last two by abdominal section.

[1] "Des ruptures vésico-utérines dans le travail de l'accouchement." Arch. de Tocologie, 1891, p. 391.

The diagnosis of this case was easy. Subperitoneal emphysema was not present, although the peritoneum was stripped from its attachments as far up as the right kidney, probably because the fœtus pushed its amniotic envelope before it and thereby protected the connective tissue from contact with air. McLean[1] believes that this envelopment of the fœtus by the membranes is a not infrequent occurrence, and lays much stress on the rôle it plays of preventing septic material from contaminating the parametrium or peritoneal cavity.

During a discussion at the Obstetrical and Gynæcological Society of Vienna, R. Braun von Fernwald[2] expressed some apprehension that in rupture of the uterus, when the peritoneum, and particularly the ligamental peritoneum, is extensively lifted up and torn from its attachments, vaginal extirpation would meet with difficulties which would make laparotomy preferable. If vaginal hysterectomy is decided on as the preferable method, no great amount of time should be wasted in futile attempts to grasp the divided vessels with clamps; the abdomen should be opened and the arteries secured, because these patients as a rule have lost much blood before the operation and are not able to stand another serious hemorrhage. The vaginal operation should be the operation of choice whenever the prevention or amelioration of sepsis is required by the removal of the uterus, because of the greater facility for drainage of the peritoneum afforded through the vagina. The vesical injury impelled me to select the vaginal method, although I was aware of Braun von Fernwald's statement. I was also aware of Bonnaire's results with abdominal section for rupture of the uterus complicated by vesical laceration, and was therefore prepared to open the abdomen if necessary, because I believed the removal of the uterus would permit the urine to flow away from the lacerated and infiltrated connective-tissue surfaces. Permit me to give you an outline of Bonnaire's[3] cases submitted to ventral section. (1) A XVIpara was submitted to four fruitless attempts at delivery by the forceps, being finally delivered by version. Bonnaire believes that the forceps caused the injury to the uterus and bladder. The next day she was operated upon by abdominal section. The tissues were in such a state that he stitched the uterus to the parietes and left the wound open so as to drain the bladder through the abdominal wound. Death occurred twenty hours later. (2) A primipara sustained a spontaneous rupture of the uterus involving the bladder. The abdomen was opened, the fœtus extracted, and the vesico-uterine wounds were drained by stitching them into the abdominal wound. As a result of this experience Bonnaire concluded that supravaginal amputation of the uterus should be performed with provision for drainage through an incision in Douglas' pouch. To my mind this method does not do away with the worst feature of the case, which is the danger of allowing decomposing urine to flow over the lacerated and infiltrated wounds, particularly when one considers the roundabout manner proposed of draining the discharges through an opening in Douglas' pouch. After the uterus is removed, the bladder sinks down and the vesical laceration can be almost entirely walled off from the general cavity of the peritoneum and the parametrium. This I have been able to demonstrate several times when the bladder has been injured during hysterectomy. The indication in these cases is pointed by the wounded bladder after the question of hemorrhages has been settled, for the arrest of hemorrhage is only the milder element in the mortality rate; Koblank's statistics show that more deaths occur from sepsis than from hemorrhage, after rupture of the uterus. A ruptured bladder requires the freest possible drainage as early as possible after the injury. The infiltrated state of the connective tissue with blood, and the bruising of the wounds, dispose the patient to the most violent septic infections when urine flows over them; the swelling and distortion render any attempt to suture the bladder futile even if it were desirable, so that vaginal hysterectomy supplies the proper means for dealing with vesico-uterine rupture, though one must be prepared to do here as elsewhere in vaginal cœliotomy, that is, to open the abdomen if contingencies arise which cannot be successfully controlled from below, and finish the case. Vaginal hysterectomy has, however, proven itself the operation of election for ruptures on the anterior and posterior surfaces of the uterus, when the broad ligaments have not been torn up so extensively as to prevent the spurting vessels being secured through the vaginal incision. Total escape or even partial fœtal extrusion into the broad ligament always indicates so severe an injury that one may expect the landmarks to be so distorted and effaced, the tissues so torn up and mixed with clots, that only favorable cases can be finished from below. You may imagine what difficulties were encountered in our case, since eleven vessels on the right side required ligation after the abdomen was opened. Nevertheless we must wait for further experience with the vaginal route for this variety of injury before positive opinions can be given.

General Considerations.—An accident which notwithstanding the best treatment results in a loss of sixty mothers in every hundred instances makes it imperative that the question of prevention be given a prominent position. Dakin[1] claims that "rupture of the uterus is almost invariably due to want of attention on the part of the medical attendant, if he has had an opportunity of watching the course of the labor from the beginning." Grandin and Jarman[2] believe that rupture of the uterus will become rarer "as the benefits of strictly elective surgery become uniformly recognized." Its possibility should be kept constantly in mind, since the most diverse conditions obtain in the etiology of uterine rupture. For instance, v. Ramdohr[3] reported two fatal ruptures following primary inertia. Albers-Schoenberg[4] reported a case in which congenital dislocation of the left kidney into the cavity of the sacrum was the cause of dystocia. Braun v. Fernwald[6] averted rupture in an VIIIpara by Cæsarean section, the cause being the incarceration of a retroflexed horn of a bicornuate uterus. Sacculation was the probable cause of rupture in Case III. Hirst[5] saw a case in which the predisposition to rupture, he believes, was caused by general obesity. Fundal rupture occurs most frequently before the commencement of labor, and while not infrequent from external violence, it has occurred even during sleep.[7] But in most instances the essential factor disposing to rupture is over-retraction of the upper segment of the uterus with consequent excessive and therefore dangerous thinning of the lower segment and cervix. The most frequent cause of this condition is pelvic obstruction, the milder forms of pelvic contraction predominating. The latter condition should be sought for in every woman during pregnancy, or at the beginning of labor if one fails to see the case earlier. The severer grades of pelvic contraction are of course readily detected, but the diagnosis of milder forms of general contraction

can be made only by careful external and internal pelvimetry, and should always include the manual examination of the size and consistence of the fœtal head, the breadth and size of the fontanelles, since a relative disproportion may be caused by abnormal development of the head. During labor the frequency, strength, and effect of the uterine contractions should also be noted. If in spite of strong uterine contractions the head fails to descend, and frequent examinations of the abdomen prove that the upper segment of the uterus continues to retract as shown by the ring of Bandl and tension of the round ligaments during the contractions—particularly if the ring of Bandl becomes oblique, one or both poles near the navel and one or both round ligaments remain tense even between the pains—we may expect rupture to ensue unless the patient is speedily delivered. In the selection of methods, the choice will be given to one which does not increase the already excessive intrauterine tension, for in that case rupture will be precipitated. Prompt and deep chloroform narcosis should now be employed to stop the uterine contractions, and thereby retard further thinning until delivery can be effected.

In mild cases, the head presenting, the forceps may be applied with the greatest gentleness, but only by a skilful accoucheur. I have already stated that the dividing line between threatened and beginning rupture cannot be determined. Is it justifiable, then, to use the forceps in high degrees of thinning of the lower segment? Of Koblank's[1] eighty cases of rupture of the uterus, ten were caused by the forceps and all ten were fatal. "According to v. Winckel and O. Schaeffer, the high forceps operation gives the worst results to the mother, because the thinning of the imperilled side is exaggerated and therefore the rupture is hastened."[2] There are, then, two distinct rules applicable to head presentations with threatening rupture of the uterus: when thinning of the lower segment is slight and the round ligaments are tense only during the contractions, other things being equal, the child should be delivered by the forceps; but when the ring of Bandl is very high or very oblique, with one or both round ligaments tense between the pains, delivery should be effected by the Cæsarean section or craniotomy, as the case may require, for, as Fritsch[3] says, in head presentations the thinning of the lower segment is apt to be localized in one or other side of the lower segment, and the practitioner's desperate hope to save the child by the forceps often sacrifices both lives. The same holds good for version in head presentations, the hand being substituted for the forceps. The rule of action in transverse presentations is simpler, for when the child is living this fact indicates that dangerous thinning has not yet occurred, therefore version may be carefully attempted in deep narcosis. When the uterus is tetanic and the thinning great the fœtus may be considered dead; version is no longer the operation chosen, but embryotomy is now considered the proper procedure.[4] Malposition of the parturient uterus sometimes predisposes to rupture by directing the fœtus against the opposite wall instead of into the cervical orifice; it is to be treated by laying the patient on the opposite side or bandaging the uterus back, as the case may require. Placenta prævia is known to dispose to rupture by softening and thinning the lower segment at the seat of placental attachment. Braun v. Fernwald[5] believes that when rupture occurs it generally does so just as the extremity is pulled down through an insufficiently dilated cervix, and he advises therefore, in order to avoid this serious accident, to extract only after the cervix is thoroughly dilated.

When rupture has become a fact, the motives for action are to deliver without increasing the injury, to arrest hemorrhage, and to prevent or limit peritoneal infection. In head presentations with a living fœtus in utero, the child may perhaps be saved by the prompt application of the forceps without submitting the mother to undue risk, providing that she is in good condition, the os completely dilated, and there exists no decided pelvic contraction. Ludwig[1] apprehends (and the writer's opinion agrees) that even under these conditions there is much risk of increasing the extent of the injury or of converting an incomplete into a complete rupture. When the head remains in the uterus and the body has escaped, McLean[2] argues that the danger of increasing the size of the laceration no longer exists, because the intra-uterine tension has been decidedly diminished by the escape of the fœtal body, and he advises, instead of losing time by attempting to grasp the high and mobile head with the forceps, if any difficulty is encountered, boldly to advance the hand (closely applied to the child) into the uterus, to steady the organ with the other hand, to grasp a limb, and to rotate and deliver the child. McLean has reported a successful case treated after this fashion, but Ludwig and Koblank claim that withdrawal of the child through the wound increases the danger of hemorrhage. Perhaps their statement applies more correctly when the head has also escaped and is dragged back again. A dead fœtus would of course be delivered by perforation and cranioclasty.

Spontaneous rupture with transverse presentation results almost invariably in fœtal death. Embryotomy would therefore take precedence when the fœtus remained either entirely or in greater part in the uterus. If rupture occurs during version the operator must judge by the circumstances of the case whether he had better continue; in general the child should have a chance for its life. When the child has escaped entirely into the peritoneal cavity, the conjugate measuring less than 8 cm., abdominal section will be necessary to deliver it. Winter[3] proposed and carried out with success the plan of removing the fœtus from the peritoneal cavity through a very small incision in the abdomen, and then extirpating the torn uterus by the vagina. When the true conjugate diameter of the pelvic inlet measures 8 cm. or more, the writer proposes in such a case to extirpate the uterus by the vagina, since the primary danger is hemorrhage; then to grasp the feet and deliver through the natural passages.[4] This will obviate the objectionable features of abdominal section, but will be applicable only to cases having a true conjugate of 8 cm. or more. If the soft parts in any case should be similar to those in Case II., the operator should remember that the vaginal Cæsarean section is contraindicated when the true conjugate measures less than 8 cm.[5] The placenta is generally loose in the uterus or vagina, but it often escapes into the peritoneal cavity, and in some instances reported much trouble was experienced in finding it.

After the fœtus and membranes are born the maternal injury will require attention. The ruptured uterus presents to us a vascular organ frequently infected by repeated digital examinations and obstetric manipulations, the lacerated parametrium infiltrated with blood, communicating with the cavity of the uterus and therefore very liable to infection. If the patient fails

to die of hemorrhage, the loss of blood has robbed her of her best barrier to infection. The requirements of an ideal procedure will be rapid and certain hemostasis, removal of infected tissues, and free drainage. The idea of restitutio ad integrum has attracted many surgeons, and has been advocated enthusiastically by Freund and Leopold in the form of laparotomy and suture of the tear. Theoretically nothing can be more correct, and some brilliant examples of successful results are reported. Nevertheless, as has been said before, with a mortality of sixty per cent. we should examine into the causes of the same and see what can be done to reduce it. The practical objection to abdominal section and suture of the wound in the uterus and parametrium is that the operation is a long one, that the majority of patients are in deep shock, that the long anæsthesia and exposure of the intestines and peritoneum increase still more this shock, and, further, the woman is left exposed to all the dangers of puerperal septicæmia because the case will seldom be aseptic. This method then would be applicable only to exceptional cases. To my mind there is another bad feature which should weigh against its acceptance, namely, the liability to rupture in subsequent labor. Subsequent ruptures are reported by Bandl, Wensel, Battlehner, Deutsch, Green, Alberts, Diepen, Bizzell, Rose,[1] Dittel,[2] and Walter,[3] and although later labors have been successfully conducted it seems illogical again to expose a woman to the serious risk of rupture. The frequency of puerperal infection spreading from the uterus with fatal results led Schultze[4] and Coe[5] to advocate abdominal hysterectomy. Reed[6] advises the removal of the uterus when it is much mutilated. Abdominal hysterectomy has never reached the popularity of supravaginal amputation of the uterus with fixation of the stump in the abdominal wound. The extirpation of the puerperal uterus by the abdominal route is always a time-consuming and sanguinary affair. By the Porro operation the abdomen can be opened, the fœtus extracted, the uterus removed, and the abdomen closed within fifteen minutes, as in Case I. The disadvantage of the Porro operation is sometimes the difficulty of applying the elastic ligature low enough to get below the rupture; it may be impossible in very deep tears, but reports demonstrate that the elevation and constriction of the stump usually suffice to close all bleeding vessels. A few instances are reported in which this failed to control all the bleeding points. Underhill[7] sutured with catgut the portion of the tear below his ligature on the cervix, and obtained a good result. Braun v. Fernwald[8] was obliged to place deep buried sutures in the floor of Douglas' pouch to control the hemorrhage. Ludwig[9] in a similar predicament resorted with success to gauze tamponade of Douglas' pouch. Had Case III. been submitted to supravaginal amputation, the elastic ligature would not have controlled the hemorrhage, because the vessels had retracted to the side of the pelvis. The Porro operation avoids the most serious features of abdominal hysterectomy; it will be often performed on account of the easy technique, and should be the method of choice by an operator of moderate experience. The treatment of a ruptured uterus by the tampon is only less objectionable than leaving the patient to the unaided efforts of nature. The arrangement of the muscular layers of the uterus is disposed in such manner that as they contract the cervix will be dilated by the impingement of the uterine contents against it. If the tampon be of an absorbent nature such as gauze, retracting fibres will push the mass of gauze against the the cervix, at the same time causing a gaping of the uterine wound (which is usually much the larger aperture), and the contents of the gauze will be squeezed into the belly. So the only remarkable feature about a case treated by the gauze packing or gauze drainage is recovery of the patient, for gauze drains only until its meshes are filled with fibrin, and this fibrinous deposition occurs as rapidly as the gauze is packed in. Dangerous hemorrhage occurs from the vessels outside of the uterus over which the gauze tampon has no control; the bleeding often ceases for several hours after rupture on account of the cardiac depression, only to recur with a fatal issue; thus the tampon gives a false sense of security. The occurrence of secondary hemorrhage is illustrated by a case of Gessner's,[1] in which the rupture was not detected until the fifth day after labor; during urination fatal hemorrhage occurred, and the autopsy revealed a rupture in the left lower segment of the uterus with a large subperitoneal hematoma extending to the kidney. Doléris and Bonus[2] also report an instance of rupture of the uterus with sudden death on the fourth day from hemorrhage; these cases were untreated, but Koblank,[3] Freund,[4] Loin,[5] and Winckel[6] report deaths of tamponed patients from hemorrhage, respectively on the seventh, ninth, third, and thirteenth days after delivery. As a result we are forced to conclude that there is no real safety from hemorrhage unless the torn arteries are secured by ligature. To the question then of "What shall we do when a case is seen six hours after rupture and no evidence of internal bleeding is apparent?" propounded by a learned writer, the most rational answer would be—operate, whether the tampon has been used or not. Backer[7] charges the tampon with increasing the size of the laceration; Fritsch and Chrobak[8] blame it for changing incomplete into complete ruptures. After a study of these clinical reports it becomes evident why the trend of opinion is increasing in favor of surgical intervention in all cases. The uterine tampon has, however, a definite place in our armamentarium as a temporary dressing to prevent prolapse of intestines or to retain them within the belly after reposition of prolapsed coils, pending the arrival of the operator or during transportation of the patient to a hospital.

To obviate the uncertainty of the uterine tampon and the risks of abdominal section, obstetricians have attempted to close the rupture and ligate the bleeding vessels from the vagina. Thus Green[9] advises drawing down the uterus with volsella after thorough exposure of the parts and applying sutures directly to the bleeding parts. Cholmogoroff[10] succeeded in suturing a bad laceration of the uterine lower segment by the vaginal route. The patient was a IVpara, bleeding profusely after a breech birth; the rupture was 10 cm. in length, situated about 3 cm. above the external os in the anterior wall of the uterus; the bladder was not injured. The placenta was removed from the abdominal cavity through the uterine wound. The cervix was steadied with volsella; the torn edges were trimmed evenly with scissors and closed with interrupted sutures, with the exception of one corner which was left open for drainage by a strip of gauze. She recovered. Cholmogoroff believes that uterine ruptures can be sutured from below, providing the tear is below the contraction ring. In Case II. suture of the rupture was relatively easy because the Cæsarean incisions permitted the approach with needles and needle-holder, but otherwise it would have been impossible. Vaginal suture will be limited to a very few favorable cases, as the objections to leaving a torn uterus in the woman obtain, and more particularly because bleeding vessels may be overlooked. Indeed, even after opening the abdomen one cannot always see where the bleeding vessels are located without opening up the pelvic serosa.

I have already mentioned that the extirpation of the puerperal uterus from the abdomen is always a lengthy and bloody operation, attended with much risk of ureteral injury, because of the great vascularity incident to gestation. It was on this account removed only when extensively mutilated or septic, but recent experiences with the extirpation of the gravid and puerperal cancerous uterus by the vaginal route have demonstrated the extreme ease and rapidity with which the freshly delivered uterus can be removed; further, that as strong downward traction on the cervix is exerted its vascular apparatus becomes so attenuated by the traction that for the time being hemorrhage almost entirely ceases. It was at first feared that the volume of the puerperal uterus would be so great as to render extirpation difficult unless the organ was morcellated, but the experiences of Fritsch,[1] Chrobak,[2] Seiffart,[3] Winter,[4] Iwanoff,[5] Solowij,[6] and Dührssen[7] have demonstrated with positiveness the ease and rapidity of the vaginal operation.

Immediately and for several hours after delivery the uterus is very soft, compressible, and withal so loosely attached, owing to the softened condition of the ligaments, that the organ can be drawn out to the vulvar orifice, a corresponding diminution of its transverse diameter occurring. Fritsch concludes that vaginal extirpation is peculiarly adapted to the treatment of ruptured uterus, because after the abdomen is opened one frequently sees only a small opening in the peritoneum, whereas in the parametrium there is a large cavity, and he claims that when hemorrhage is severe after the child has been delivered by the natural passages, vaginal hysterectomy will give better results than the abdominal operation. Iwanoff arrives at the same conclusion after removing a ruptured uterus per vaginam. Winter believes vaginal hysterectomy preferable to abdominal extirpation or conservative treatment in all cases of complete uterine rupture. Johannosky[8] and Solowij are not so favorably impressed by the vaginal operation, because they cannot overlook the field of operation. The writer's experience with Case III. and the reported cases in the literature have convinced him that the vaginal operation for rupture of the uterus, like the vaginal operation for other pathological conditions, has its limitations, and is not applicable to all cases and conditions without discrimination. Partial or total escape of the child from the uterus results in such extensive displacement of the pelvic and abdominal structures that the damage done to the ureters or intestines may demand abdominal section as a supplement. For anterior and posterior ruptures vaginal hysterectomy has proven itself an ideal procedure, and in the light of my own experience I will add that it is the operation *par excellence* when the rupture is complicated by vesical laceration, also in those utero-vaginal lacerations which occur from neglected transverse presentations, and in all cases attended with septic endometritis. Another commendation is that it may be performed if need be without general anæsthesia, as in Iwanoff's case.

Technique of the Vaginal Operation. — The patient is prepared for abdominal section and vaginal hysterectomy, narcotized with ether, and placed in the lithotomy position. The catheter is passed, the urine withdrawn into a glass and inspected for blood. If the patient is undelivered, the true conjugate diameter will be measured again.

I shall suppose the case to be one in which the fœtus has escaped into the peritoneal cavity through a rupture in the anterior wall of the uterus, the placenta remaining in the uterus, with a conjugate diameter of the pelvis of 8 cm.

The placenta is removed from the uterus and all blood quickly swabbed away from the field. The labia and vaginal walls are drawn apart with broad retractors. The cervix is grasped on each side with a strong volsellum forceps and drawn down to the vaginal orifice; then with strong scissors the fornix is incised all around the cervix. Douglas' pouch is opened by blunt dissection, the retro-uterine ligaments are severed, the bladder[1] and the plica are opened, the uterus is retroverted, the ligaments are tied off from above downward, and then the uterus is cut away. The hand is passed into the wound and all tears of the peritoneum are followed up and examined for incarcerated intestinal loops, which if found are gently loosened, drawn down into the vagina, and inspected for injury before being returned into the abdominal cavity. The fœtus is grasped by the feet and delivered; if the intestines give much trouble by prolapsing before the child, Dührssen advises delivery in the Trendelenburg position. The peritoneal cavity is now cleansed of clots, amniotic fluid, and meconium, and gauze inserted for drainage. Saline transfusions should be administered with a free hand during the operation to replace the lost blood and combat shock. The after-treatment is that of an ordinary hysterectomy.

It will by this time be noted that the writer has not laid the stress which the text-books do on the differentiation of complete from incomplete tears. After all, this distinction is not of so much importance, for we have seen that in Case III., of subperitoneal rupture, the patient would have died of hemorrhage if the bleeding vessels had not been ligated, and Paschen[2] lost a case of incomplete rupture from pelvic abscess four weeks after the occurrence. On the other hand, in many cases of complete rupture the patients recover. Of main importance is the determination whether infectious material has entered the abdominal cavity or not; it seems to me that the thermometer is the more reliable guide, for Kroner found that all of his patients who had fever either before or during the period of rupture died of septic infection.

[1] When vesical rupture complicates the uterine lesion, according to Dührssen it happens that trouble may be experienced in detaching the bladder. Dührssen, therefore, advises that the rear wall of the uterus be split to the fundus, the uterus retroverted and drawn out through the rear wound in the fornix, and the separation completed from above downward. Dührssen stated that the neglect to split the opposite wall of the uterus caused Winter so much difficulty that he was obliged to morcellate the retroverted uterus before he succeeded in detaching the bladder; this entails much loss of time.

[2] Centralblatt f. Gynäk., 1891, p. 915.

When intestines prolapse into the uterine cavity or the child escapes into the belly, the question of peritoneal laceration will be easily solved, but when delivery has been effected by the natural passages, even if the hand is passed through the uterine tear the untorn peritoneum often adapts itself so gently to the fingers that intestinal coils may be felt with deceiving accuracy, and undue force would rupture the delicate serosa. The writer agrees with those who regard every diagnosticated uterine rupture as an indication for operation; reasoning that if a woman subject to this calamity does not die of primary, she may die of secondary, hemorrhage, and that if she is fortunate enough to escape death from hemorrhage she will be still more fortunate if she escapes death by sepsis. I believe that prompt and radical surgical intervention presents the only solution to the question of reducing the mortality of uterine rupture, and the vaginal operation appears to answer both requirements, but should be supplemented if need be by abdominal section. Rupture of the uterus will always be a serious affair, and while the general rule enunciated holds good, the practitioner should not forget that his attitude must be modified by circumstances. To operate on a patient in collapse would only hasten death, but to transfuse several thousand cubic centimetres of decinormal salt solution into her veins will promptly revive her and give the surgeon time to remove her uterus and close the bleeding vessels. Neither should commencing peritonitis be regarded in any other light than as a peremptory command for immediate operation and provision for the very freest drainage, as patients not infrequently recover under the most adverse circumstances. Thus Reussing[1] reported an instance of rupture in which the fœtus remained in the abdominal cavity for three days before its removal by cœliotomy, but the patient recovered. What is known as conservative surgery should be avoided unless the relatives of the patient expressly forbid the radical procedures. If a conservative operation is performed one must be prepared for long suppurations and pelvic abscess; and if pregnancy occurs subsequently the practitioner will be called upon to choose either the Cæsarean section at term or to induce premature labor earlier in pregnancy. Should the undelivered patient be dying or just dead, the physician will examine for fœtal movements and heart sounds; if the child is living the post-mortem Cæsarean section should be performed. Kendall[2] reports two instances. The first child was born alive but died soon after; the second child was still alive a year later.

Résumé.—I. In threatened uterine rupture the woman is to be delivered at once by the method which does not increase the excessive intra-uterine tension.

II. After rupture occurs, delivery by the natural passages is permissible only if the uterine injury is not aggravated thereby.

III. If the true conjugate diameter of the pelvic inlet measures less than 8 cm. a completely intra-peritoneal fœtus should be delivered by abdominal section.

IV. But if the conjugate measures 8 cm. or more, the uterus should be removed by vaginal hysterectomy and the child delivered by the feet through the natural passages.

V. If life is detected in the child after the mother's death, the post-mortem section should be performed.

VI. The uterine tamponade is useful only as a dressing to prevent intestinal prolapse or to retain reposited loops of intestine within the abdomen until the case can be submitted to operation.

VII. Conservative surgery exposes the woman to the serious risk of subsequent rupture, and should therefore not be elected unless expressly commanded by the patient or immediate relatives.

VIII. Vaginal suture is open to the objection that bleeding arteries in the parametrium are apt to be overlooked.

IX. When laparotomy becomes necessary for the birth of the fœtus, the uterus is to be removed by supra-vaginal amputation, with the extra- or intra-peritoneal treatment of the stump, according to the exigencies of the case or ability of the practitioner.

X. Vaginal hysterectomy is the elective procedure in all cases, but should be supplemented by abdominal section whenever necessary.

LOSS OF HAIR; A CLINICAL STUDY FOUNDED ON THREE HUNDRED PRIVATE CASES.[1]

By GEORGE THOMAS JACKSON, M.D.,

INSTRUCTOR IN DERMATOLOGY IN THE MEDICAL DEPARTMENT OF COLUMBIA UNIVERSITY, NEW YORK CITY; CONSULTING DERMATOLOGIST TO THE PRESBYTERIAN HOSPITAL AND TO THE NEW YORK INFIRMARY FOR WOMEN AND CHILDREN.

In 1892 the subject of loss of hair was discussed by this association, following the reading of a paper upon the subject by Dr. George T. Elliot. In 1893 I published in *The American Medical and Surgical Bulletin*[2] a clinical study of one hundred private cases of loss of hair. Both Dr. Elliot and I maintained the same proposition, namely, that a disease of the scalp variously called seborrhœa, pityriasis, dandruff, seborrhœal eczema, or dermatitis was the cause of a great majority of the cases. In the present study I have not endeavored to touch upon any pathological or bacteriological question, but have simply tried to find out what my clinical experience teaches. I have chosen the term loss of hair rather than alopecia so that it would be readily understood that baldness was not present in every case. Most of the patients who consult us are *losing* their hair, and have not *lost* it.

Of the three hundred cases, a study of which forms the basis of this paper, one hundred and fifty-eight occurred in men, and one hundred and forty-two in women.

In this paper I have made no account of the nationality of the patients, as naturally the vast majority of them were natives of this country.

Condition: Married, 38 men and 61 women, or 99 in all. Single, 97 men and 60 women, or 157 in all. Widowed, 1 man and 7 women, or 8 in all. Not recorded, 36.

Occupations—of the men: Actor, 2; architect, 3; banker, 1; bookkeeper, 1; bookbinder, 1; broker, 9; butcher, 2; clergyman, 2; clerk, 20; commercial traveller, 1; dentist, 2; electrician, 1; engraver, 2; farmer, 2; grocer, 1; gymnast, 1; hotelkeeper, 1; lawyer, 8; lecturer, 1; librarian, 1; manufacturer, 2; mechanic, 4; merchant, 8; musician, 1; physician, 40; printer, 1; student, 13; tailor, 1; teacher, 4; telegrapher, 1; waiter, 1; not stated, 21. Of the women: Artist, 2; clerk, 1; domestic, 1; dressmaker, 1; glover, 1; housekeeper, 56; musician, 2; nurse, 3; physician, 1; proofreader, 1; reporter, 1; student, 1; teacher, 4; unstated, 67.

Age at beginning: From ten to twenty years, 27 men and 24 women, or 51 in all. From twenty to thirty years, 97 men and 50 women, or 147 in all. From thirty to forty years, 31 men and 36 women, or

---

[1] Read before the American Dermatological Association, May 1, 1900.

[2] Amer. Med. and Surg. Bull., 1893, vol. vi., p. 1047.

67 in all. From forty to fifty years, 3 men and 17 women, or 20 in all. Over fifty years, 19 women.

The largest number of cases in any one year was 20 cases in the twenty-sixth year. The next largest was 18 in the twenty-second year. It is notable that 12 cases began under sixteen years of age.

Regions affected: General thinning, 21 men and 80 women. Crown, 56 men and 21 women. Crown and forehead, 18 men and 3 women. Crown and temples, 16 men and 2 women. Temples and forehead, 24 men and 8 women. Occiput, 1 woman. The tonsure was formed in 19 men and 3 women.

Diseases of the scalp and hair, as probable causal factors in the production of the loss of hair: Atrophia pilorum propria, 13 cases; atrophy of the scalp, 6 cases; canities, 9 cases; dandruff, 218 cases; dryness and heat of scalp, 6 cases; hyperæmia of scalp, 1 case; hyperidrosis capitis, 10 cases; keratosis capitis, 1 case; seborrhœa oleosa, 6 cases; erysipelas, 1 case.

General diseases as probable complicating factors: Anæmia, 15 cases; chorea, 1 case; constipation, alone 7 cases; with and without dyspepsia, 39 cases; gall stones, 1 case; gonorrhœa, 2 cases; gout, 1 case; hypochondria, 1 case; inebriety, 3 cases; insomnia, 2 cases; invalidism, chronic, 1 case; malaria, 10 cases; malnutrition, 1 case; menopause, 8 cases; neuralgia, 3 cases; nervousness, 11 cases; neurasthenia, 5 cases; obesity, 1 case; overstudy, 2 cases; over-training, 1 case; poor circulation, 1 case; spermatorrhœa (?), 1 case; urethritis chronica, 1 case; uterine disorders, 4 cases.

Family history: A history of baldness in the family was found in 132 of the 300 cases, as follows: Father only, 27 men and 6 women; father and paternal uncles, 13 men; father and paternal cousins, 1 man; father and paternal grandfather, 2 men; father, paternal grandfather, and brother, 1 man; father and brother, 17 men; father, brother, and maternal aunt, 1 woman; father and mother, 4 men and 6 women; father, mother, and brother, 2 men and 4 women; father, mother, and maternal grandfather, 1 man and 1 woman; father and sister, 1 woman; father and maternal aunt, 1 woman. Paternal uncle and brother, 2 men; paternal uncle, 3 men; paternal uncle, maternal grandfather, and uncle, 1 man; paternal grandfather and cousins, 1 woman. Mother only, 3 men and 13 women; mother and maternal grandfather, 1 man and 1 woman; mother and maternal grandmother, 2 women; mother and maternal aunt, 5 women; mother and paternal uncle, 1 man; mother and sister, 1 woman; mother and brother, 1 man and 1 woman. Maternal uncle, 3 men; maternal uncle and brother, 1 man; maternal aunt, 1 woman; maternal grandmother, 1 woman. Brother, 8 men; brother and sister, 1 woman. Sister, 1 woman.

What inferences can be drawn from these statistics?

1. It would seem at first glance that loss of hair was more common in men than in women, as 158 is to 142. But I feel sure that the proportion is not altogether correct, because it is well known that women value a good head of hair much more than do men. They will do everything in their power to save their hair. Men either regard the loss of their hair as inevitable, or will not take the time or trouble even to try to save their hair. It is therefore probable that the statistics represent fairly well the prevalence of loss of hair among women; but that they inadequately represent the prevalence of loss of hair among men, which is doubtless greater than they show. It can, then, be fairly inferred that loss of hair is much more frequent among men than among women, which is the general impression without the aid of statistics.

2. It would seem at first glance that the unmarried state is specially bad for the hair, as we find that there are 157 unmarried men and women to 99 married. But when we note that the number of the unmarried women (61) and of the married (60) is practically the same, while the bachelors outnumber the married men by 59, or are nearly three times as many, we suspect that our first inference is a little lame. The reason why the number of bachelors is so far in excess of that of the married men is found in the expression I hear so often from them: "I would not mind growing bald if I were married." When a man marries, grows old, and has resting upon him the task of winning a living for himself and his children, his personal appearance usually is a matter of secondary importance, and he bears the loss of his hair with equanimity. A woman, no matter how old she may be, nor how heavy her cares, still studies her personal appearance, and glories in her hair, or mourns its waning luxuriance. The correct inference, then, should be drawn from the statistics of the women, and that is, that neither the married nor the single state has any influence in the production of baldness.

3. We now come to the question: What influence does occupation have in causing loss of hair? My statistics show a great variety of occupations among those who are losing their hair. Two facts come out prominently, namely: (1) The great majority of my patients lead indoor lives. The 67 women put down as having no occupation belong to the leisure class of unmarried women, and are housed most of the time. (2) Nearly all of my patients belong to the intellectual class. That $13\frac{2}{3}$ per cent. of them are physicians does not necessarily mean that physicians are specially prone to loss of hair, any more than because $18\frac{2}{3}$ per cent. of them are housekeepers means that that occupation specially tends to loss of hair. And yet perhaps it does in both cases. The life of the physician and the housekeeper is alike in that their work is never done, and in that worry and nerve strain are constant elements. If we add together the actors, architects, bankers, brokers, housekeepers, lawyers, manufacturers, merchants, nurses, physicians, students, teachers, and telegraphers, all of which can fairly be regarded as occupations in which the elements of worry and nerve strain enter largely, we have 155, or more than one-half of our cases, subject to these influences. It may, then, be fairly inferred than an intellectual, indoor life, specially when coupled with worry and nerve strain, is a predisposing, if not a determining cause of baldness.

4. Without doubt my statistics show that the majority of the cases of loss of hair begin before the thirtieth year of age, sixty-six per cent. Further, more cases begin in the decade between the twentieth and thirtieth years than in any other decade, the largest number in any one year being 20 in the twenty-sixth year. It would seem, then, that if one passes the thirtieth year of age without showing signs of incipient baldness, the chances for keeping the hair intact are very much increased. This would seem to apply specially to men, though here again comes in the fact that married men care less about their hair than do single men. Here again, also, the figures in regard to the women are probably most to be depended upon, and we can infer that loss of hair occurs with rapidly decreasing frequency in the decades after thirty years, as represented by 36, 17, and 9.

5. My statistics show that loss of hair in women most often takes the form of a general thinning, while in men the whole top of the head is most often affected. The receding temple is very common in men, exceptional in women. Though not brought out in my statistics, I would say that I have come to regard the receding temple as a family trait, having often found it so in talking with patients. The tonsure was formed in only 19 of my male and 3 of my female patients. That the top of the head was so much more often affected in men than in women is doubtless due to the well-known difference in the make-up of the

scalp in the two sexes, the woman preserving the infantile fatty cushion under the scalp much longer than the man. If you put your hand on the head of a man you will usually find the scalp close down on the skull, while under the scalp of a woman you will feel a more or less thick layer between it and the skull.

6. As to the causes of loss of hair, apart from acute febrile diseases causing defluvium capillorum, which are not included in this study, we have predisposing and exciting causes. I believe that my statistics show that the great predisposing cause is heredity. We find that out of the 300 cases 132 have a well-marked family history of loss of hair. Without doubt in many of the cases of baldness in ancestors dandruff has played an important part. Still in a great many other diseases heredity is recognized as a predisposing factor, and it cannot be lightly set aside in the etiology of alopecia. I believe that in some families the hair falls at an early age without any discoverable cause in the scalp itself. The, to me, most interesting fact brought out both by my former statistics and the ones now before you is that the hereditary tendency to loss of hair runs in sex. So far as I know I am the first to draw the attention of the profession to this. If you study my figures you will find that when the father and father's family only show a tendency to loss of hair, there are 75 men and 21 women; while when the mother and mother's family only are concerned, there are 18 men and 32 women. When it was the father only who was bald, there are 27 men and 6 women; while when it was the mother only who was bald, there are 3 men and 13 women.

It seems to me that it is a fair inference to draw from the above that heredity is a factor of marked influence, a strong predisposing cause of loss of hair at least, if not in many instances the actual cause of baldness.

A glance over the list of complicating diseases noted in 122 cases shows us that they are all disorders that affect the general nutrition of the body. It is recognized that the hair sympathizes with the general nutrition of the body, falling out after fevers and the like. There does not seem to be any reason why it should not suffer in anæmia, 15 cases; dyspepsia, 30 cases; malaria, 10 cases; neurasthenia, 16 cases; and we see that it does. Therefore it can be stated as another conclusion that all diseases of lowered nutrition are predisposing, and at times determining, causes of loss of hair.

As exciting causes of loss of hair we find in ninety per cent. of all the cases some disease of the scalp or hair itself. In 218 cases, or 72⅔ per cent., there was dandruff. I use this term to include both pityriasis and seborrhœa sicca, both forms of seborrhœal dermatitis, so-called. In Dr. Elliot's statistics the proportion of dandruff cases was even greater, 88⅖ per cent. There is, therefore, no doubt that dandruff is found in connection with loss of hair in the majority of cases. It is a matter of common experience that dandruff may be present in large amount for years and the hair escape all damage. It does, however, antedate the loss of hair so often that it must be regarded as the most active exciting cause of alopecia.

I would state my belief in regard to the etiology of alopecia as follows: In a small minority of cases it is due to heredity alone; that heredity or any debilitating disease predisposes to loss of hair; that dandruff in some form is the exciting cause in the great majority of cases; that atrophic processes in the scalp, hyperidrosis and keratosis and a few other diseases may cause loss of hair in exceptional instances. Or, to state it differently, I believe that while it is possible for one without a family tendency to loss of hair to have dandruff for years without losing his hair, the same disease affecting one coming of a family the members of which lose their hair early is very sure to cause alopecia unless the dandruff is held in check by treatment. The important part played by dandruff in the production of alopecia is shown by the fact that if we can cure the dandruff the loss of hair is checked, unless the scalp has been too much damaged by the atrophic processes to which it gives rise. If the dandruff relapses the fall of hair will begin again.

Treatment.—On looking over my notes I find that I was able to follow only about a third of my cases long enough to draw conclusions in regard to the effects of treatment. Many of my patients were seen but once in consultation with other physicians. In others the calvities had gone too far for any hope of making the hair grow. But enough of them were followed sufficiently long, and from a number of them I have heard more or less directly as to the results of treatment to enable me to form quite definite ideas in regard to what may be expected from treatment.

If there is absolute baldness, and the scalp is atrophied and bound down, there is little use in trying to treat the case. All such a patient can do is to endeavor to stay the evil day by keeping his scalp in as good a condition as possible by hygiene, massage, and applying remedies for the dandruff if it is present. What the latter are will appear later. It is possible to stimulate the dying hairs for a time into a stronger growth, but ultimately calvities is inevitable.

I have had positive results in checking the fall of hair and increasing its amount by using precipitated sulphur 10 per cent. in a good cold cream with or without either salicylic acid, three to five per cent., or extract of jaborandi, a drachm to the ounce. These are my favorite remedies. The ointment proposed by Dr. Bronson, composed of ammoniated mercury gr. xx., calomel gr. xl., in an ounce of vaseline, has also done good service in some cases. In a few cases resorcin in solution and in increasing strength has proved helpful. On the other hand, naphthol and cantharides have proved perfect failures; resorcin has failed as often as it has helped; and my favorite sulphur preparations have failed about one-third times as often as they have been successful.

Medicated ointments and lotions are useful for overcoming the dandruff. I believe that there is no permanent cure for that disease, because it is parasitic, and the scalp once having been infected is all the more liable to reinfection. Therefore I am in the habit of telling my patients that they must expect relapses, and have their remedies constantly at hand so as to apply them as soon as the dandruff reappears.

For stimulating the growth of the hair I believe that there is only one remedy worthy of the name, and that is massage. For this a skilled professional is best, but a great deal can be done by the patient pinching up the scalp between the ends of the extended fingers of both hands for five minutes night and morning. Massage must not be used until the dandruff is checked.

To state it clearly, my treatment for the ordinary case of loss of hair with dandruff is as follows: I first attend to the general condition of the patient. The patient is given one of the sulphur preparations and is directed to use it once a day for three days, and then to wash the hair and scalp. Immediately after the hair is dried, the ointment is again applied and repeated every other day for ten days. The scalp is again washed and the ointment continued twice or three times a week until the dandruff is controlled, the washing being repeated from time to time. When the scalp is in good condition massage is ordered. If the patient will not use an ointment I order a lotion of resorcin, at first three and afterward five and ten per cent. strength, to be used morning and night. If the sulphur is used in the form of what my druggist calls "sulphur cream" it is not at all objectionable, and being used but twice a week or so, it is not so much trouble as it is to use a lotion twice daily. For a case of loss of hair without any apparent trouble with the scalp I rely mostly upon massage, using the sulphur preparation occasionally to keep the scalp a little oily.

Prognosis.—The prognosis is bad when calvities is already present. A bad family history as to the hair is a bad element in prognosis. The longer the dandruff has lasted the worse is the prognosis. It is less easy to help a man than a woman. The best prognosis is founded upon the patient being a woman without a history of baldness on the maternal side, the loss of hair not being of long standing.

14 East Thirty-First Street.

CELLULAR SPECIFICITY AND ITS BEARINGS ON NEOPLASMS.

By B. H. BUXTON, M.D.,
NEW YORK.

The question of the specificity of cells could not arise so long as their origin remained obscure; that is to say, until about 1840, when Schleiden for the vegetable, and Schwann for the animal kingdom, demonstrated that cells cannot arise *de novo*, as had been supposed, but only from pre-existing cells, and Virchow, applying their discoveries to pathological processes, formulated the axiom, "Omnis cellula e cellula." According to Virchow, the sole agents in regenerative and neoplastic processes are the connective-tissue cells, which, assuming embryological characteristics by a kind of atavistic change, are then enabled to differentiate themselves and form various tissues, of connective or epithelial types, according to circumstances. These views were generally adopted and held good until 1865, when Thiersch, after an exhaustive study of epitheliomas of the skin, arrived at the conclusion that the epithelial elements in these tumors are derived solely from the epidermis; the connective tissue taking no part in their development. Waldeyer followed suit in 1867 and 1872 with extended observations on epithelial, principally glandular, tumors, in two hundred of which he found that new-formed epithelial masses were always in connection with pre-existing epithelium, and there was no evidence whatever that the development of these masses proceeded from the connective-tissue cells.

Rémak had already maintained that from the moment the germinal layers are fully formed there can be no metaplastic interchange between the cells composing them, but beyond this he did not go, and it was not until the publication of Thiersch's and Waldeyer's researches that the theory of cellular specificity was generally adopted. From this time the idea rapidly developed, and has been carried to what appear absurd lengths by Bard, whose first article on the subject appeared in 1886. Bard starts with the ovum as the most complex cell, from which less and less complex cells arise by a process of what he calls dédoublement, in which the cells resulting from division are of unequal value—as opposed to simple multiplication, in which they are of equal value. He supposes the first division of the ovum to be such a dedoubling, giving rise to two less complex transitory cells of unequal value, which continue to increase by a simple multiplication until there is another dedoubling process, so that cells become less and less complex as they recede from the ovum; the finished tissue consisting of simple cells which can reproduce their own species only by a process of multiplication, and are unable to take on the properties of other species by metaplastic interchange. He expands Virchow's axiom into "Omnis cellula e cellula ejusdem generis," and draws up a scheme for a histogenetic tree in which the branches increase by dichotomic division, the nodal points representing the dedoublings and the final twigs the various species of cells.

Bard gets along swimmingly until he has to account for the appearance of ova and spermatozoa in the newly formed organism, which carries him into a maelstrom of speculation where no one can follow, for he has to assume that there are cells which have been derived direct from the ovum by simple multiplication and have never passed through stages of dedoubling. This not only contradicts his own view that the first division of the ovum is a dedoubling—a matter of little moment—but is utterly opposed to all that is known of the histogenesis of ova and spermatozoa. That they arise by differentiation of the columnar mesothelium of the peritoneum is a fact which cannot be disputed, and there is no evidence whatever to show that they are set aside from the beginning of things to fulfil their special functions.

Bard's ideas are evidently too simple for the German mind to grasp, so Hansemann, basing his belief in cellular specificity chiefly on the fact that each type of cell has certain mitotic characteristics peculiar to itself, elaborates a more complicated theory. He supposes that the ovum is a complex cell containing a large number of what he calls plasmas, each plasma having a potentiality of forming a certain type of cell. On repeated division each cell contains all the plasmas, but in unequal quantities, so that one particular plasma, Haupt or chief plasma, is developed in each cell at the expense of the other Neben or secondary plasmas. No metaplastic interchange can take place except between cells whose Hauptplasma is similar.

Supposing the ovum to contain equal quantities of three plasmas, 6*a*, 6*b*, 6*c*; on division one resulting cell may contain 4*a*, 3*b*, 3*c*, and the other 2*a*, 3*b*, 3*c*. In the first case, therefore, the chief plasma would be *a*, and the secondary ones *b* and *c*, and this inequality would go on increasing as the cells receded from the ovum. By this method he is able to explain the formation of new ova by supposing a gradual re-equalization of the plasmas; this re-equalization being the sole function of the ovum.

Both Bard and Hansemann maintain that the function of a cell is strictly limited by its origin; for example, certain cells are predestined to form fat, others bone, and yet others fibrous tissue, and between these there can be no interchange of functions. The same, in their opinion, holds good for the different kinds of epithelium. Facts, however, hardly justify these conclusions; it seems more probable that the function of a cell depends more on its environment than its origin, and that, except when the function is already of a highly complicated nature, cells may vary both functionally and morphologically within very wide limits if there is a change in their environment. Lubarsch says: "Such already differentiated cells always produce like offspring under like conditions, but only then."

All cells form certain derived products which must not be confounded with their products of excretion. The former may be called synthetical, and the latter analytical, products. The synthetical products may be (1) intracellular, as those of striated muscle or nerve cells, and contribute to the activities of the organism; or (2) extracellular, as those of connective tissue or epithelium, and contribute to the support of the organism.

I. Striated muscle and nerve cells, both functionally and structurally, have reached a very high degree of organization. No instance of metaplastic interchange between themselves or between them and any other group of cells has ever been observed, and they may safely be considered to constitute distinct species. Death is the only result of a change in their environment, so that their power of reproduction and tumor formation is practically *nil*.

II. In this group the synthetical products, after being formed, are removed from the cell and contribute in various ways to the support of the organism. It may be at once conceded that there are apparent exceptions to this rule as in the cells of the sebaceous glands and epidermis, but in these cases the cells themselves die and are cast off with their contained products, so that, as far as the living organism is concerned, the latter may be regarded as extracellular. In other instances, the formation of synthetical products is reduced to a minimum, as in the lining cells of ducts and vessels.

The cells forming this group may be subdivided into A, the epithelial, in which the synthetical products on being separated from the cell are removed to a distance, and B, the connective tissue in which they remain practically *in situ*.

A. The epithelial sub-group may be classified according to its morphological and functional properties:

Morphological.	*Functional.*
1. Stratified.	Defence—external influences.
2. Columnar.	Transmission or absorption.
3. Flattened.	Defence—internal influences.
4. Cubical or spherical.	Specialized secretions.

The functions of the first two classes are simple, and the cells manifest a comparatively low grade of organization in their capability of proliferation and regeneration, of metaplastic interchange, and formation of neoplasms if there is any change in their environment.

Their capability of regeneration is too well-known to be dilated upon, but it may be mentioned that Hansemann, Bizzozero, and other recent investigators maintain that in the normal adult organism mitoses can be observed in some tissues; in epithelial principally those communicating more or less directly with the exterior, as the epidermis with its hair follicles and sebaceous glands, mucous membranes of the intestinal and respiratory tracts, the epithelial recesses of the uterus, etc., and finally the ducts of glands, all of which can undergo physiological regeneration, *restitutio ad integrum*. Such mitoses are scarcely to be found in the more complicated glands, with the exception of the mammary and testicular, and when present indicate considerable proliferative power.

Metaplastic interchange between the first two classes may take place physiologically. Examples of this are monotremes, marsupials, and edentates, in which the teeth are absent or rudimentary, so that the task of mastication falls to the lot of the stomach, the epithelium of which takes on the functions and structures of the epidermis, even to the formation of keratohyalin, as shown by Ernst and Posner, the latter of whom remarks that keratinization is not a monopoly of the epiblast as had been hitherto supposed. Huxley compares the stomach of edentates with that of graminivorous birds, which is also lined with stratified keratinizing epithelium, but in his day the minute anatomy had not yet been fully studied. In the above instances the unusual environment necessitating increased defence is evidently the cause of the structural changes.

In the domain of pathology Virchow was the first to point out the change to flattened stratified epithelium, which often occurs along the track of the tracheotomy cannula; a similar change having been also observed in the nasal passages in ozæna, in chronic endometritis, and in inversion of the uterus. To these it may be objected that the change has been brought about by progressive invasion of the epidermis from without, rather than by metaplasia, but such objections can have no weight in the cases reported by Ernst, Siegert, Gruenwald, Ohloff and others, of primary keratinizing epitheliomas arising in the bronchi and gall bladder. Here the natural conclusion is that, in consequence of long-continued irritation from foreign bodies, the epithelium has to assume the defensive and changes its character accordingly. Such occurrences may be relatively frequent, but except when there was subsequent tumor formation would be liable to remain unnoticed.

That metaplastic interchange can take place between columnar and stratified epithelium seems certain, and they cannot therefore be regarded as distinct species, although they may be of widely different origin.

As regards neoplastic formation, it is astonishing how closely the cells of tumors derived from these two classes often resemble those of the parent tissue, although malignancy may already be pronounced, showing that their power of proliferation is great, even in the adult though not very highly differentiated condition. As examples may be quoted keratinizing epitheliomas of the skin, malignant adenomas of the rectum, and tubular carcinomas of the liver arising from the gall ducts.

A very generally accepted hypothesis, first mooted by Weigert, for the etiology of tumors is that of a disturbance of balance within the organism. Certain tissues become weakened and are unable to maintain their normal physiological resistance to the encroachments of other neighboring tissues which have retained their vigor. The functions of the cells under consideration being simple, they are less liable to regressive changes than certain others; any possible relative weakening of their neighbors constituting a change of environment for them, of which they are able to take advantage by virtue of their proliferative capabilities. This is in reality a regenerative effort, but, not being controlled by the normal resistance, it proceeds lawlessly and gives rise to a structurally atypical growth. The flat single epithelium lining the vessels and the large serous cavities appears to be more highly differentiated, and yet more so are the secreting cells of the true glands, in which latter the conditions are favorable for specialization. Being for the most part deeply situated, they have, from the earliest ages, been protected against changes in their environment, and have therefore been enabled to devote all their energies toward providing materials for the support of the body, in which process they have reached a high level of organization. As already remarked, in the adult normal state mitotic figures can rarely be observed in them, showing that their capabilities of proliferation and regeneration are comparatively slight. In organs composed of such cells there can never be a *restitutio ad integrum* on loss of substance, although there may be, and usually is, a compensatory hypertrophy of the remaining parts. If, for instance, a lobe of the liver be removed, although the organ may regain its normal size, the lost lobe is not regenerated, but the individual microscopic lobules of the remaining lobes, being stimulated to unusual activity, increase in volume, though not in number, as shown by Meister.

Metaplastic interchange is unknown among the secreting cells of deep-seated organs; like muscle and nerve cells they are to be considered as constituting distinct species. Primary carcinomas of compound glands almost always arise from the ducts and not from the specific secreting epithelium. In the pancreas they start, as a rule, at the head, in which the ducts are most numerous, and in the liver, in which their origin can be traced, it is usually found to be in the gall bladder or bile ducts. The small multiple adenomas found in cirrhosed livers or kidneys are probably more in the nature of localized compensating hypertrophies than true tumors.

Siegenbeck von Heukelom describes three cases of adeno-carcinoma of the liver with cirrhosis, numerous small nodules up to the size of a cherry being scattered throughout the organ; a condition, the "cirrhosis carcinomatosis" of Perls, occasionally observed though by no means frequent. Von Heukelom is unable to account for the combination, but it seems probable, as suggested by Orth, that "compensating hypertrophic patches from some unknown cause may overstep the limits of hypertrophy, and by a typical growth lead to the formation of malignant tumors."

The glands arising from the epidermis are more exposed to external influences than the deep-seated ones, and their secreting cells have not become so highly specialized. Sebaceous glands can apparently become formed *de novo*, and Fabre Domergues maintains that remains of sweat glands on a denuded surface can assist in the regeneration of the epidermis by becoming transformed into stratified epithelium. Tumors, both benign and malignant, arising from these glands are by no means infrequent.

In the mammary glands, which are probably modified sebaceous glands, mitoses are frequent in the cells of the acini, even in the adult state. The necessity for proliferative power in these cells is obvious, and the frequency of mammary tumors may not only be ascribed to this, but also to the fact that the mamma is both phylo and ontogenetically the last of the organs to attain its full functional activity, so that, its stability being naturally less than in older organs, a disturbance of balance between its epithelial and connective-tissue elements can more easily occur. Among domesticated animals, statistics of carcinoma in seventy-eight cases, collected by Casper, show about eighteen per cent. both in dogs and horses, including both sexes, to be mammary; no other organ giving such a high percentage. On the other hand, McFadyean maintains that mammary carcinomas in animals are relatively uncommon, and in sixty-four cases only quotes five or eight per cent. among horses and dogs, while in the cow, so far as he is aware, there is no authentic case on record. Still even eight per cent., including both sexes, is a high percentage, and seems to indicate that among domesticated animals, as in the human species, malignant tumors are more likely to arise in the female breast than in other organs.

B. Connective Tissue: The second sub-group comprises the connective-tissue cells, whose different kinds of synthetical products assist in building up the endoskeleton and—following Mark—may be called sustentative. It is not, however, quite determined in what way the intercellular substances are formed by the cells, although it is certain that the presence of the latter is essential to their development and continued existence.

Acording to Goette, the primary mesenchymal substance is formed by transfusion from the entodermal canal, and is destitute of cells. Later on cells become detached from the mesothelium, and by amœboid movements penetrate into the mesenchymal fluid; further differentiation being influenced by them, but the actual changes occurring altogether outside of the cells. It may be taken for granted, then, that the secretions of the cells so act upon preformed undifferentiated intercellular substance as to cause it to assume various characteristics, and the question then arises: "Is the character of the secretion of a mesenchymal cell dependent on its inherent specificity, in which case there can be no metaplastic interchange between the different kinds, as maintained by Bard and Hansemann; or is it merely dependent on the cell's environment, so that with a change of the latter the cell can alter the nature of its products?"

Those mesenchymal cells which are purely sustentative will alone be considered here. Some have taken on other functions, as the fat cells which form a reserve fund, the involuntary muscle cells which contribute to the activities of the organism, and the lymph and blood cells. The mesenchymal fluid at first is probably only a serous effusion (Minot) either derived primarily from the entodermal canal, as already mentioned, or, as Hertwig maintains, from the cells of the middle germ layers—the mesothelium—and later by transfusion from the immature blood-vessels which penetrate it in every direction; mucin being the first product added to it by its own contained cells. In the resulting gelatinous tissue, the cells are no longer able to wander freely, but become fixed; assuming a stellate form with branching anastomosing processes. Mucoid tissue then is œdema plus mucin, as maintained by Köster and Kickhefel, and in the embryo is the first stage in the differentiation of connective tissue. In the lower vertebrates mucoid tissue persists in places throughout life, but in the higher is purely embryonic, except in pathological conditions. As the walls of the blood-vessels reach a higher stage of organization, the serous effusion becomes relatively less; the intercellular substance condenses and under the influence of the cellular products assumes by degrees its various adult forms. Of the three kinds of sustentative connective tissue, cartilaginous, fibrillar, and osseous, the former is both phylo- and ontogenetically the oldest, being found in invertebrates, and appearing before either of the others in vertebrate embryos.

Schmiedeberg has studied the constitution of cartilage, and finds the matrix to consist of a meshwork of fibrils, identical with those of fibrillar connective tissue and bone, the interstices of which are filled with chondrin, which by long-continued maceration in potash can be dissolved out, leaving the form of the cartilage intact. The synthetical products, therefore, of cartilage cells act on the intercellular substance, mucus plus serum, in precisely the same way that those of fibrillar or osseous connective tissue act, viz., by transforming it into gelatinous fibres or collagen. But in addition there is formation of chondrin, and Schmiedeberg has isolated from this substance an acid, freely soluble in water, which he calls chondroitin sulphuric acid. If a solution of this be added to gelatin, a precipitate is formed which is identical with chondrin; the same occurring, though not so readily, with egg albumen and serum albumin. We may infer from this that the cartilage cell secretes the acid in order to give stability to the matrix by the formation of chondrin.

Cartilage may be considered as the first crude attempt at the formation of an endoskeleton. In the life history of animals, as the necessity for increased support in certain places arises, there is first a massing together of the mesenchymal cells, which become so closely packed that the blood-vessels are to a great extent excluded. Further support is then attained by the production of gelatinous fibres and chondrin, which afford a certain amount of stability and flexibility combined. There is, however, no provision for the entrance of vessels, and the way in which cartilage cells obtain nourishment is somewhat obscure, though there can be little doubt that it is the chondrin which in some way or other enables them to carry on their existence in the absence of blood-vessels. However this may be, formation of cartilage seems to be favored by a deficiency of vascular supply. In the course of development the structures affording stability and flexibility become separated, cartilage is supplanted by osseous and fibrillar connective tissue, and in the higher vertebrates remains only in isolated patches, where it can be utilized as pads or for keeping tubes open, for which purposes it is admirably adapted. But it must not be forgotten that the cells of these three tissues have one property in common; that of secreting a substance—possibly in the nature of an unorganized ferment—which can change the mesenchymal fluid into gelatinous fibres, other secretions being secondary and depending on the environment of the cell. Where support is needed and vessels are few, there may be deposition of chondrin; where rigidity is needed and vessels are plentiful, there may be calcification; and where flexibility is the main requisite, there may be formation of elastic fibres. It would, therefore, not be surprising to find the connective-tissue cells capable of changing their secondary secretions in order to adapt themselves to a change of environment whether occurring physiologically or pathologically.

Physiologically, in the formation of the shaft of a long bone, for example, we find the bone being formed by the action of connective-tissue cells which remain in the osseous tissue as bone cells. As the bone increases in size, the necessity for lightness arises, and the centre becomes hollowed out by absorption of the calcified matrix, setting free the bone cells, which again take on the functions of fibrillar connective-tissue cells and form lymphadenoid tissue, which can be regarded only as fibrillar connective tissue, in which the fibres are reduced to a minimum and the lymph spaces enormously distended.

As an instance of metaplasia in cartilage, the history of Meckel's cartilage is instructive. To quote Minot: "The lower portions of the cartilage ossify metaplastically, and the bony part is incorporated in the permanent mandible, but the rest of the cartilage atrophies and entirely disappears except a small portion of the end next the malleus, which becomes changed into fibrillar tissue, and remains as the ligamentum internum maxillæ inferioris." Minot explains elsewhere, that by metaplastic ossification he means a direct conversion of the cartilage cells into bone cells, which here occurs, although in ossification generally the cartilage cells are destroyed in the process. Here, then, we have connective-tissue cells developing a cartilaginous bar, one end of which is further converted into bone, while the other end becomes a variety of fibrillar connective tissue; the change taking place metaplastically in both places, obviously on account of the cells adapting their secondary synthetical products to perform functions indicated by their environment.

Pathologically, metaplastic interchange often occurs between the different kinds of sustentative tissues. In experiments on rabbits Ribbert transplanted pieces of periosteum into intermuscular connective tissue and other places. He found they would frequently take root and grow up to a certain point, after which regressive changes occurred, and they were resorbed. Cartilage was always produced first, after which was occasionally some attempt at osteoid formation.

Birch-Hirschfeld, also working on rabbits, rubbed up early embryos in which there was not yet any differentiation of the connective tissues, and injected them into various organs and tissues—principally under the capsule of the liver. His experiments were mostly failures, save when growth cartilage was the only tissue produced. He argues from this in favor of the specificity of cartilage cells, holding that the cells predestined to form cartilage alone survived, but it seems much more probable that, in his cases and also those of Ribbert, the cells, finding nourishment scarce in their new situation, secreted chondroitin sulphuric acid, so that by fixing serous effusion from the surrounding tissues in the form of chondrin they were enabled to continue their existence for a time by drawing supplies from a distance.

In callus formation, cartilage is formed from the periosteum, especially, as Bonome points out, "just at the seat of fracture where circulatory disturbances are greatest, while further away the osteoblasts change directly into bone corpuscles without passing through the intermediate chondroblast stage."

Warren Coleman, in reporting a case of osteosis of the cutis occurring in the foot, refers it to metaplasia of the connective tissue, comparing it to the osseous formation in rider's bone, and in myositis ossificans. Rider's bone, however, according to Berthier, arises from torn-off pieces of the periosteum, and he was able to produce it experimentally on rabbits by cutting out the insertions of the adductor muscles, together with small fragments of the periosteum, which were then dragged off by the contracting muscles and formed foci of ossification. As an argument in favor of metaplasia rider's bone would, therefore, be ruled out by strict adherents of cellular specificity, but in myositis ossificans, as shown by Mays and Caen, foci of ossification occur for the most part in the intermuscular connective tissues quite unconnected with the periosteum.

According to the "disturbance-of-balance" theory for the causation of connective-tissue tumors, it would naturally be supposed that where loss of normal resistance is slight and sharply localized the cells would proliferate slowly, and be able to attain their normal life cycle; elaborating their synthetical products as usual, and forming the benign so-called adult connective-tissue tumors.

If the loss of resistance be considerable, the cells by virtue of their proliferative power multiply in order to fill up the breaches, but their increase being met by little or none of the usual counteracting influence, they continue to multiply rapidly and lawlessly, no time being allowed them to attain functional activities. It is not necessary to suppose that the cells themselves assume embryological characters. The conditions—plenty of elbow-room—existing in the early embryo are reproduced to a greater or less extent, and the cells conduct themselves according to their environment. It is evident, therefore, that the cells which take part in the formation of the three varieties of sustentative tissue cannot be considered as distinct species. According to their environment they can produce any one of these tissues, proving, by their power of multiplication whenever a chance is given them, that they have not reached a very high degree of organization. The differentiation of the sustentative tissues appears to lie more in the intercellular substances than in the cells themselves.

NOTE ON THE TREATMENT OF CHRONIC HEART DISEASE BY THE ARTIFICIAL NAUHEIM BATHS.[1]

By ABRAHAM MAYER, M.D.,
NEW YORK.

THE balneo-therapeutics of chronic disease of the heart as practised at Bad Nauheim originated with Professor Beneke, of Marburg, physician at Bad Nauheim, in the year 1859. Beneke observed that in treating chronic articular rheumatism with the carbonic-acid mineral waters of Nauheim, patients suffering from valvular lesions of the heart were not only vastly benefited, but in many cases the improvement became permanent; that relapses were the exception, not the rule. About this time Beneke began the treatment of chronic valvular disease by the use of carbonic-acid mineral baths and drinking-waters in a more systematic manner, finding that the results obtained were so extraordinary that other therapeutic measures could not be compared with them.

Of course he found that new connective-tissue formation about the valves or contractions produced stenosis, especially when the result of an infectious endocarditis could not be overcome, but the general condition of such patients was vastly relieved, and cyanosis and œdema disappeared. About thirteen years later, in 1872, Beneke published a history of one hundred and one cases of disease of the heart principally the result of an endocarditis, showing that the benefits derived from these carbonic-acid mineral baths were beyond question. Later Groedel, the Schott brothers, Bode, Graeupner, and others not only verified these observations but systematized the methods, and introduced a series of exercises framed to replace Oertel's Terrainkur, which exercises were for the purpose of increasing the lumen of the arterial vessels, filling the arteries with more blood, and thus relieving passive congestion. So that to-day, in the treatment of chronic diseases of the heart, we have no therapeutic measures so potent as the Nauheim baths and exercises.

Until within two years ago the writer had frequent occasion to send patients suffering from chronic disease of the heart to Bad Nauheim for treatment as prescribed there by the Schott brothers, the elaborators of this therapeutic measure. The Schotts have always claimed that similar results could be obtained from baths artificially prepared so as to resemble the Nauheim waters, and, if they were carried out on the same principles, a journey to Germany would be entirely unnecessary. Not considering the expense of such a trip, a great many patients afflicted with heart troubles cannot stand the debilitating effects of an ocean voyage. It occurred to me that if the Nauheim baths and system of exercises could be carried out here these drawbacks would be obviated.

Various methods may be employed for the production of a carbonic-acid effervescent bath. The action of hydrochloric acid on bicarbonate of sodium is a simple way for generating the gas. Used in conjunction with the saline mixture (described below) in varying proportions, the degree of effervescence may be regulated by the quantity of acid and alkali employed, so that a mild, medium, or strong ebullition results. The mild bath is prepared by adding three-quarters of a pound of hydrochloric acid to one-half pound of bicarbonate of sodium; the medium, by doubling these quantities; the strong bath by the action of three pounds of hydrochloric acid on two pounds of bicarbonate of sodium. The procedure is as follows: A given quantity of the saline mixture is dissolved in thirty gallons of water, 4 or 5° warmer than the bath calls for. Bicarbonate of sodium is now added and thoroughly mixed with the saline solution. The hydrochloric acid, contained in a stoppered bottle, is placed at the bottom of the tub, the stopper is removed, and the acid is slowly distributed throughout the lower layer of water. In this way rapid effervescence takes place, and the bath is ready in a few minutes.

Or the acid sulphate of sodium (or potassium) and bicarbonate of sodium may be used with great advantage. The acid sulphate of sodium is fused into suitable cakes weighing about two ounces. Six or eight of such cakes are placed on tinfoil strips or in saucers at the bottom of the tub containing the saline solution of proper strength and temperature, and two pounds of bicarbonate of sodium added. Effervescence begins at once, and the patient is immediately immersed in the bath, his head only being above the level of the water, properly supported by a cross-piece of webbing. The strips of tinfoil protect the porcelain or wooden tub from any deleterious effect. It is wise to distribute the cakes on the bottom of the bath in such a way that two each will correspond to the shoulders, buttocks, and feet of the patient. Fused cakes of the acid sulphate of sodium or potassium may be procured in the shops, and produce with the bicarbonate of sodium an ideal effervescence.

The employment of liquid carbonic acid gas may be mentioned here. Unless used in conjunction with a suitable apparatus this method may prove dangerous on account of the poisonous nature of the gas when inhaled.

I use the following mixture for preparing the saline bath: Sodium chloride (sea salt), 30 lbs.; potassium chloride, 10 oz.; calcium chloride (granular), 30 oz.; magnesium chloride, 8 oz. These ingredients are thoroughly mixed and kept in a moisture-proof tin box till required for use. It is advisable to begin with a weak saline solution, three pounds of the above mixture in thirty gallons of water, and increase gradually until five pounds of the mixture in the same quantity of water is used. The latter strength closely resembles the Nauheim Spring No. VII., called the Grosser Sprudel, the strongest of the waters there. The temperature of the bath should be 95° at first, which is gradually reduced in each succeeding bath till a temperature of 85° F. is recorded. The duration of the first bath must not exceed five minutes. As the strength of the bath is gradually increased and the temperature diminished, so the period of immersion is lengthened until the limit of fifteen to twenty minutes is reached. Following the usage at Nauheim it is necessary to omit the baths every second or third day. The number of baths necessary varies with each individual case; usually a course of treatment extending over several months is required. During the past year, 1899, twenty-eight patients with chronic diseases of the heart have been treated by me with these artificial Nauheim baths. The results obtained have been so gratifying that I can without hesitancy claim that the therapeutic influences of these baths are identical with the natural ones.

The baths in Nauheim consist of various saline thermal waters impregnated with natural carbonic acid gas. In some of the bathrooms these waters enter a specially designed wooden tub in a continuous flow, and leave by an overflow pipe, so that during the entire immersion bubbles of carbonic acid gas are constantly rising to the surface and adhere with great tenacity to the body.

---

[1] Read before the Metropolitan Medical Society, January 23, · 00.

The effects of the Nauheim baths, as given by Schott, Thorne, and others, are "to lower the frequency and increase the force of the action of the heart, to cause a recession of cardiac dulness of considerable amount, and to induce a sense of refreshment and invigoration which is shortly followed by an agreeable inclination to avail one's self of rest in the recumbent position." The effect of the immersion in the artificial bath is exactly similar. One of the effects noticed is sometimes a slight oppression for the first few seconds, a diminution of pulse beat amounting to ten or twenty pulsations at the end of two minutes, which continues for the next ten minutes. In an individual case of a boy seven years of age, suffering from mitral insufficiency with considerable enlargement, the pulse was reduced in frequency from 90 to 70 at the end of two minutes, with a further reduction to 64 at the end of ten minutes; so that in ten minutes the pulse ran down from 90 to 64. This subsequently rose a few beats at the end of another ten minutes. The dyspnœa, which in this case was very striking, was entirely relieved while the patient was in the bath. Such effects last for some hours after the bath, the pulse rate being only slightly raised by the exertion of dressing.

In order to verify the observations of Schott, Thorne, and others, and to prove that the effect of the artificial bath was identical with the natural one, the writer submitted to a test bath in the presence of Drs. J. Kaufman and M. S. Kakels, who were asked to witness it, make the physical examination, and record the observations. The temperature of the bath was 92° F. The saline solution contained three pounds of the saline mixture in thirty gallons of water. Carbonic acid gas was equal to 900 c.c. to the litre. The bath was taken December 17, 1899, at 4:20 P.M. The pulse in sitting position before entering the bath was 76. Immediately after entering the bath a sense of oppression was experienced, which lasted about a minute. during which time the writer was forced to take very deep inspirations. After two minutes' immersion the pulse was 65 and a sense of glow came over the entire body. At the end of three minutes the pulse was 62 and the whole body was covered with bubbles of gas. After ten minutes the pulse was still 62 and a sense of exhilaration was felt. Then arising from the bath and getting a brisk rub while enclosed in a warm bath robe, I rested ten minutes in the recumbent position. The pulse then taken was 64. Dressing leisurely, the pulse rose to 68 and remained so for several hours. The most astonishing feature of the bath was the effect on the area of cardiac dulness. Before immersion a careful physical examination of the heart and liver was made, and the area of cardiac dulness and liver was carefully outlined on the chest and abdomen. These areas being normal, it was doubted whether any diminution would take place after the bath. Nevertheless, the area of cardiac dulness decreased nearly half an inch; over the liver a somewhat larger diminution was observed.

As said before, there is produced a momentary effect of oppression in breathing which causes one to breathe deeply and slowly, and which is followed by a reduced and more rhythmic inspiratory and expiratory movement. As Thorne justly remarks: "The carrying power of the peripheral vessels is increased and a sense of warmth in the extremities and on the surface of the body is experienced. The general arterial capacity, systemic and pulmonary, is increased, and without the loss of blood the relief of a general bleeding is afforded to an overloaded and laboring heart." In neurasthenics, and in patients suffering from a scanty flow of urine, it was also noticed that a series of baths caused increased diuresis. These baths through their action on the heart, and lessening its burden, indirectly relieve the deep-seated organs, and consequently cause them to resume a general normal functional condition. The mineral and gaseous constituents of the water produce a cutaneous excitation and thereby reflexly the above effects are produced. Schott supposes that from the surface of the body by imbibition into the superficial layers of the skin an influence is transmitted to the central nervous system which is centrifugally reflected to the vasomotor system and the ganglia which control the action of the heart. That the nerve centres are influenced is attested by improvements noticed in patients suffering from neurasthenia, anæmia, etc., nearly all of whom showed decided amelioration of their symptoms. There is no doubt, according to my observations of the invigorating influences which these baths exert on the heart and circulation, of the improvements observed, lasting for three or four months after a series of immersions. Excepting in cases of arteriosclerosis and advanced cardiac degeneration due to myocarditis, benefits may be expected in all cases of chronic heart disease.

The therapeutic influences of the baths are augmented by a system of exercises, the results of which are nearly as efficacious and which can be employed in conjunction with the baths, or independently especially in obese or bedridden patients. Schott calls these exercises "Wiederstands-Gymnastik," or resistance gymnastics. They consist of regulated movements of the entire voluntary muscular system, which are resisted by an expert attendant in such a way as slightly to oppose the muscular action without arresting it. These exercises, originating with the Schott brothers, have been carefully studied by Thorne, Lauder Brunton, Morrison, Gibson, and others. Without going into details of these various resistant movements, it will be sufficient to state here that the operator must be thoroughly conversant with the actions of the different groups of muscles; the patient must be carefully observed during the manœuvres, which must be at once suspended on the slightest symptom of circulatory or respiratory interference. The results of the exercises are similar to those of the baths; that is, a correction of circulatory disturbances and strengthening of a diseased and weakened heart. The changes which attend these graduated exercises are disappearance of cardiac irregularity, palpitation, and uneasiness, better filling of the arterial system, reduction of the frequency of the pulse, increased energy of the heart, and absence of all respiratory distress. The increased capacity of the blood-vessels enables the heart to contract in such a manner as to empty its cavities with each beat. The exercises taught in a scientific manner by the physician to his patient can be successfully carried out by him at home without an attendant. We can readily see that these measures can be utilized and are within the reach of every sufferer from chronic disease of the heart.

This paper has not been written for the purpose of presenting a statistical report of cases, and so I have refrained from burdening you with histories.

In considering the treatment of chronic heart disease we must consider that there is a loss of the equilibrium normally existing throughout the circulation. This loss of normal relation produces a tendency to a diminished amount of blood in the arteries and an excessive amount in the veins, from which there results a liability to the accumulation of fluid in the system. In consequence of these disturbances all the great functions are interfered with. Venous stasis results with its pernicious effects on all the important organs; lungs, stomach, liver, kidneys, and the nervous system, all suffer from the disturbed circulatory condition. These results are again reflected on the blood and through it on the heart, and hence a continuous circle of vicious influences is kept up.

Of all methods of treating chronic diseases of the heart—and by treating I mean relieving not only the circulatory disturbances but the concomitant effects on the different organs of the body—I am convinced that the artificial Nauheim baths, like the natural ones, together with the resisting exercises, are the most efficacious and lasting therapeutic remedy yet devised.

40 East Sixtieth Street.

Remarks on Facial Paralysis with Special Reference to Treatment.—T. Sydney Short states that researches tend to show that in Bell's paralysis, in some cases at least, the lesion is a real parenchymatous inflammation of the nerve structure itself, and not due to pressure alone. Pain seems to be more frequently absent than present. The writer divides the treatment into local, general, and electrical. He believes counter-irritation to be of great value early in the condition. Potassium iodide is usually given. Galvanism is the most valuable treatment. Short also describes the "face crutch."—*The Birmingham Medical Review*, April, 1900.

The Therapeutic Uses of Yeast.—Elsie Reed Mitchell reviews Landau's work on this subject, then giving her own experiences. Out of eight cases of leucorrhœa treated by local applications of yeast, one was entirely unaffected. This was a syphilitic and the discharge was not of local origin. Five cases were still under treatment or passed from under observation, markedly improved, one of these being of known gonorrhœal origin. Two cases were cured, with relapses under peculiarly unfavorable circumstances, possibly a reinfection. One case was cured with a relapse after four months. The writer has observed no unpleasant after-effects. Brewers' yeast was used when it could be obtained: when it was not to be had, compressed yeast gave apparently similar clinical results. A quarter of a cake of "Fleischmann's" was dissolved in half a cupful of water mixed with about a teaspoonful of either flour or sugar.—*The Woman's Medical Journal*, April, 1900.

The Motor Innervation of the Palate.—From the prolonged observation of a child who presented total loss of power on the right side of the palate and larynx, and who was operated on for a left tuberculous otorrhœa by the radical method, Brindel comes to the conclusion that the motor innervation of the palate is through the vago-spinal nerve. He expresses the hope that the statement which appears in even the most recent treatises, that the innervation is through the facial, will speedily be corrected.—*Revue Hebdomadaire de Laryngologie, etc.*, March 3, 1900.

On the Administration of Anæsthetics to Children.—W. I. McCardie and C. F. Marshall consider the main physiological differences between the child and the adult which concern the induction of anæsthesia, and lay stress upon the fact that the administration of anæsthetics, especially chloroform, is by no means so free from danger in childhood as is generally supposed. They also consider the question of the best anæsthetics to employ in the various operations performed on children. Chloroform is never free from danger, and it is better to use, as a routine anæsthetic, ether, A. C. E. mixture, or a mixture of two parts of ether to one of chloroform. Nitrous oxide followed by ether may be given to the older children. Nitrous oxide alone has been used by one of the authors successfully in operations lasting from five to ten minutes. It should never be followed by chloroform. Local anæsthesia is inapplicable to children owing to the great difficulty in keeping them quiet and overcoming terror.—*Treatment*, April, 1900.

The Mosquitos of the City of Grosseto.—Francesco Testi made a study of more than five hundred mosquitos collected chiefly in the city of Grosseto. He found that while the variety Culex was most abundant in all houses where there had been cases of malaria, the Anopheles was so rare that only eighteen were found to four hundred and forty-nine Culex. The fact is a curious one, in view of the importance attributed to the Anopheles in the dissemination of malaria. The author does not draw any conclusions therefrom, but merely mentions the fact as such. The Anopheles is more apt to be found in the country than in the city, and the persons suffering from malaria may have become infected out-of-doors, especially toward the evening hours.—*Giornale Medico del Regio Esercito*, March 31, 1900.

A Case of Meningism from Helminthiasis.—C. A. Annaratone reports the case of a patient who died apparently of meningitis. No abnormality was found in the meninges or brain, but in the stomach was a mass of ascarides lumbricoides. Chauson has found that by injecting the juice of ascarides obtained from horses and pigs into guinea-pigs, death was produced. The author believes that in the reaction against the too great importance which used to be attributed to intestinal worms as a cause of disease, their real powers of injury by the production of intoxication has been overlooked or underrated. The subject deserves study.—*Giornale Medico del Regio Esercito*, March 31, 1900.

Facial Hyperidrosis of Nervous Origin.—E. Ruggiero reports the case of a young sailor, aged twenty years, whose face is constantly covered with perspiration, both summer and winter, day and night. There are no symptoms of hemicrania, facial neuralgia, cephalalgia, disturbance of facial muscles, of cutaneous or olfactory sensation. The chief seat of the disturbance is the tip of the nose, where in freezing weather the perspiration freezes. The author believes the trouble to be of nervous origin, probably in the anterior horns of the cervical spinal marrow, the lesion involving the fibres which the trigeminal receives from Gasser's ganglion. The prognosis in this case is bad, as the disorder has already lasted seven years. Local remedies have had no effect, and nothing can be hoped from the use of electricity. It might be useful to resect the nerves distributed to the affected region, the naso-lobular nerves of Chaussier.—*Annali di Medicina Navale*, March, 1900.

Adherent Pericardium.—H. W. Rogers reports the case of a colored woman, about twenty-five years of age, who was brought to the hospital suffering from intense dyspnœa, with physical signs of delirium cordis and a pulse which was rapid, irregular, and arrhythmic. The right heart was much dilated and extended over to the right side of the sternum, passing beyond at least two fingers' breadth. The left heart did not show any very marked degree of enlargement. There was a murmur heard with greatest intensity at the apex, presystolic in time and of a musical intonation. A diagnosis was made of mitral stenosis with a presystolic murmur and excessive dilatation of the right heart. The necropsy revealed extensive adhesions between the layers of the pericardium and a band of adhesion extending over both ventricles, and also attached to the apex down to the diaphragm. There was no pulsus paradoxus.—*Cleveland Journal of Medicine*, March, 1900.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, May 26, 1900.

MEDICAL LEGISLATION IN NEW YORK STATE.

THE last legislature passed several amendments to the public health law; but none of them was so important as the entire recasting of Article XI. The amendment is the result of several years' agitation and several failures to secure satisfactory legislation. There have been three boards of pharmacy, one in New York, one in Erie, and one whose province was the remainder of the State. The new rule provides for a single board for the whole State.

The State is divided into three sections. The eastern (New York) comprises New York, Kings, Queens, Nassau, Suffolk, Richmond, and Westchester counties; the western (Erie) section takes in the counties of Erie, Niagara, Orleans, Genesee, Wyoming, Allegany, Cattaraugus, and Chautauqua; and the middle (Albany) section comprises the other counties in the State.

The members of the board, to the number of fifteen, are to be elected every June, five from each section, and they must be licensed pharmacists, one from each section to go out of office every year. The maximum term is five years. For the eastern section two members are to be elected from the Manhattan Pharmaceutical Association, two by the Kings County Pharmaceutical Society, and one by the New York German Apothecaries' Society. The members for the western section are to be elected at a meeting of the licensed pharmacists and druggists residing in such section, called by the Erie County Pharmaceutical Association, and those for the middle section are to be elected at the annual meeting of the State Pharmaceutical Association, at which meeting all licensed pharmacists and druggists residing therein are entitled to vote.

The State board is to meet in January annually in Albany, and elect a president and a secretary, who shall also be treasurer. The board fixes the salaries of the secretary of the State board and the secretaries of the branches for the eastern, western, and middle sections. After the organization of the State board, the members of the State board from the respective sections shall organize branches therein and elect a chairman and secretary and treasurer. Each member of the State board shall receive $5 for each day actually engaged as a member of such board, or one of its branches, provided that no member shall receive more than $150 in any one year, together with his necessary expenses.

The State board is empowered to regulate the practice of pharmacy, the sale of poisons, the character and standard of drugs and medicines dispensed in the State; to employ inspectors of pharmacy; to examine all applicants for license or registration, and to issue two grades of licenses to be known respectively as that of "licensed druggist" and "licensed pharmacist," and one grade of certificates as "registered apprentice"; except that, in New York City, a license for the grade of "licensed druggist" shall not be issued; to investigate and prosecute violations of law governing the practice of pharmacy and sale of poisons; to require the annual registration of every pharmacy, store, dispensary, or place where drugs are dispensed or sold, and to charge a fee of $2 therefor; and to revoke for cause any license issued. Existing licenses are continued, and as regards the issuing of licenses the law does not take effect until the end of the year.

After next January 1st, any person who holds a certificate of registration granted upon examination as an "assistant pharmacist" from any legally constituted board of pharmacy of the State, the same not having been revoked, may apply to the State board, surrendering such certificate, accompanied by a fee of $1 and an affidavit that he or she has had three years' practical experience in the compounding, dispensing, and retailing of drugs, medicines, or poisons, and may be granted a license as a "licensed druggist," entitled to practise outside of New York City.

Any person holding a certificate of registration as a "pharmacist" granted upon examination by any legally constituted board of pharmacy of the State may be granted by the State board a license to practise as a "licensed pharmacist" anywhere within the State, upon the payment of $1 fee. Provision is made for the registration of apprentice pharmacists for a fee of 50 cents.

Otherwise no person shall be granted a license as a "licensed druggist" who has not had three years' practical experience in the business and passed an examination, and the fee is $5. To be licensed as a pharmacist a person must have four years' experience and have passed an examination. The fee is $10.

The bill very properly prohibits the sale of the usual domestic remedies by country stores, and provides that they can be dealt in only by regularly licensed dealers. A provision for the proper labelling of poisons is also incorporated. The State board is empowered to regulate the hours of labor of employees in drug stores and pharmacies in New York City, which shall not exceed one hundred and thirty-six hours in two consecutive weeks.

Another amendment to the public health law provides that the commissioners of quarantine, at the port of New York, shall pay all salaries of persons appointed by them from money appropriated by the State. They shall collect from the owners, agents, or consignees of vessels all bills for the care and maintenance of persons detained in quarantine, and shall have power to enforce such payment by process of law against the vessel upon which such detained persons have arrived, or against the agents, or owners, or consignees of such vessels, and, in case of an emergency arising, the quarantine commissioners shall, upon the certificate of the health officer that such an emergency really exists, use all means conducive to the protection of the public health, except when such emergency calls for the expenditure of money beyond such amount as may be in the hands of the commissioners, when such expenditure may be made only by and with the approval of the attorney-general and controller. The health officer is also directed to inquire relative to the plague and all other infectious diseases on board incoming ships; and he is required to keep the department of health of the city of New York informed of the number of cases of quarantinable diseases and the character of the same held at quarantine, and he may receive any vessel or merchandise sent to him by the health authorities of New York which in his opinion is dangerous to the public health.

The commissioners of statutory revision offered a bill amending, generally, the public health law, but it did not pass; neither did proposed amendments relative to imperfect licenses of physicians and surgeons, and relative to the practice of dentistry.

A charter was granted to the New York State Medical Association for the purpose of the cultivation and advancement of the science of medicine, the promotion of public health, and the establishment of a death benefit fund for the dependents of its members. It may hold property to the amount of $100,000. The incorporators are: D. Ayres, J. C. Bierworth, L. J. Brooks, J. D. Bryant, H. D. Didama, C. E. Denison, E. D. Ferguson, J. M. Farrington, C. E. Fritz, C. H. Glidden, G. W. Goler, J. W. S. Gouley, E. E. Harris, N. H. Henry, J. G. Hunt, F. W. Higgins, W. E. Johnson, E. M. Lyon, E. M. Moore, D. C. Moriarta, M. C. O'Brien, T. D. L. Rochester, B. T. Smelzer, E. H. Squibb, W. H. Thornton, M. W. Townsend, T. A. Wales, and F. W. Wiggin. An unsuccessful attempt was made to exempt from taxation the property of certain medical societies situated in cities of the first class.

A law was passed providing that pharmacists and drug clerks shall not work to exceed one hundred and thirty-six hours in any two weeks; and that an employee shall have at least one full day off in two consecutive weeks. Several amendments to the charter of New York, relative to pharmacists and druggists, were not passed because what they proposed seemed to be covered in the amendment to the public health law, first noted above.

The code of civil procedure was amended so as to include malpractice, along with slander, assault, etc., in the limitation of actions to two years. An unsuccessful attempt was made to amend the same code, relative to disclosures by physicians and surgeons, by making an exception that in any action heretofore or hereafter brought by a person authorized to practise physic or surgery, or by his legal representatives, for the value of any professional services alleged to have been rendered or performed for such patient, the plaintiff in such action or any other physician or surgeon assisting him in the performance of such services may testify concerning the same, so far as may be necessary to prove the performance or the value thereof; provided, that the court in its discretion may exclude any testimony tending to disgrace the patient. The medical profession successfully opposed the bill regulating the practice of midwifery in the city of New York.

A law was passed providing that whenever the board of health in Buffalo shall declare that rabies is prevalent in the city, or in the vicinity thereof, the commissioner of public health shall prepare ordinances prescribing the conditions under which dogs may be kept, brought, or allowed to be within the city, and providing for the destruction of dogs suffering from rabies and to prevent the spread of the disease, with penalties for their violation. An unsuccessful attempt was made to amend the charter of New York City relative to the sale of lymph and antitoxin; also to give the State board of health unlimited power to designate the style of boxes or bottles in which poisons shall be put up; also to repeal the school law relative to instruction in hygiene and narcotics; also to require that no person, association, corporation, or company shall sell, offer for sale, or dispose of within this State any proprietary or patent medicine or tonic, snuff, tobacco, or headache, catarrh, or hay-fever remedy containing cocaine.

A bill for the protection and improvement of the purity of the waters of the State, and conferring additional powers on the State board of health, did not pass; neither did a bill allowing New York City to spend unlimited amounts for the sanitary protection of its water supply.

A law was passed establishing a State hospital, in some suitable location in the Adirondacks, for the treatment of incipient pulmonary tuberculosis. The city of New York was authorized to accept the real and personal property of the Brooklyn Homœopathic Hospital. The authorities of New York City were authorized to change certain leases to the Mt. Sinai Hospital. The city of Buffalo was authorized to issue $50,000 in bonds to erect a quarantine hospital; and Lockport, $5,000 for a city hospital. Bills calling for the establishment of a State hospital for crippled children, and for New York City hospitals for pulmonary tuberculosis and contagious eye diseases, did not pass.

REPORT OF THE ELMIRA STATE REFORMATORY.

The 1899 report of this institution provides much instructive and interesting reading. It appears that the gross number of inmates who had been upon the books from September, 1898, to September, 1899, was 2,035, of which number 556 have been received during that period and 651 discharged, producing a daily average of 1,474.6. No transfers to State prisons have been made, but with the exception of fourteen per cent. who were specially paroled invalids, etc., of the 651 discharged 425 were sent out on regular parole to work at trades taught them at the Reformatory. The health of the inmates is stated by the physician on the whole not to have been so good during the past six years as in the preceding twenty years, but the increase in the death rate is attributed to overcrowding. The remedy for this state of things suggested by the board of management is a reduction of the population to 1,200. A large amount of attention is paid to gymnastic training, including Turkish baths and massage, with, it would appear, most satisfactory results. Personal instruction is also given in elementary physiology and the hygienic care of the body. In the physician's report attention is drawn to the fact that tuberculous disease appears as the largest single cause of admission to the hospital and as the greatest factor of mortality. The reason suggested for the prevalence of this disease is that at the present time the hospital has inadequate accommodations except for those in whom the disease is well marked and progressive, but that an unrecognized case, or a person in the incipient stage, may so infect a cell that it becomes a menace to the health of succeeding occupants. During the period covered by the report forty men were transferred to the Matteawan State Asylum for the Insane, and for the first time since 1894 there were two cases of suicide.

SIR WILLIAM MACCORMAC ON THE SOUTH AFRICAN WAR.

Sir William MacCormac, like Mr. Treves, has been making public the result of his experiences in South Africa. His opinions as to everything connected with the medical arrangements were in a high degree laudatory; he nevertheless permitted himself to criticise, although in words much less pungent than used by his professional brother, the hampering interference of certain ladies ignorant of hospitals and nursing, and whose inexperience rendered their services ineffective for good. Hospital trains were referred to by him in the most favorable manner, and as in some instances they were enabled to go on to the field of battle itself, the fact may be easily understood that by their aid the removal of the wounded to the base hospitals was facilitated to an extent not known in any previous war.

There has been an altogether universal consensus of opinion among surgeons serving in the present campaign with regard to the humaneness of the Mauser and Lee-Metford bullets. Sir William, who has several times drawn attention to this matter in his letters to the London *Lancet*, reverts to the subject at some considerable length in an account published in the New York *Sun* of May 13th, a part of which reads as follows: "Speaking generally he found the wounds inflicted by the Mauser and Lee-Metford to be very similar and both much less fatal than the larger projectiles used in former wars. As many as ninety-six per cent. of the cases in the general base hospitals recovered and were discharged, a very large proportion being able to return to duty at the front." He says: "One finds case after case convalescent after a bullet has traversed the lung and in many cases both lungs. The heart and pericardium have so often been found to lie in the track of the bullet that it seems probable that these, highly vulnerable structures must in several instances have been actually pierced." Sir William expresses himself as by no means in favor of laparotomy, as he feels sure that the mere fact of a Mauser or Lee-Metford rifle bullet traversing the abdomen is of itself no sufficient indication of the necessity for abdominal exploration or operation.

It is satisfactory to notice that notwithstanding the many charges made by both British and Boers as to the alleged use by the former of Dum-dum bullets, and by the latter of explosive or soft-nosed bullets, Sir William declares that he never came across a wound caused by a Dum-dum bullet, and tha the saw no evidence of the use of explosive bullets, although it was reported on good authority that some of the wounds had been caused by them. With respect to inoculation against enteric fever, which was largely practised by British troops before proceeding to South Africa, the distinguished surgeon says: "No decided opinion can yet be given on this point, since there are not sufficient data for statistics. The observations made seem to show that those inoculated are less apt to take the disease, or if they are attacked they have it in a milder form; but the question is still *sub judice*." Whether the lyddite shells were so destructive to life as the British assert, or whether they were, in accordance with the testimony of the Boers, comparatively innocuous, is a point that has not been made clear. At any rate it has been conclusively shown in our war with Spain, and on a larger scale in the South African campaign, that even within the past twenty years the conditions of warfare have greatly changed for the better, and indeed that, contrary to general prognostications, modern weapons have been mainly responsible for this state of things.

News of the Week.

A Correction. — Dr. Paul F. Mundé writes: "Permit me to correct an error in the discussion on fecal fistula at the last meeting of the American Gynecological Society, published in the Medical Record of May 19th. Your reporter makes me say that I 'agree with Dr. Currier that it was well to wait in fistula of the *small* intestine; but with fistula of the *large* bowel the abdomen should be opened.' (Italics are mine.) Now, I said exactly the opposite, for in my experience fistulæ of the large intestine, especially when near or in the pelvic cavity, show a great disposition to contract and in time heal spontaneously; whereas fistulæ of the small bowel usually require operation, either. if small, by trimming and uniting the edges and adjacent peritoneal coat, or, if large, by free opening of the abdomen and enterorrhaphy or Murphy button. The point is of sufficient practical importance to warrant my wishing to be correctly reported in the matter. I may add that this tendency to spontaneous closure of fistulæ of the large intestine was first impressed on me by three cases of gunshot wound of the ascending and descending colon and of the upper pelvic part of the rectum which I saw in the Austro-Prussian war of 1866, and which I described in a letter to the *Boston Medical and Surgical Journal*, January, 1867, under the title of 'Gunshot Wounds of the Pelvic Viscera.'"

Post-Graduate Medical School.—Dr. Charles Warrenne Allen has been elected adjunct professor of skin diseases.

Philadelphia Polyclinic.—Dr. James Thorington has been elected to a new chair of diseases of the eye, created by the trustees.

Gloucester County (N. J.) Medical Society.—At a meeting held at Woodbury on May 17th Dr. Judson Daland, of Philadelphia, read a paper on "Aneurism," and Dr. G. Betton Massey one on "Mercurial Cataphoresis."

The New York Eye and Ear Hospital.—A two-story addition to the New York Eye and Ear Hospital will soon be erected on the lot 311 East Thirteenth Street, in the rear of the present buildings of that institution at the northeast corner of Second Avenue and Thirteenth Street.

College of Physicians of Philadelphia.—At a stated meeting of the section on general medicine, held May 14th, Dr. F. Savary Pearce exhibited a case of hysterical monoplegia cured by suggestion. The patient was a colored woman who presented at first paralysis upon one side of the body, with improvement in the condition in the lower extremity, while that in the upper disappeared in the sequence of hypnotic suggestion and applications of static electricity. A similar attack had occurred on a previous occasion. Dr. William G. Spiller exhibited a case of unilateral progressive ascending paralysis, with exaggerated scapulo-humeral reflex (v. Bechterew), occurring in a man who presented symptoms of spastic hemiparesis, with fibrillary tremor, of several years' development. Dr. Spiller exhibited also a case of pseudo-rhizomelic spondylosis, occurring in a man in whom the apparent rigidity of the spine was due to muscular pain. He exhibited further a man who presented brachial palsy following a fracture of the arm, together with atrophy of the thenar eminence and the interossei muscles, the latter being found on careful inquiry to have been an antecedent condition and not related to the accident. Dr. A. A. Eshner presented a communication upon "Angina Pectoris," in which he deprecated the use of the terms true and false, preferring rather those of mild and severe, contending that the two sets of cases are essentially of the same nature, though differing in degree, both clinically and pathologically. He reported a case in a man thirty years old, in which typical paroxysms of angina pectoris occurred in the absence of demonstrable organic disease related to the heart. Dr. M. H. Fussell exhibited a case of myxœdema with complications. The patient was a boy eighteen years old, exhibiting marked dementia of gradual development, together with excessive accumulations of fat upon the abdominal wall, and to whom thyroid extract had been assiduously administered in large doses without noteworthy therapeutic effect. Doubt was expressed as to the exact nature of the disease, the symptoms of which did not wholly conform with those of myxœdema. Dr. Walter I. Pennock read a paper entitled "An Unusual Influence of Strychnine in Diseases of the Kidneys," reporting two cases in which the administration of strychnine in full doses induced symptoms closely simulating those of uræmia.

The Cholera is spreading rapidly in India. A despatch to a London paper from Hyderabad says that in one division no fewer than forty-five famine camps have been attacked by the pestilence. The most virulent type is at Gujerat, where many thousands have perished. In the Godhra camp alone there have been thousands of victims. An appalling loss of life seems inevitable.

A Man with a Quiver Full.—A French Canadian living in a Rhode Island town was recently presented by his third wife with his forty-first child. His first wife gave birth to several pairs of twins, and his second presented him with three sets of triplets. Thirty-six of the children are living and many of them have families of their own. Eight of the grandchildren also are parents.

China a Field for Women Physicians.—At the graduating exercises of the Woman's Medical College of Pennsylvania, the Chinese minister, Wu Ting Fang, delivered an address to the graduates in which he advised them to seek their fortunes in China. In that country, he said, there are about two hundred million women, but the number of woman physicians is very small. Midwives there are, but few or no women with medical knowledge and training, and the speaker said he was sure women doctors would receive a welcome and good treatment in China. Twenty-six women received diplomas.

Bureau of Information for the Members of the American Medical Association Passing through Philadelphia.—The directors of the Philadelphia County Medical Society will establish a bureau of information for the benefit of physicians on the way to Atlantic City, at the College of Physicians of Philadelphia, northeast corner of Thirteenth and Locust streets. This bureau will be open from 10 A.M. until 5 P.M. daily except Sunday, from Monday, June 4th, to Monday, June 11th. Physicians are invited to make free use of the bureau, where they may obtain full information relative to the situation of the various hospitals, medical colleges, and other scientific institutions of Philadelphia, and the time of operations and clinics at the different hospitals throughout the city.

Testimonial to Dr. Jacobi.—On Wednesday of last week the Woman's Health Protective Association of New York presented to Dr. A. Jacobi a set of resolutions of esteem and congratulations on the recent celebration of his seventieth birthday. After the congratulations and wishes for many more years of usefulness and honor, the resolutions spoke of Dr. Jacobi's wise counsel to the association, and aid in enforcing the health laws of the city, and also of his services as a public benefactor, and his devotion to children. The resolutions were handsomely bound in pamphlet form, and were presented with an appropriate address by Mrs. Esther Herman, vice-president of the association.

The New York Polyclinic.—Drs. Francis J. Quinlan and R. C. Myles have been elected professors of laryngology and rhinology in this school.

The New York County Medical Association has become a part of the New York State Medical Association under the new charter of the State society.

A New Investigation of Yellow Fever.—The Liverpool School of Tropical Medicine is soon to send a commission to Brazil to study yellow fever.

A Large Dose of Electricity.—An electrician in Mount Vernon, N. Y., recently received a discharge of 1,040 volts, and though badly burned and made insensible was not otherwise seriously injured.

Trinity Hospital, Varick street, was closed Tuesday for the first time since its foundation, twenty-seven years ago. It will reopen October 15th, after extensive alterations, in charge of trained nurses, instead of the Anglican Sisters of St. Mary, headed by Sister Eleanor, who has been in charge of it since its inception.

St. John's Hospital, Brooklyn, will, it is said, soon be taken from the list of city hospitals and become a private institution to be under control of the Episcopal Church Charity Foundation. The reason for this change is said to be that Comptroller Coler's recent cutting down of appropriations to institutions of the sort has greatly impaired the working efficiency of the hospital.

Formalin as a Milk Preservative.—It is reported from Chicago that the health department of that city has decided that the use of formalin as a preservative of milk must be stopped. Experiments have been made proving to the satisfaction of the health officers that formalin is poisonous. Kittens fed on milk preserved with this substance died in a few days, while other kittens from the same litter fed on ordinary fresh milk grew plump and fat. Guinea-pigs were also experimented on with the same result.

The Section on Materia Medica of the American Medical Association.—The troubles of the American Medical Association are perennial. For years the annual quarrel surged around the permanent secretary, and now, no sooner has the permanent secretary been unseated and removed from the scene of conflict, than clouds gather round the section on materia medica. The American drug manufacturers are alarmed by a report that the section is to be captured by members of the American Medical Association who are on the side of German chemical houses, and who will turn the work of the section into an advertising bureau for foreign drugs. The medical press is urged to raise its voice to thwart this nefarious scheme. But surely this alarm must be without foundation in fact. The American firms seem to have forgotten that every member of the American Medical Association is an avowed upholder of the code of ethics, and no one whose life is regulated by this moral law could descend so far as to bamboozle his fellows in this unprincipled manner.

Yellow Fever is reported epidemic in San Salvador, the capital of the Central American republic of Salvador. In a communication from the United States consul there, dated April 11th, it is stated that eighteen cases were in the pest-house and twenty known cases were being treated in their homes. The mortality had been very considerable and many persons were leaving the city on account of the disease, which had appeared at a much earlier period than usual. No foreigner had so far been attacked, the disease being confined to natives of Central America.

The Plague is reported to have spread to nearly every seaport town in Australia and to have invaded many places in the interior. In Sydney there have been one hundred and forty-two cases and forty-nine deaths up to April 25th.—The board of health of San Francisco has adopted a resolution declaring that the plague exists in that city. Surgeon-General Wyman of the Marine-Hospital service states that March 8th Surgeon Kinyoun reported that a suspicious case had been fatal in Chinatown, and on March 11th he found the plague bacillus. On April 27th another case occurred, verified by bacteriological examination and so reported on May 2d. On May 13th there were two cases from plague. On May 16th another case was reported. There have been six cases, and so far as known the disease has appeared only among the Chinese. Four marine-hospital surgeons, in addition to those already there, have been ordered to San Francisco. A large supply of Haffkine's serum has been sent, and an endeavor will be made to vaccinate all the Chinese in the city. The timid health officials of Texas have taken alarm and have declared a rigid quarantine against freight and passengers from San Francisco.—It is reported from Tokio that Kitasato has discovered a second plague bacillus which is thought to explain the fact that the Yersin serum has had such different effects in different cases. Kitasato is preparing a new serum from which he hopes to obtain more satisfactory results.

Home of the Kings County Medical Society.—On Saturday last the new library building of the Medical Society of the County of Kings, on Bedford Avenue, Brooklyn, was dedicated in the presence of many of the members of the society and guests from other cities. The building, of colonial design, is fifty-nine by eighty-five feet, three stories in height, and fireproof in construction. Entering the building, one steps into a foyer from which three doorways lead into the main auditorium, which will seat about four hundred. Opening from the foyer are a reception room, a women's room, and a cloakroom. The library is on the second floor and the third story is devoted to the apartments for the librarian and custodian of the building, storage rooms, and two large section rooms, which may be used separately or in conjunction. Dr. Lewis S. Pilcher, president of the society, presided. After a prayer by the Rev. Dr. A. J. Lyman, addresses were made by Drs. G. M. Gould, James R. Chadwick, and A. Jacobi. Dr. William Maddren, chairman of the building committee, transferred the building to the trustees, and the building was then accepted with brief remarks by Dr. Frank E. West, chairman of the board of trustees, and Dr. Pilcher in behalf of the society. After a benediction by the Rev. John P. Chidwick, United States navy, there was a reception to the women present from 5 to 6 P.M. In the evening a dinner in honor of the occasion and for the entertainment of the invited guests was held at the Farmhouse, Prospect Park. Dr. Pilcher was toastmaster, and among the speakers were the Rev. A. J. Lyman and Drs. Abraham Jacobi, William Browning, Fairbairn, McLean, and J. H. Hunt.

Navy Department, Bureau of Medicine of Surgery, Washington, D. C., May 12, 1900.—Changes in the medical corps of the United States navy for the week ending May 19, 1900. May 17th (changes by cable from Asiatic station).—Assistant Surgeon J. C. Thompson detached from the *Bennington* and ordered to naval hospital, Mare Island, Cal., for treatment. Assistant Surgeon E. O. Huntington detached from the *Newark* and ordered to the *Bennington*.

The New Hampshire Medical Society.—The one hundred and ninth annual meeting of this society will be held on Thursday and Friday, May 31st and June 1st, at Concord, under the presidency of Dr. Charles R. Walker, of Concord. The secretary is Dr. Granville P. Conn, of Concord. The annual meeting of the alumni of Dartmouth Medical College will be held on May 31st, and the first annual meeting of the New Hampshire Association of Military Surgeons will also be held on the same day.

A School of Instruction for Health Officers.—The second annual school of instruction for health officers, conducted by the Vermont State board of health, was held on Tuesday, Wednesday, and Thursday of this week in Burlington. The object of the annual sessions of this school of instruction is to have a conference and discussion between the officers of health of the State as to the latest and most efficient means at command for preserving the health of the citizen and of communities, and it is believed that this is the most practical way of accomplishing the purpose.

Prof. Wilhelm Conrad Roentgen will be awarded the Barnard medal, in commemoration of his discovery of the *x*-rays, at the commencement of Columbia University on June 13th. The award will be made on the recommendation of the National Academy of Sciences. The medal is of gold and was established by the provisions of the will of former President A. P. Barnard, of Columbia University, and endowed by him. It is awarded every five years "to such person, if any, whether a citizen of the United States or any other country, as shall within the five years next preceding have made such discovery in physical or astronomical science to purposes beneficial to the human race, as in the judgment of the National Academy of Sciences of the United States shall be esteemed most worthy of such honor." The award of 1895, which was the first, was made jointly to Lord Rayleigh and Prof. William Ramsay.

Acting Assistant Surgeons in the Army.—A bill is before Congress granting to all acting assistant surgeons of the army of the United States the same rights and privileges as regards leaves of absence, quarters, and commutation, and all other rights, privileges, allowances, and emoluments (except pay, which shall be, except as otherwise stipulated, at the rate of $150 per month) as commissioned officers of the army of the grade of first lieutenant, mounted. The bill provides also for back pay, rank, etc., for acting assistant surgeons who served during the Spanish war and who were dropped for illness or disability, and also enacts that those who have served for one year or more shall be commissioned assistant surgeons of volunteers with the rank of first lieutenant, mounted, subject to honorable discharge whenever their services are no longer needed.

Obituary Notes.—DR. WILLIAM R. RAMSEY died at Norristown, Pa., on May 13th, from some disease of the throat, at the age of sixty-eight years. He was a student and subsequently an assistant of the late Dr. William Corson. He was assistant surgeon in the United States army during the Civil War, and was in charge of the field hospital at the battle of Gettysburg. Subsequently he practised medicine at Hazleton and Norristown.

DR. COLEMAN F. LEAMING died at Cape May Court House, N. J., on May 13th, at the age of eighty-two years. Early in life he engaged in mercantile pursuits, but at the age of twenty-one he began the study of medicine and was graduated after three years, settling in New York and practising there for some time. Later he returned to his native place, where he acquired a fortune from business enterprises.

DR. CHARLES S. COLLINS, of this city, died on May 20th from the effects of an overdose of chloral. He was a graduate of the College of Physicians and Surgeons in 1884.

DR. SHERRARD R. TABB, of the United States Marine-Hospital service, stationed in Savannah, disappeared on April 30th, and his body was found on May 10th in a dense thicket near the Bonaventure cemetery. He had committed suicide by means of chloroform. He was born in Virginia in 1869 and was a graduate of the medical department of the University of Virginia in the class of 1892.

The Frequency of Goitre at Different Ages.—Lucien Mayet presents the results of the tabulation of over thirteen thousand cases of goitre, occurring in those parts of France where the affection is endemic, with a view especially to determine the age at which the disease is most frequently encountered. This age was found to be, for both sexes together, between forty-six and fifty years. In men the greatest number was in those from twenty-one to twenty-five years, and in women between the ages of forty-six and fifty.—*Lyon Médical*, April 15, 1900.

Progress of Medical Science.

Journal of the American Medical Ass'n, May 19, 1900.

A Case of Hysterical Hip-Joint.—J. L. Porter reports a case of this nature occurring in a girl aged eleven years, who stood with the right thigh flexed and rotated outward and only the toes touching the floor. In walking, the same position was maintained, the weight being carried on the toes, but the flexion increased each time the weight was borne by the right leg. On inspection the affected hip and leg seemed perfectly normal, there being no swelling. The length of the two legs was the same, but the circumference of the right thigh was one-half inch greater than that of the left one. The latter was easily flexed, rotated, and put through the normal motions, but as soon as any motion was attempted in the affected leg a resistance was felt. If the leg was forcibly flexed and suddenly released, it assumed extension without any evidence of pain. If the forcible flexion was continued until all resistance was overcome, the thigh went up into normal flexion on the trunk and could be rotated freely. Though she covered her face with her arms and cried a little, she did not shed tears or give indications of pain. The thigh was forcibly flexed on the pelvis several times, and if flexion was maintained until she found that resistance was useless, it ceased. No acute symptoms whatever followed the forcible manipulations. The foregoing examination, together with the absence of any objective indication of intra- or para-articular disease, such as swelling, thickening of the tissues, or local elevation of temperature, gave the findings on which a diagnosis of hysterical hip-joint was made.

Vesico-Rectal Anastomosis, with Special Reference to the Treatment of Exstrophy of the Bladder.—J. Frank believes that from the careful histological and bacteriological examination which was conducted in a number of the cases experimentally operated on by him, it appears beyond a doubt that vesico-rectal anastomosis may be performed on a dog without leading to an infection of the kidneys. In two instances both the histological and bacteriological examinations showed a total absence of infection, and one of these cases was that of a dog killed six months after the operation. If the results on dogs, which naturally cannot be kept under the best hygienic conditions and in which no after-treatment could be instituted, furnished results like the above, it is not unreasonable to expect far better terminations in the human patient when after-treatment such as washing out the bladder could be commanded. The advantages of vesico-rectal anastomosis may be summarized as follows: (1) Simplicity and shortness of time required for the operation; (2) no danger of ureteral constriction by the bowel scar, nor sloughing of an implanted trigone, as in Maydl's operation; (3) comparatively little danger of infection; (4) it is applicable not only in exstrophy of the bladder but also in other pathological conditions of that organ rendering life a burden.

Use of Opium in Infancy, seen in Adult Life.—T. D. Crothers states that the use of opium and its alkaloids in infancy creates a diathesis or predisposition to its use in later life. Acting as they do on the most unstable organisms, the brain cells and centres, they not only retard but prevent healthy physiological growth. Another point which must be remembered is the concealed danger from opium drugging in infancy. If only neurosis is present, if defects of growth and function exist, opium will of necessity increase this condition. Anæmia, exhaustion, and perversion of organic activity follow. If some temporary state is present, opium, by covering up the pain signal, is not curative but may be destructive in many ways not easily recognized until later in life. No one can tell whether this danger begins with the first dose or only after a succession of doses.

Antitoxin and Intubation, with a Report of One Hundred Cases.—B. R. Shurly gives the following summary of results: number of operations, 100; recoveries, 69; deaths, 31; mortality under three years, 49 per cent.; mortality over three years, 19 per cent.; complicating measles, 8 cases, 5 deaths. Age of patients operated on: One to two years, 16, of whom 9 recovered, 56.25 per cent.; two to three years, 23, with 11 recoveries, 47 per cent.; three to four years, 20, of whom 16 recovered, 80 per cent.; four to five years, 15, of whom 12 recovered, 80 per cent.; five to six years, 11, with 10 recoveries, 90.9 per cent.; six to eight years, 10, of whom 7 recovered, 70 per cent.; eight to twelve years, 5, of whom 4 recovered, 80 per cent.; number of doses of antitoxin, 160. Eighty-five per cent. of the cases occurred on streets that were not paved.

Eustachian Catheterization.—S. O. Richey makes a plea for the greater use of the Eustachian catheter, claiming that it is far superior in its action to either politzerization or the method of Valsalva. An astringent or antiseptic solution may be blown through it into the tube, later into the cavity. It dilutes the secretion it reaches, destroys germs more or less, and its astringency increases the calibre of the tube, acting antiphlogistically. Secretions can also be withdrawn from the tube by suction. The two methods above alluded to are in the opinion of the writer a frequent cause of extension of inflammation from the middle ear to the mastoid antrum. For the catheter, the small hand-bulb of the atomizer is preferable to the large, unwieldy Politzer bag.

Abdominal Surgery; Five Interesting Cases—Pancreatic Cyst, Hepatic Calculi, Fecal Fistula, Combined Appendectomy and Nephrorrhaphy.—By F. W. McCrae.

Cleft Palate; A New Urano-Staphylorrhapy.—By A. H. Ferguson.

Bubonic Plague in San Francisco. By W. H. Kellogg.

Philadelphia Medical Journal, May 19, 1900.

Common Colds; their Cause, Prevention, and Treatment.—D. H. Bergey finds absolute immunity from colds quite rare. Specific micro-organisms have not been demonstrated, hence it is probable that micro-organisms commonly found are the cause, anatomical differences in tissue giving the various inflammations encountered. Constitutional conditions render one portion more vulnerable than another and act in influencing location. Constitutional symptoms indicate that large quantities of the poisons generated *in loco* are absorbed into the circulation. One person in a family may infect the whole household, and a subject of chronic catarrh must be looked upon as a source of danger, and as such should be excluded from public schools. Mouth washes are discussed and therapy is suggested.

Rupture of the Plantaris Muscle.—John H. Gibbon reports the case of a man aged thirty-eight years who while playing tennis was suddenly seized with a sharp pain in the calf. As soon as the diagnosis was made, a firm bandage was applied from the toes to the knee. In a month the function was re-established. The writer suspects, in severe cases, a laceration of the deeper calf-muscles.

A Case of Chronic Pneumonia.—M. S. Councill reports a case of unusual persistence, extending over a period of about twelve months in a child of two years. Tuberculosis was excluded. The writer thinks such cases will be found to be more frequent when all means of diagnosis are brought to bear upon them.

Mütter Lectures of the College of Physicians of Philadelphia.—By J. B. Roberts.

Intestinal Indigestion and its Consequences.—By W. H. Porter.

Gastric Analysis.—By A. P. Francine.

New York Medical Journal, May 19, 1900.

The Genesis of Antitoxins.—J. D. Lisle states that antitoxins are the result of cell stimulation. The question is, How does the cell produce the antitoxin?—admitting, for the time, that the antitoxin is the product of the cell. If a cell, when properly stimulated, will produce an antitoxin, the question naturally arises, How or what is the process? A cell receives a stimulus; now, what does the cell do? According to the theory of Ehrlich, the protoplasm of each living cell is divided into a number of groups, and each group is susceptible to a different stimulus. Among these groups there is one or more which, when stimulated by a toxin, begins an internal molecular change that results in the production of the antitoxin. If the impression of the stimulus upon the cell is only slight, the effect is only molecular rearrangement and nothing is excreted; this is called vaccination, and accounts for cellular resistance; but if the stimulus is increased or is caused by another class of toxins, the process of molecular change goes on, and an antitoxin is poured into the circulation as fast as it is made. Ehrlich has given to these groups of hypothetical elements the name of "side chain," a term borrowed from modern organic chemistry, and which contributes nothing toward solving the mystery of the function of the cell in its production of the antitoxin.

Trachoma.—N. B. Jenkins gives a general description of this affection. In speaking of treatment he says that perfect rest will usually give relief to trachomatous eyes. This may be had by instillations of atropine, together with protection of both eyes from light and use by bandages, cataract shields, etc., put on as after a major operation on the eyeball. Before bandaging, a weak iodoform ointment may be put in the eyes and on the lids. At night these blinds are removed and the patient is kept in an absolutely dark room. No ray of light should enter the eyes. Uncomplicated trachoma may, in time, be cured by this treatment. Proper glasses, in the writer's limited observation, cure simple trachoma without other treatment, but if there is much organic destruction, of course they can have little if any curative effect.

Cystitis.—H. H. Morton concludes a lengthy article with observations on treatment. For acute cystitis, he believes that the only application which can be used without harm is nitrate of silver beginning with four grains to the ounce, twenty drops of this solution being deposited every second or third day in the posterior urethra, from which point it flows back into the bladder. The indication for its use is painful and frequent micturition, provided the bladder is capable of emptying itself. For chronic cystitis, the indications to be met are: (1) To remove any source of local irritation within the bladder or any obstacle to its evacuation; (2) to remove the urine from the bladder and keep it empty; (3) to destroy micro-organisms or check their growth, and remove pus and fermentation products from the bladder.

Study of the Blood in Cancer of the Stomach.—W. Osler and T. McCrae come to the following conclusions: (1) In a doubtful case a blood count below 1,000,000 red blood corpuscles is strongly in favor of pernicious anæmia. (2) While nucleated red blood corpuscles are present in all very severe anæmias, megaloblasts rarely if ever occur in cancer of the stomach. (3) Neither an increase in the leucocytes nor special variations in the forms appear to be of any moment in the diagnosis of cancer of the stomach. (4) The presence or absence of digestion leucocytosis is too uncertain to be of much assistance in diagnosis.

"Æstivo-Autumnal Fever" in New Orleans, Summer and Autumn, 1899.—By H. A. Veazie.

Physical Training in School and Home.—By H. S. Pettit.

Medical News, May 19, 1900.

The Status of Gynæcology in 1876 and 1900.—Alexander J. C. Skene says that in 1876 gynæcology may be said to have graduated with honors and to have taken a well-merited position among the grand divisions of the profession. The author describes the condition of knowledge at that time, in respect to various uterine diseases. There were few actual specialists or experts in the branch. There were only three journals and one society exclusively gynæcological in 1876; now they exist in every town, and the books have multiplied from three hundred to one thousand. All that was obscure then in regard to inflammation of the uterus twenty-five years ago has now been cleared away; equally strong lines and high light may be used in sketching the present status of uterine displacements. There has been extraordinary advancement in the knowledge of neoplasms, great improvement in ovariotomy, and knowledge of diseases of the urinary organs. Many other advances are mentioned by the author, but are too numerous to find place in an abstract.

The Treatment of Suppurative Otitis Media in Young Children.—George L. Richards, in chronic cases, syringes the ear with warm sterile water or with a solution of bichloride 1:1,000, dries the canal, and inspects the ear. If there is much destruction of the tympanic membrane he applies peroxide of hydrogen on a cotton pledget, as long as there is any exudation of gas, and after again drying the parts applies on a cotton pledget a saturated solution of boracic acid in from forty to ninety per cent. alcohol. He then dusts the ear lightly with powdered boracic acid, and lightly stops the ear with a narrow wick of antiseptic gauze which must reach the bottom of the canal. Careful instruction is given the mother as to home treatment.

Fibroid Tumor of Uterus; Enteroptosis; Retroversion; Ruptured Perineum; Operations; Recovery.—By Matthew D. Mann.

The Pharmacopœia of 1900.—By Horatio C. Wood.

Boston Medical and Surgical Journal, May 17, 1900.

A Case of Pernicious Vomiting of Pregnancy.—E. L. Twombly reports a fatal case which illustrates that displacements and faulty positions of the pregnant uterus which delay its rising out of the pelvic cavity and press upon the cervix are more often the causes of excessive vomiting than has been generally supposed. If all measures of replacement of the uterus and correction of the faulty position fail in the early months of pregnancy, we should not trust to nature and time to effect a cure, but should proceed to empty the uterus by surgical means. Indication for emptying the uterus are: (1) Inability to retain any food taken by the mouth; (2) intolerance of rectal enemata; (3) more or less albuminuria; (4) progressive emaciation; (5) constant headache; (6) frequent and feeble pulse; (7) a certain apathy on the part of the patient.

Bicornate Uterus with Twin Pregnancy; Abortion from One Horn.—Charles H. Winn reports a case in which the salient features are: (1) An abortion with twins some years ago, in which one fœtus was macerated and the other not. (2) A second twin pregnancy, both horns being occupied. Abortion of one fœtus was complete, as shown by foul, decomposing tissue removed by a vigorous curetting, and the immediate relief of septic conditions which followed. (3) The demonstration of the bicornate condition by the facts mentioned, and by the finding of a contracted horn on the left side of the pregnant uterus. (4) The probability of superfœtation. (5) The tolerance of the pregnant uterus to adverse influences is shown by the persistence of pregnancy, in spite of catheters, abortion, sepsis, curetting, intra-uterine douches, and iodoform gauze intra-uterine packing.

A Study of the Nature and Significance of the Symptoms in Disorders of the Stomach.—Henry F. Hewes states that the results of his investigations have been (1) to show that there are certain symptoms which are common to all affections of the stomach, and that they frequently form the whole symptomatology of cases with distinctly opposite causes, as in cases of hyperacidity and hypoacidity; (2) to show what symptoms are the manifestation of this habit. The author considers the habit as the manifestation of the organ working to perform its function under untoward conditions. Hyperæsthesia of the stomach would explain the functional cases to some extent, but it does not explain the hypoacidity cases.

A Case of Pernicious Vomiting of Pregnancy.—H. S. Knight reports a case in which vomiting was so excessive and so continuous that it seemed as if the end must be fatal. The vomiting was found to be due to anteflexion of the neck of the uterus. Packing the vagina and the use of the ball pessary were not entirely satisfactory, but the insertion of a small soft-rubber pessary, which raised the uterus and also gave an opportunity for the cervix to straighten itself, was followed by the best results. There was gradual cessation of the vomiting, with return of sleep. The patient is now on a generous diet, and everything promises well.

The Question of Supernumerary Fallopian Tubes; with Specimens of Fallopian Tubes with Supernumerary Ostia.—By Agnes C. Vietor.

The Ideal Ration for an Army in the Tropics.—By Edward L. Munson.

Berliner klinische Wochenschrift, April 30, 1900.

The Struggle against Tuberculosis as a Universal Disease.—W. Winternitz makes a plea for the systematic use of hydrotherapy in the treatment of tuberculosis. He finds as the great characteristics of this disease a weakening of the circulation and a condition of anæmia. He claims for this mode of therapy that it strengthens the heart action, increases vascular and tissue tone, and calls forth an active or collateral hyperæmia in the affected organ, re-establishes the normal relations in and about the organs involved, and strengthens the entire organism, especially innervation and circulation. Hæmoptysis, hectic fever, and night sweats are all benefited. The remainder of the article is devoted to an explanation of methods of application.

What Chances Have We to Eradicate Infectious Diseases, Especially Tuberculosis?—D. Dönitz traces the various steps which have led up to our present knowledge concerning immunity and the preparation of the various therapeutic serums. He finds great encouragement in the progress made, and believes that we shall some day succeed in obtaining an antitoxin which will combat tuberculous ravages. He calls attention to the fact that it has been found that under some circumstances it is possible to use the serum of an immunized animal or human being for purposes of further immunization in others.

The Occurrence of Peculiar Crystals in the Bones of Rachitic Children Treated with Suprarenal Substance.—By Stoeltzner and Salge.

Observations on the Demonstration by the Roentgen Rays of Bone Structure.—By J. Wolff.

French Journals.

Post-partum Hemorrhages Cured by Simple Drainage and followed by a Psychosis.—C. Zalackás says we can admit a post-puerperal psychosis; that the psychoses following gynaecological operations are very exceptional, and when they exist we usually have to do with women predisposed or already affected with insanity. There is no connection between the psychoses and the operative procedure. Psychic troubles can be produced as well after any other operation as after ovarian castration. The operation never of itself produces madness. There exists a psychic state before operation, called phobia, which may persist after the operation. In psychoses at precocious menopause a certain predisposition is at work. The fear of mental perturbation should not deter one from operating when the indications are clearly present.—*Le Progrès Médical*, May 5, 1900.

Infantile Typhoid Fever of the Exanthematic Forms.—E. Weill and Ch. Lesieur report upon a remarkable frequency of typhoid in children presenting an abundance of rosy spots. They find that classic cases with few spots have marked or intense intestinal symptoms, and that the prognosis is often grave. Slight fever with few spots and intestinal symptoms slightly marked has a good prognosis. Intense fever with abundant spots and marked intestinal symptoms has a very grave prognosis. Purely exanthematic typhoid, such as exemplified in the cases now studied, with very abundant rosy spots, intestinal symptoms slight or almost nil, has an extremely benign prognosis.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, May 6, 1900.

Bathing in the Typhoid Fever of Childhood.—E. Ausset finds a series of cases in children more severe than the adult form. He never finds at autopsy in an infant typhoid which has escaped recognition during life. In forty-five cases there were four before the fifth year, twenty-nine between five and twelve years, and twelve between the twelfth and fifteenth years, with two deaths in each series. The author believes in systematic bathing from the very onset. The temperature should be regulated for each case. The younger the child the less cold is the bath. It is unnecessary to give baths as cold as the pure Brand method calls for.—*Journal de Medecine de Paris*, May 6, 1900.

Note on Two Cases of Cutaneous Manifestations in the Course of Infectious Diseases of the Digestive Tube.—P. Engelbach found in the recent epidemic of typhoid fever at Havre that severe eruptive phenomena were frequent. He cites an instance of scarlatiniform generalized eruption in typhoid with cardiac complications followed by death, and a case of enteritis with similar eruption and death in the course of convalescence. He does not look upon the erythema as belonging to the typhoid process, but as a secondary infection.—*La Revue Médicale de Normandie*, May 10, 1900.

The Permanent Sound in the Treatment of Urinary Infection.—Félix Guyon discusses, with temperature chart illustrations, the use of the catheter *à demeure* in prostatic and urethral hemorrhages attended with infection. It constitutes the method of choice of bladder drainage in febrile cases. In a study of fifty cases we find forty-two cases and eight deaths or twenty per cent. mortality. The decline of fever is, as a rule, rapid. The instrument must be carefully managed and watched to get the best results, but this is not a contraindication to its employment.—*La Presse Médicale*, May 5, 1900.

The Treatment of Large Rectal or Ano-Rectal Prolapse by Excision of the Rectal Mucous Membrane.—Professor Delorme concludes that ablation of the rectal mucous membrane, reserved hitherto for the treatment of prolapse purely mucous, is equally applicable to prolapse of the second group, in which all the tunics of the intestine participate in the rectal protrusion, whether or not there be invagination.—*Le Bulletin Médical*, May 9, 1900.

The Practitioner, May, 1900.

The Distinguishing Features of Rheumatoid Arthritis, Gout, and Rheumatism.—Arthur P. Luff believes many cases of rheumatoid arthritis are diagnosed as rheumatism or gout. Chronic rheumatism of the joints is a comparatively rare affection. It may not manifest itself as an arthritis at all. A rough clinical test is to ascertain the effect of treatment with salicylate of sodium. By rheumatoid arthritis the writer means the same as arthritis deformans or polyarthritis deformans, or rheumatic gout. The latter term is confusing. It occurs most often in females, while gout occurs mostly in males. It occurs among the poor and ill nourished. There is little pain at first, but some aching in the joint, and the onset is very insidious. He accepts neither the uric-acid nor the lactic-acid theory. In a great number of cases it is an infective disease, due to a settlement of micro-organisms in the affected joints, in which they produce a toxin, which passing into the circulation is responsible for the nervous symptoms. In children it is often secondary to scarlatina, rheumatic fever, and acute septic tonsillitis. In adults it also follows ulcerative disease of the tonsils or of the gastro-intestinal tract. Rheumatism certainly predisposes to rheumatoid arthritis.

Some Clinical Varieties of Osteo-Arthritis.—A. E. Garrod finds it an open question whether we have here a single morbid process. In young patients a rapid course may cause widespread deformity. In older subjects the progress is much more gradual. The more acute cases of early life may be further subdivided into the fusiform and crippling varieties, the former being the more common. The vertebral column is usually involved early, and stiffness of the neck is a common symptom. The crippling variety is usually met with in early adult life and shows little tendency to be restrained by treatment. In nodular cases no marked degree of repair is possible. The fusiform variety is beneficially influenced by attention to certain points: perseverance in treatment; rigid dietary is injurious; drug medication should be tonic, and not depressant. Mineral baths often prove most helpful.

Osteo-Arthritis or Rheumatoid Arthritis; its Pathology and Treatment.—G. A. Bannatyne thinks more care should be exercised in differentiation. There are three types: (1) An acute polyarticular disease; (2) a chronic polyarticular disease of primary and secondary forms; (3) a monarticular disease. These are not all one disease. There is no connection between the acute polyarticular and the monarticular affection, or between the latter and the chronic polyarticular condition. The conditions under which the different forms occur are treated at length. The pathology is entered into, and treatment appropriate to the various conditions is laid down, with indications for baths, etc.

Mechanical and Traumatic Arthritis.—W. A. Lane employs the term mechanical or traumatic arthritis to cover all the pathological changes known as rheumatoid arthritis. True rheumatoid arthritis resembles in no manner the pathological condition to which the same term is still almost universally applied. A series of excellent drawings shows modifications of bone at joint regions due to occupation, injury, etc.

The Varied Forms of Osteo-Arthritis, with Illustrative Cases.—By William Armstrong.

The Treatment of Osteo-Arthritis at Aix-les-Bains.—By H. Forestier.

Archives of Otology, vol. xxix., No. 1, 1900.

Suppurative Disease of the Temporal Bone.—S. M. Burnett reports a series of cases, the paper being of special interest from what the author observes concerning diseases of the temporal bone in the negro. He had previously stated his belief that the affection of the middle ear, known as sclerosis or dry catarrh, was much less common among the negroes than among the whites. This referred particularly to the adult. Furthermore, his added experience has shown him that suppurative diseases of the temporal bone are also very uncommon among negro adults. He has never seen a case of mastoiditis in an adult negro. This is by no means the case, however, with the negro in infancy and childhood. Negro children are very subject to diseases of the bones, particularly in the form usually called "tuberculous." Not only this, but suppurative disease of the bones when once established is very difficult to eradicate, and relapses are frequent. The negro child is almost without exception badly nourished, and nearly always "scrofulous." It would not perhaps be safe to say that in every case this means tuberculosis in a demonstrable form in some organ, though few autopsies show its absence, but the power of resistance is much reduced and recuperation sluggish. Whether all cases of temporal-bone suppuration in these children start in the middle-ear inflammation is doubtful. There seems at any rate to be a strong predisposition among them to take on suppurative disease in these bones on slight provocation.

Facial Paralysis as a Complication of Acute Otitis Media.—W. R. Murray has seen this complication twice in two hundred and fifty-eight cases of this form of ear trouble. He says that during its passage through the Fallopian canal the anatomical position of the nerve accounts for the somewhat unusual complication of facial paralysis attending an otitis media, and, when present in an acute catarrhal case, is due to the direct extension of the inflammatory process to the nerve sheath, which, lying within the unyielding bony walls of the Fallopian canal, may be subjected to sufficient pressure, from the swelling attending a slight inflammation of the nerve sheath, to interfere, partly or completely, with the functions of the nerve, and is probably due to some abnormality of the bony structure surrounding the nerve, probably in the neighborhood of the fenestra ovalis, in the internal wall of the tympanum, where the canal turns from its horizontal course and passes downward to its exit at the stylo-mastoid foramen.

Excessive Hemorrhage following the Removal of a Myxo-Fibroma from the Ear.—C. R. Dufour has recently met with an experience of this kind, his patient being a woman aged fifty years. The tumor protruded in a polypoid form and was surrounded with the wire snare, but the latter could not cut through, so the growth was removed by torsion. Severe arterial hemorrhage followed, which hot water did not control but which was entirely checked by compression of the carotid. Release of pressure was followed by immediate recurrence of the bleeding, so under anæsthesia the meatus was packed with gauze, which stopped all further trouble. The gauze was removed without incident in four days.

The Rinné and Gellé Tests.—G. Brühl comes to the following conclusions: (1) If the Rinné test is positive, then Gellé is also unexceptionally positive, and the impaired hearing is due to nervous affections. (2) If the Rinné test is negative absolutely and totally or up to c', the Gellé test is unexceptionally negative, and the impaired hearing is due to a stapes ankylosis. (3) If the Rinné test is negative below or up to the c limit, and positive above it, then the Gellé test decides whether a stapes ankylosis exists or not.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

DINNER TO RETURNED CIVIL SURGEONS—MR. TREVES AND THE PLAGUES OF SOUTH AFRICA—CAUSE OF SCURVY—CYSTS OF THE BREAST—CIRRHOSIS OF THE LIVER—STATUE TO HUXLEY—SIR BATTY TUKE—DEATH OF PROF. VINER ELLIS.

London, May 4, 1900.

Lord Rosebery presided at the dinner to Sir William MacCormac and Mr. Treves. In commending their work in South Africa he extended his praise to the army medical service which has so completely done its duty in the campaign. As the only department which has been on all hands pronounced perfect the Royal Army Medical Corps has justified its position and its profession. Lord Rosebery's eulogy of the service will do much good, and it was indorsed by both the distinguished guests. Sir William MacCormac spoke of the war as one of the happiest things that could have happened in view of the way it has brought out the noblest part of the national character and consolidated the power of the empire to put an end to the most corrupt oligarchy. Mr. Treves confined his remarks to more professional topics, but in speaking of amateur nurses he put his foot in it, and the screaming sisterhood are seeking revenge. He is a bold man and refuses to retract, but he has expressed to an interviewer his amazement at the misunderstanding of his remarks. It is true he said there were two plagues in Africa—the flies and these women. The women were those who went out apparently in search of a novel excitement—society butterflies, who knew nothing and cared nothing for real nursing, and only hindered the surgeons in their duties. I hear army men declaring what he said is too true, and it needed some one out of the army to say it. Sir A. Milner had spoken, but it seems these women could not take a hint, so Mr. Treves has translated it into vigorous denunciation.

The Times made an extraordinary blunder by attributing the perfection of the Royal Army Medical Corps to Sir William MacCormac and Mr. Treves. Those gentlemen accordingly at once wrote a joint letter to *The Times* disclaiming any share of the credit, as they went to South Africa only after the Royal Army Medical Corps had completed all its arrangements, and could therefore only testify to the efficiency of those arrangements. That letter in *The Times* will be appreciated by their army brethren and by the public. Its prompt appearance does justice to the writers' sense of right.

That scurvy is caused by lack of fresh vegetables and may be prevented by lime-juice is still, I believe, generally thought to be an indisputable fact. Even when the precise manner in which the result is brought about is disputed, the fact has been admitted for more than a generation. Still here and there doubts have been expressed, chiefly on account of the impossibility of reconciling some outbreaks with the theory, which may yet have to be greatly modified or discarded. A communication has been made to the Royal Society by Mr. Frederick G. Jackson and Dr. Vaughan Harley, detailing an investigation into this matter which points to the conclusion that ptomain poisoning is the cause of scurvy. The suggestion is not novel, but it is now founded on a careful research. A number of monkeys were kept under the same circumstances on a strictly regulated diet. In one group fed on boiled rice and maize with fresh meat mixed in it, they lost weight and diarrhœa was produced. The diet was probably insufficient, and monkeys are not carnivorous. In another group on exactly the same diet, except that the meat was tainted instead of fresh, the same wasting occurred, but the diarrhœa became bloody, in some cases the motions just before death consisting principally of blood and mucus. Further, five out of the eight monkeys in this group developed spongy gums, in some ulceration occurring. A third group of five, dieted in the same manner, except that an apple or banana was added daily, showed similar effects but not so intense. Four had blood and mucus in the stools, and two of them spongy and bleeding gums. Thus it would seem that the vegetable only restrained but did not prevent the symptoms of scurvy. The facts of Arctic expeditions are in agreement with the conclusion that vegetable food or lime-juice is not alone able to prevent scurvy when the meat is tainted. Therefore the condition of the diet generally must be considered, and most of all the state of preserved meat, whether tinned or salted.

The blood of two of the scorbutic monkeys was analyzed, and that of a healthy monkey, and these analyses were compared with those recorded in cases of human scurvy. The results supported the conclusion that the two diseases corresponded.

A paper on cysts of the breast comes opportunely after the Lettsomian lectures of Sir W. M. Banks on cancer of that organ. At the Medical Society the relative frequency, diagnosis, and treatment of such cysts was considered by Mr. Bryant. This communication was a sequel to one he read before the same society in 1896. From an analysis of two hundred and forty-two consecutive cases seen by him in the last ten years he was brought to the following conclusions: (1) Simple cysts are more common than is generally believed; (2) they are chiefly found at the period of life in which cancer is met with; (3) they are amenable to treatment without the sacrifice of the gland; (4) there is no reason to believe that women who have these cysts are more liable than others to cancer. Separating the cases proved by operation to be correctly diagnosed, Mr. Bryant was able to report that of every four cases which simulated cancer one proved to be cystic. He then showed how safely these cysts may be dealt with either by simply laying them open and plugging with iodoform gauze after destroying the inner surface with carbolic acid or solution of iodine; or by dissecting the cyst from the gland, when intracystic growths can be seen attached to its walls. In his cases permanent recovery has always followed. But should the cyst be found to contain solid cancerous or sarcomatous growth he would remove the whole gland, and, indeed, had done so on two occasions, the cases being classed as solid tumors. If one in four cases simulating cancer turned out to be cystic, Mr. Bryant thought that eliminating cases with clear indications of cancer it might be that half the remaining doubtful cases would be cystic. Such an inference may well give pause to the practitioners who would regard every lump in the breast as cancer. An exploratory incision would make the diagnosis clear. Mr. Bryant admitted that the figures had somewhat surprised him, particularly as they were of consecutive cases. Cysts were generally thought rather uncommon, but these figures disproved that.

Some remarks were made by fellows on the difficulties of diagnosis, and one said he thought innocent tumors were even more common than Mr. Bryant's statistics showed, but these were of course restricted to cysts.

At the same meeting Dr. Campbell Pope read a paper on "Twenty-four Years' Death Certificates in General Practice." His figures pointed to the prevalence of respiratory diseases in the district, situated in West London, the slight fatality of infectious diseases, and the frequency of cancer. Further, influenza was not very fatal, and the infantile death rate was high. In the absence of statistics from other general practices in the district it seems to me difficult to assign a proper value to these.

When a question arises as to the condition of the liver in a given case, I am reminded of a remark once made by Addison. After careful palpation, percussion, and consideration in a consultation on an obscure case, that able observer said: "We feel, and feel, and give a guess." The difficulties of diagnosis remain much the same, and the clinical history of hepatic disease has not kept pace with the progress of our knowledge of other maladies. Still some points have been made clearer and others are being elucidated. They were well treated by Dr. Cheadle in his recent Lumleian lectures on "Some Cirrhoses of the Liver." He has for a long time taken great interest in this subject, and was able to enforce his views from extensive experience. I need only mention one or two practical points to show the value of his lectures. The advent of ascites is so often regarded as the beginning of the end that practitioners will be glad to learn that Dr. Cheadle has not found it so surely and rapidly fatal as many suppose. In the contracted, atrophic form of cirrhosis, due to alcohol, he admits the full gravity of the symptom and thinks that to these cases is to be attributed the hopeless prognosis generally entertained. On the other hand, in hypertrophic and syphilitic cases the advent of ascites is less serious. The cirrhosis is of course incurable, but in itself of little consequence, only important by the pressure it produces. Therefore a certain degree may persist for a long time without precipitating the end. Another point relates to treatment. Dr. Cheadle is a thoroughgoing advocate of early and repeated paracentesis, and some of the cases he related were very convincing as to the value of this practice. Every one will admit that the indication is to get rid of the fluid, and most will subscribe to the doctrine—the sooner the better. But many, perhaps too many, cling to the hope that diuretics or cathartics may suffice. The futility of the former has too often been experienced, and the latter Dr. Cheadle finds do not often reduce the ascites, though they do reduce the patient's strength. He therefore deprecates the postponement of paracentesis until the vital powers are exhausted, and would repeat the operation as it may be called for until the fluid ceases to accumulate.

On Saturday the Prince of Wales unveiled the statue of the late Professor Huxley in the Natural History Museum. He referred to the fact that he had fifteen years ago unveiled a similar statue of Darwin.

It seems that Sir Batty Tuke will have a walk-over for the vacant Scottish University seat.

An outbreak of typhoid at Leeds is causing some anxiety.

It seems like going back for a generation to record the death of George Viner Ellis, the professor of anatomy and author of the "Demonstrations." He died on the 25th ult. at the advanced age of eighty-eight years. He retired as long ago as 1877 to his country house, where he died. The beautiful colored plates he issued in his "Illustrations" were drawn from his own dissections.

THE MEDICAL ASPECTS OF THE SOUTH AFRICAN WAR.

(From our Special Correspondent.)

Lord Roberts' Genuine Success in occupying Brandfort, and his more qualified successes both to the north and the southeast of his halting-place at Bloemfontein, all of which have taken place since I last wrote, may be of more significance than they appear. But few prisoners have been taken, and there is no evidence that the Boers have lost more than a dozen lives, while their guns and provisions have been safely removed and all attempts at cutting off their retreat upon their main army have failed. But, on the other hand, the fertile country from which they have been ousted is the best corn land in South Africa, a consideration to both sides now that the immense importance of cavalry in this war is recognized, while the onward march of the British is sure to lead, as it did previously, to desertions from the Boer commandos.

The Total British Casualties, according to a War Office return published on April 21st, amounted to just about fifteen thousand men, this total being exclusive of sick and wounded actually in hospital at the time of publication of the return. No official return has been made by the Pretorian government of the Boer losses, and the reason of this is probably the apprehension of the Boer leaders lest appreciation of the risks should prevent some of the burghers from joining the flag; but as a matter of fact it is common knowledge that the Boers have not lost anything like so many men as the English. Sir William MacCormac has said, after walking round the trenches of Colenso, that the place was practically impregnable. At the battle of Colenso there were eleven hundred and forty British casualties, while the Boer losses, if the figures of Mr. Fischer, the secretary of the Free State, are received as accurate, amounted to five killed and twenty-five wounded.

Rain and Dust Storms are causing the British troops much discomfort and some sickness. There are now considerable differences in temperature during the twenty-four hours, for the night temperature falls very low, while the torrents of rain occasionally swamp out the tent-dweller. The rain storms are usually preceded by a wind which sweeps up with it the dust of the veldt to deposit it in a fine layer over everything and into everything. This dust makes the mucous membranes of nose and mouth and pharynx sore, causes sore throat with headache and feverish symptoms, and, in the opinion of some, is responsible for diarrhœa. The lull in fighting is enabling the base hospitals to get empty of their patients. Most of those sent down to the base are suffering from enteric fever, but the number is not very great when the size of the British army is considered. It will be interesting to see if any proofs can be obtained that the dust storms are followed with any regularity by enteric symptoms.

The Boer Prisoners at Simonstown are still suffering from enteric fever. The number of cases is great and the mortality considerable. A special hospital has been established at Simonstown for their treatment, and every comfort and even luxury compatible with their condition is provided by the British government. The Boers must have brought the disease down with them from their trenches, which were in a terribly fetid and unsanitary condition, for there was no enteric fever at Simonstown previous to their arrival, and none of the British transports has put in from England with the disease on board.

Moral Support.—I referred in my last letter to the value of the moral support which Sir William MacCormac has been able to give to the Royal Army Medical Corps during their campaign, and a striking illustration of my meaning has been furnished by Sir William MacCormac himself, who has thus summarized his opinion of the department:

"The professional surgical effectiveness shown by the officers of the Royal Army Medical Corps during my intimate connection with them, while they have struggled with difficulties of location, transit, want of water, and a hundred and one other impediments never experienced in a civil hospital in peace, is, in my opinion, of a very satisfactory character, and everything has been done which one could possibly suggest under the varying circumstances for the comfort and skilful treatment of the wounded. The rapidity and completeness with which large field hospitals were conveyed by road or rail, unpacked and re-erected, reflect great credit upon the organizing powers of the officers and the effective carrying out of their orders by the hard-working and patient non-commissioned officers and men of the corps under them."

Such a testimonial from the president of the Royal College of Surgeons of England will be of great value to the corps. Hitherto even when praised (which seldom occurred) the praise was always bestowed with somewhat doubting accents, for the commendation had to come from men with no expert knowledge whatever of the work of the military surgeon. In the South African campaign Sir William MacCormac, and in no less degree such civilian surgeons as Mr. Treves and Mr. Watson Cheyne, are vouching and will vouch for the standard of the scientific work, and will thus enable the commander-in-chief to understand the merits of the corps. Sir William MacCormac, who, by the way, is a strong and sensible man, quite unlikely to bespatter with praise undeserving objects for the sake of making himself agreeable, describes the work of the nursing sisters also in terms for which they will be grateful. "The work of the army nursing sisters," he says, "has been admirable and endless. As soon as one batch of serious cases from the front was comfortably settled and a partial rest seemed possible, another batch arrived. The untiring energy and patience shown by these ladies under great difficulties and stress have been beyond praise."

The "Maine."—The American hospital ship *Maine* is now nearly due again at Cape Town. Lady Randolph Churchill, who has acted as chairman of the American ladies' committee, has published a statement explaining why only male nurses have been engaged for the second voyage.

"Our sisters," she says, "were not 'lady volunteers,' but skilled professionals, having received the same training and receiving the same salaries as the male nurses from the Mills schools, the whole nursing staff having been sent to us by Mrs. Whitelaw Reid. In reference to the sisters, nothing could exceed their excellent work, and if we are parting with them, our decision casts no reflection on their efficiency. It has been found that the nursing staff was too large for the number of patients we could take on board, and for the class of cases which hospital ships, practically three days' journey from the front, necessarily received. There is no doubt that a wounded or sick man at death's door prefers a woman to nurse him; one before whom he need not fear to break down, one whose gentle touch no man can replace. But the bulk of our patients were men able to do a good deal for themselves, who, if given the choice of equally good men or women nurses, would prefer the former. Under these circumstances, and added to them the fact of the cramped accommodation and want of privacy the ship affords for women, it has been thought advisable to dispense with their services."

Lady Randolph Churchill's explanation was probably due to the feeling that the public, reading Mr. Treves' estimate of the value of amateur nurses, and hearing that the *Maine* was going out on its second errand of mercy with only male nurses, might jump to the conclusion that the women who had nursed on the *Maine* were exactly the incompetent ladies of fashion whose actions had been so criticised. I do not know if any one has had this erroneous idea, but I do know that the patients on board the *Maine* were excellently looked after in every way.

Firing on the Red Cross.—Sir William Thompson, who is head surgeon with the Irish Hospital, has publicly stated, in reference to the oft-repeated allegation against the Boers that they fire on ambulances and hospitals, that when this occurs it may well be an accident; for the Red Cross markings are not made the proper size to be visible at the present long ranges, and can be seen only at a distance of six hundred yards or so.

METHYL BLUE AND METHYLENE BLUE.

To the Editor of the Medical Record.

Sir: In the Medical Record for April 28, 1900, in Dr. Willy Meyer's article on "Bottini's Operation for the Cure of Prostatic Hypertrophy," he mentions his use of methyl blue in two- to three-grain doses three times daily, combined with quinine in eight-grain doses. He must mean methylene blue, which is used in cystitis, pyelitis, malaria, rheumatism, and carcinoma. Methyl blue, on the contrary, is never used internally, but is dusted on the throat in diphtheria in a two-per-cent. mixture with sugar powder.

Methylene blue with sodium hydrate is changed to a violet color; methyl blue with sodium hydrate (NaOH) is changed to a reddish-brown.

CHARLES TEUBNER, M.D.

2387 HOWARD STREET, SAN FRANCISCO, CAL.
May 4, 1900.

LYMPHATIC INVOLVEMENT IN CANCER OF THE STOMACH.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the issue of the MEDICAL RECORD for May 5, 1900, is an abstract of a paper on "Malignant Diseases of the Stomach and Pylorus," which I read before the American Surgical Association, in which I am made to say that lymphatic involvement, so called, is now known to be a simple septic glandular enlargement—the relation between the abdominal glands and the carcinoma being utterly different from that which exists between the breast and axilla; and that abdominal adenitis is, therefore, of little importance.

What I did say was: "Lymphatic infection is a still more serious complication because, if palpable glandular malignancy can be established, it is altogether probable that the involvement has passed beyond reach. In twenty-eight cases of non-malignant dilatations of the stomach from various causes which I have operated upon, in more than half enlarged glands could be palpated, due to an accompanying chronic gastritis. This may be, and frequently is, true of cancer of the stomach, the enlarged glands being the result of septic complications. The modern operation for the removal of the glands with carcinoma of the breast suggests a similar glandular extirpation in radical operations on the stomach. Linder does not believe this feasible. In twenty-eight recurrences after extirpation, fifteen were local, twelve distant, and only one involved the glands. An investigation leads to the belief that glandular infection in cancer of the stomach is not uniform, many such cases die without such involvement, and that a moderate enlargement may be septic. Should they become infected their situation renders radical removal practically impossible."

As involvement of the lymphatics takes place in at least two-thirds of the cases of cancer of the stomach, I feel that the statement should be corrected, and more especially when I consider the large circulation of your journal.

W. J. MAYO, M.D.

ROCHESTER, MINN.

PEROXIDE OF HYDROGEN AS A LOCAL ANÆSTHETIC.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I have not seen anywhere peroxide of hydrogen spoken of as a local anæsthetic, and as it has proved very satisfactory in my hands I venture to mention it in your paper. Injected under the epidermis it produces immediate and complete anæsthesia of the whole skin. I have used it for over a year, in opening abscesses, cutting off redundant tissue in in-growing toe-nails, opening the pleural cavity, and in one case the abdominal cavity. I do not think any absorption takes place, as the intercellular inflation from the gas generated seems to produce such pressure that the skin cuts like frozen tissue.

H. E. KENDALL, M.D.

SYDNEY, NOVA SCOTIA, May 4, 1900.

PRIORITY IN THE PUBLIC-BATH QUESTION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In reply to the editorial in the MEDICAL RECORD of May 12th, permit me to say that a careful reading of my article will show that I made only two claims—first, that so far as I knew the Lunacy Commission were the first (1891) to introduce spray bathing into institutions for the insane; second, that I was the author of the first general State legislation (1892) providing for the erection and maintenance of free public baths and making their erection mandatory (1895). Dr. Baruch did not secure me as a coadjutor. The first act was passed in 1892—three years before I knew Dr. Baruch. In 1895, at his request I met him and subsequently invited him to appear with me before a legislative committee, but he was unable to do so.

Dr. Baruch is entitled to great credit for his efforts in behalf of public baths, but he was in no wise reponsible for the acts of 1892 and 1895, nor, I am satisfied, would he claim to be so.

All of the experiment with rain and spray bathing were made about the same time—1890–1891—and by many people at different dates. It is not strange that I did not learn of Dr. Baruch's, for I did not know of him or meet him until 1895.

GOODWIN BROWN.

Reviews and Notices.

PRACTICAL TEXT-BOOK OF MIDWIFERY FOR NURSES AND STUDENTS. By ROBERT JARDINE, M.D. Edin., M.R.C.S. Eng., F.F.P. and S. Glasg.; Physician to the Glasgow Maternity Hospital, Glasgow. With thirty-six illustrations. 245 pages. New York: The Macmillan Company. Edinburgh: William F. Clay. 1899.

THIS volume treats of midwifery in a simple, direct way especially adapted for beginners. The descriptions are clear and concise, and technical terms are avoided as much as possible. The actual duties of nurses are well described and the procedures for asepsis particularly insisted upon. The author does not claim to have written for practitioners, but merely for those who are their assistants, and he has succeeded admirably in his task of pointing out what they should observe and what the probable meanings of the more evident symptoms are.

A MANUAL OF SURGICAL TREATMENT. By W. WATSON CHEYNE, M.B., F.R.C.S., F.R.S., etc., and F. F. BURGHARD, M.D. and M.S., Lond., F.R.C.S. Vol. II.: The Treatment of the Surgical Affections of the Tissues, including the Skin and Subcutaneous Tissues, the Nails, the Lymphatic Vessels and Glands, the Fasciæ, Bursæ, Muscles, Tendons and Tendon Sheaths, Nerves, Veins and Arteries, Deformities. Philadelphia and New York: Lea Brothers & Co. 1900.

THE second section of this commendable work is now before us, and we find that the promise of the first volume is well maintained. The book is especially strong from the practical point of view, and contains many useful hints, often upon minor details, care for which contributes so much to surgical success. As the title indicates, the subject of treatment receives a very large share of attention, and most of the illustrations bear upon this part of the subject. The deformities, congenital and acquired, of the hand and foot occupy considerable space in the first part of this volume, and make a very concise and readable section upon orthopædic surgery. Under the division devoted to the surgical affections of the tissues, among other matters, the subject of the treatment of many of the minor surgical conditions, especially of the extremities, receives attention, and adds much to the interest and value of the book. Pathology does not receive much consideration either in text or in illustrations. It is good advice which tells us to make the curved incision in front of the knee, when removing a bursa, with the curve up instead of down, so as to keep the cicatrix out of the way when the patient kneels later. The chapter upon diseases of the tendons and their sheaths is satisfactory and complete, but there is no noteworthy departure from generally understood and accepted principles. We do not think it necessary to suture a ruptured quadriceps-femoris tendon with silver wire, because it is not logical to depend on strength of suture material to maintain apposition against a pull, when we know that sutures which exert tension upon living tissues will cut through. The authors have not had satisfactory permanent results with nerve stretching for sciatica and allied conditions, and with this experience our own coincides. The last part of this volume is devoted to diseases of the blood-vessels, the treatment of aneurism of course receiving most attention. A short description of the older methods, some non-operative, is followed by a very complete discussion of the later procedures. The authors' materials of preference for ligatures are thick chromicized catgut and kangaroo tendon, these substances having the advantage of slow absorbability. The illustrations in this part of the book are clear and useful, and the index has evidently been very carefully made. The introduction of so much advertising matter at the end of the volume is offensive to those who are fond of a well-made book.

EXPERIMENTS ON ANIMALS. By STEPHEN PAGET; with an Introduction by LORD LISTER. London: T. Fisher Unwin. New York: William Wood & Co. 1900.

THERE could not be a fairer or more convincing statement of what animal experimentation has done for the progress of medicine than is to be found between the covers of this volume. Its appearance is opportune, and a United States Senator who has been persistently advocating a certain ill-advised and thoughtless bill should have a presentation copy. The first part of the book is devoted to a description of what the older investigators have accomplished for physiology by experiments upon animals, and contains much of historical interest. The main part of the book contains an exceedingly accurate, interesting, and concise description of the results of bacteriological and pathological investigation of the various infectious diseases, in which, of course, experiments upon animals have figured largely. We do not think that even the most confirmed "antivivisectionist" could be so bigoted or wrong-headed as to read the chapters upon diphtheria, or tetanus, or the plague, among others, and still continue to deny the usefulness and propriety of our use of animals in this connection. The book is a timely one, and we have seldom seen a work on a scientific subject so well written.

Nordrach at Home. By Joseph J. S. Lucas. Bristol: J. W. Arrowsmith.

This little sixty-page brochure gives the hygienic open-air or "sanitorium" treatment of consumption adapted to English home life. The simple directions, if followed, would go far toward diminishing the spread of the disease while contributing to the patient's comfort and cure.

Essentials of Physical Diagnosis of the Thorax. By Arthur M. Corwin, A.M., M.D. Third edition, revised and enlarged.

This work, though revised and enlarged, still remains a book essentially adapted to the use of the student, and as such, without doubt, will continue to be appreciated. It successively deals with: I. Topography and Landmarks of the Chest; II. Methods of Physical Diagnosis; III. Physical Signs in Diseases of the Chest; IV. Diseases of the Pericardium, Heart, and Great Vessels. The various subjects are, as far as practicable, presented in a tabulated form, thereby increasing its value as a handy book of reference and a useful guide to the intelligent examination of the thoracic cavity and its contents.

The Rise and Development of the Liquefaction of Gases. By Willett L. Hardin, Ph.D., Harrison Senior Fellow in Chemistry in the University of Pennsylvania. New York: The Macmillan Company. 1899.

The work is a very timely one, considering the general interest which has recently been aroused by the liquefaction of hydrogen. The worker in this field has found his literature rather scattered, and will welcome a book bringing together foreign investigations and discoveries, as well as those with which he may be more familiar. This small volume of two hundred and fifty pages gives a rather complete account of methods now in use, while enough of the theoretical aspects of liquefaction have been included to enable the layman to grasp the subject intelligently. It is the references to scientific works which make the book most valuable to one already up in the general subject, while the style is one which will appeal to the popular reader. The work is illustrated with a number of drawings.

Text-Book of the Embryology of Invertebrates. By Dr. E. Karschelt, Professor of Zoölogy and Comparative Anatomy in the University of Marburg, and Dr. K. Heider, Professor of Zoölogy in the University of Berlin. Translated from the German by Matilda Bernard. Revised and edited with additional notes by Martin F. Woodward, Demonstrator of Zoölogy, Royal College of Science. Vol. II., 374 pages, and Vol. III., 441 pages. London: Swan, Sonnenschein & Co. New York: The Macmillan Company. 1899.

These volumes follow the one translated by Professors Mark and Woodworth, who were obliged to abandon the work in favor of the present translator and editor. Vol. II. deals with the embryology of phoronidea, bryozoa ectoprocta, brachiopoda, entoprocta, crustacea, and palæostraca; Vol. III. is devoted to arachnida, pentastomidæ, pantopoda, tardigrada, onychophora, myriapoda, and insecta. Although a work of such scope and abounding in such minute details would naturally appeal more strongly to the special student, the general reader cannot fail to be impressed with the amount of erudition displayed, as well as by the clear and orderly arrangement of the subject-matter. Each chapter is richly illustrated, and is followed by an exhaustive bibliography. To those who are familiar with the difficulties attending the translation of a German book abounding in such ponderous scientific terms as a work on comparative embryology, it must be evident that the present volumes are singularly free from idioms and obscure sentences. The English edition will be invaluable to special students.

The Urine and Clinical Chemistry of the Gastric Contents, the Common Poisons, and Milk. By J. W. Holland, M.D. Forty-one illustrations. Sixth edition, revised and enlarged.

In view of the fact that the above work has reached its sixth edition but little need be said of its merits. Originally intended for the student, its present form is such as to render it of value to the general practitioner as well. It is divided into the following chapters: I. Examination of the Urine; II. Examination of the Gastric Contents; III. Examination of Common Poisons; IV. Study of Normal Milk, and Milk Examination. For convenience the more important matter is printed in large type. The text is clear and concise, and the microscopical drawings are well reproduced.

Loveliness. By Elizabeth Stuart Phelps. Boston: Houghton, Mifflin & Co. 1899.

This is a charming tale which will, however, pervert none of those who believe that vivisection in the hands of the humane and scientific investigator has proved and ever will prove an inestimable boon to mankind. The story tells how Loveliness, the pet dog of a little invalid girl, is stolen, bringing the child to death's door. The dog is finally recovered by her father in a somewhat dramatic fashion, at the very moment it is about to suffer vivisection in the medical college of which he himself is one of the professors. Carried home in triumph, it is the means of restoring its young mistress to health. Had the author in her task gone one step further and actually depicted her canine hero suffering various tortures without the boon of an æsthetic, we would have heartily concurred with her in condemning such an act as one of unnecessary cruelty. Let us be mindful, however, that but for vivisection many branches of medical science would to-day be but in an embryonic state, and countless lives be sacrificed through ignorance of the functions governing that intricate and wonderful mechanism, the human body.

A Text-Book of Embryology for Students of Medicine.. By John Clement Heisler, M.D., Professor of Anatomy in the Medico-Chirurgical College, Philadelphia. With 190 illustrations, 26 of them in colors. Pp. 405. Philadelphia: W. B. Saunders. 1899.

This volume is a worthy companion of the others in this well-known series. The author has succeeded in presenting a subject which has always been the *bête noire* of medical students in an unusually clear and interesting way, though necessarily much condensed. The introductory chapter deals with ovulation and fertilization. We note on page 33 the surpassing statement that if the ovum "instead of passing into the tube drops into the abdominal cavity and is fertilized there, it undergoes partial or complete development *in situ*; this condition is known as extra-uterine pregnancy or ectopic gestation." Chapters II. and III., on segmentation of the ovum and the germ layers, are followed by a chapter on the beginning differentiation of the embryo. The two succeeding chapters, on the fœtal membranes and the deciduæ, are beautifully illustrated by colored plates. Chapters VIII. to XVIII., inclusive, take up the development of the various systems of the body, beginning with the connective tissues and lymphatics, and concluding with the skeleton. A tabulated chronology of developments is appended. The index is unusually full and accurate. While a work which deals largely with dry anatomical details does not admit of criticism from a literary point of view, it may be said that the author's style is lucid and pleasing. Each sentence is so clearly expressed that there is no chance of misunderstanding its meaning. The illustrations are excellent; in fact, the book is in every way worthy of commendation.

Ueber Gangrän bei Diabetes Mellitus. Von Dr. Fritz Grossman, in Berlin. 8vo, 134 pages. Berlin: August Hirschwald. 1900.

In this excellent monograph the author considers the various theories as to the cause of gangrene and trophic disturbances in diabetes mellitus; his conclusions are that these are due either to arteriosclerosis (thrombosis) resulting from the abnormal products, such as acetone, lactic acid, butyric and oxybutyric acids, which are present in the blood of diabetics, or due to inflammatory processes induced by bacteria whose virulence has been increased by the hyperglycæmia acting on tissues whose resistance has been lessened by the diabetes mellitus. The author has also fully discussed the relation of nerve degeneration to the arteriosclerosis and to the trophic disturbances and gangrene; he rightfully concludes that the nerve degenerations are not the cause of these pathological states, but are in themselves only a manifestation of a diminished nutrition of the nervous system, resulting from the arteriosclerosis. In the chapter on treatment the author advocates the use of local anæsthesia when operating on diabetic patients, and also the employment of "digital" compression for temporary hæmostasis during an amputation. In view of the frequent association of arteriosclerosis with the gangrene he prefers to amputate at a high level. The monograph contains a critical review of cases of diabetic gangrene reported in literature, and also a report of the author's experimental investigations concerning the action of bacteria on diabetic tissues.

LETTER-, WORD-, AND MIND-BLINDNESS. By JAMES HINSHELWOOD, M.A., M.D., Surgeon to the Glasgow Eye Infirmary. London: H. K. Lewis. 1900.

THE subject-matter here presented is largely made up of papers published by the author in *The Lancet*, and covers a field which has hitherto had not very much attention in English literature. There are five chapters. The First, "Visual Memory," is strictly new. A case is given of partial mind-blindness with dyslexia—a peculiar form of word-blindness. Word- without letter-blindness, and letter- without word-blindness are also considered.

LEADERS IN TYPHOID FEVER. By E. B. NASH, M.D., author of "Leaders in Homœopathic Therapeutics." Philadelphia: Boericke & Tafel. 1900.

IN this little monograph of one hundred and thirty-five pages, are given, without the description, merely the leading indications in treatment. The remedies are grouped according to stages of the disease. The author believes that no hemorrhage should occur under proper treatment; he has seen but one case in fifteen years, since he has learned how to use the remedies. He thinks hunting after something better than the "superb homœopathic therapeutics" for typhoid is time wasted. The type is large, so that the amount of reading matter is quite limited.

HEALTHY EXERCISE. By ROBERT H. GREENE, M.D. New York: Harper & Brothers. 1900.

THIS is an excellent little manual for the laity, setting forth the necessity of exercise as a means of preserving health. It is divided into three parts—the first dealing in a general way with the theory of exercise and bathing, the second discussing the choice of an exercise according to the age and physical condition of the person, and the third describing briefly the manner of carrying out the different forms of exercise. The description of the respiratory and abdominal exercises in Part III. is supplemented by some useful outline sketches. The book is full of sound advice, and the general adoption of the author's suggestions would go far to reduce the physician's income.

DISEASES OF WOMEN: A TREATISE ON THE PRINCIPLES AND PRACTISE OF GYNÆCOLOGY. For Students and Practitioners. By E. C. DUDLEY, A.M., M.D., Professor of Gynæcology, Northwestern University Medical School; Gynæcologist to St. Luke's Hospital, Chicago, etc. Second edition, revised and enlarged. With 453 illustrations, of which 47 are in colors, and 8 full-page plates in colors and monochrome. Pp. 719. Philadelphia and New York: Lea Brothers & Co.

THE appearance of a second edition of this work within a little over a year after the first is a proof both of the successful reception it has met, and of the energy and progressiveness of the author. As we have already pointed out the many excellent features of the book, we need only indicate the changes which have been made. Part VI., including four chapters, is new. It includes the disorders of menstruation and sterility, which the author, though properly regarding them as symptoms, has seen fit to consider under separate headings—to the detriment of the book in our opinion. The same grouping of subjects, "not by the more common regional method, but so far as possible from the standpoint of pathological and etiological sequence," is still maintained. Apropos of this we may add that not a few practical teachers have not found it such a decided advance on the old "regional method." Certainly there seems no sufficient reason for the close juxtaposition of tumors, tubal pregnancy, and malformations in Part III. We had rather hoped that the subject of inflammation of the uterus might have been retouched and rendered a little less confusing. We are less pleased with the author's handling of Part II. than with any other portion of the book. Since he is an avowed exponent of the school of gynæcology represented by the Woman's Hospital, it would be unfair to comment too severely on the unusual amount of space devoted to plastic operations on the cervix, as compared with others which would seem to the ordinary reader to be equally if not more important. Dr. Dudley is a loyal follower of Dr. Emmet, as well as a brilliant alumnus of the institution which he adorns. A table of illustrations is much to be desired, if for no other purpose than to call attention to the numerous original drawings, of which we would mention especially figures 412 to 416, representing the various steps of the author's ingenious operation for anteflexion. In dwelling upon a few minor defects of this excellent work, we seek only to emphasize the fact that, while original, it is not yet a perfect text-book for the student. That it is a distinct addition to the literature of gynæcology no one can deny. We heartily congratulate Dr. Dudley on its continued popularity.

THE PRINCIPLES OF TREATMENT AND THEIR APPLICATION IN PRACTICAL MEDICINE. By J. MITCHELL BRUCE, M.A., M.D., F.R.C.P., Physician and Lecturer on the Principles and Practice of Medicine, Charing Cross Hospital; Consulting Physician to the Hospital for Consumption, Brompton; Examiner in Medicine, University of Cambridge. Adapted to the United States Pharmacopœia by E. QUIN THORNTON, M.D., Demonstrator of Therapeutics, Pharmacy, and Materia Medica, Jefferson Medical College, Philadelphia. Philadelphia and New York: Lea Brothers & Co. 1900.

THERE are two distinct parts to this work, which may be called the theoretical and the practical. The first part deals with the general indications for treatment, based upon the etiology, pathology, and symptomatology of the disease, and modified by the age and sex of the patient, and also with the means and art of treatment. In the second part the author furnishes special illustrations of the principles of treatment, previously outlined, applied to diseases of the circulatory, respiratory, and digestive systems (the latter including the urinary), to a few cerebral affections, neuritis, and typhoid fever. The first part should be read through and pondered especially by young physicians just starting on their life work, with a good supply of knowledge but a lack of ability to apply it; the second part will serve as a work of reference and a guide, for older practitioners as well as the young, to the management of any of the maladies here discussed. The work is one that can be commended without reservation to young practitioners especially, and it may also be read with interest and profit by those of long and varied experience.

A SYSTEM OF MEDICINE, BY MANY WRITERS. Edited by THOMAS CLIFFORD ALLBUTT, M.A., M.D., LL.D., D.S.C., F.R.C.P., F.R.S., F.L.S., F.S.A., Regius Professor of Physic in the University of Cambridge, Fellow of Gonville and Caius College, Honorary Fellow Royal College of Physicians of Ireland. Volume IX. New York: The Macmillan Company. 1900.

THIS, the final volume of Allbutt's excellent System, contains a presentation of mental diseases and the dermatoses, together with the concluding portion of diseases of the nervous system, and an appendix to malarial fever showing the part played by the mosquito in the spread of this affection. There is also a general index to the entire work, which will probably provoke to more profanity than anything of the kind attempted in the past century. We have repeatedly noted the confusion of volumes in this work, the number of the volume on the book seldom agreeing with that on the title-page. The same confusion is carried through the general index. This volume is called ix., both on the back and on the title-page, yet all the references in the general index to the articles in it are to volume viii.—and so with the references to all the other volumes. The index is, furthermore, wretchedly incomplete. One's fault-finding must, however, cease with the index, for the two treatises on diseases of the skin and mental maladies are deserving of naught but praise. The list of writers contains the names of nearly all the best known dermatologists and alienists in Great Britain and Ireland, and almost without exception they have handled their subjects in a most acceptable manner. The supplementary article on malaria is written by Dr. Patrick Manson.

A Case of Flat Condyloma of the Vocal Cords.—Domenico Tanturri Fu Vincenzo reports a case, a study of which justifies the following conclusions: Among the manifestations of syphilis of the larynx may be included flat condyloma; this may be the first manifestation of the second stage. Its structure is the same as that of condyloma of the mucous membrane of the upper passages. The affection most likely to obscure the diagnosis is primary laryngeal tuberculosis. Specific treatment is valuable in clearing the diagnosis. The symptoms of the lesion are a constant dysphonia, and sometimes a laryngeal stenosis. The prognosis is good, these growths usually yielding to antisyphilitic treatment.—*Giornale Internazionale delle Scienze Mediche*, February 28th.

Surgical Suggestions.

Perforating Typhoid Ulcer.—The incision should be made on the right side, the ulcer inverted without cutting away its edges, the abdomen flushed, and a drain inserted.—J. E. Platt.

Cancer of the Rectum.—Do not operate radically if the patient is very weak; if there are metastases; if the mass is firmly anchored in the pelvis; if glandular infection passes beyond the reach of the finger; and if acute obstruction arises.—Hochenegg.

Adhesive Perigastritis of the pyloric region with symptoms of ulcerative stenosis was successfully treated by gastro-enterostomy. This is the rational method in the vast majority of cases.—Westphalen and Fick, *Deutsche med. Wochensch.*, No. 52, 1899.

Neuralgia.—Successful resection of the perineal branch of the internal pudic nerve for severe urethro-cystitis, is accomplished by cutting down upon the internal pudic at its point of passage through the small sacro-sciatic notch.—Rochet, Report of French Association of Urology.

Anthrax.—Make a ring of dough about the pustule about 4 cm. deep, and fill the centre with lye made from equal parts of wood ashes and lime; leave on for four hours. The best results are obtained by early and complete excision, but this is not always possible to carry out.—Andreu y Pahi, *Gaceta Med. Catalana.*

Post-Puerperal Psoitis is to be thought of after severe labor when fever is associated with marked pain in the iliac fossa, especially on extending the leg, and a tumor is made out. It must not be confounded with renal affection, perinephritic phlegmon, abscess by congestion, and especially appendicitis with abscess. The best possible drainage is the proper treatment.—Walter C. Wood.

Secondary Hemorrhage will be less likely to occur if just before closing the abdomen the operator carefully inspects all ligatures and raw surfaces and takes a final look at any portion of the omentum which has been adherent or ligated. If the table be lowered to the horizontal position and a clean sponge be introduced into Douglas' pouch for a few minutes, the stain noted after removal will be an index of the amount of oozing.—M. A. Crockett, "Gynæcology."

Operation in Gastric Ulcer should be done (1) in all cases of perforation at the very earliest possible moment—also in subphrenic abscess; (2) in cases of hemorrhage (*a*) when there is continual oozing of blood, especially if the stomach be dilated, and (*b*) in cases of repeated severe hemorrhage; (3) in cases in which there is severe pain and vomiting unaffected by treatment, and which is producing progressive emaciation; (4) in case of dilatation of the stomach from contraction within or from adhesions outside the stomach.—Bidwell.

Operations for Ascites.—In the ascites of cirrhosis the liver may be exposed by an abdominal incision and the adjacent surfaces of the liver and diaphragm scraped by means of the finger or a sponge.—Drummond.

A ligature may be passed through the edge of the liver, the omentum, and the cut parietal peritoneum. The omentum can be brought up between the liver and diaphragm by tying the three sutures together.—Rolleston.

Suprapubic drainage is necessary when there is a large amount of fluid present and when there has been a rapid reaccumulation of fluid after tapping.—Swain, *Bristol Medico-Chirurgical Journal*, March.

Carbuncles are best treated by extirpation, which is no more painful than incision.—Rushton Parker.

Pylorectomy will give better results as time goes on, especially if performed early when the patient's strength is retained.—Richardson.

Stammering in a boy aged thirteen years was cured by temporary craniectomy for depression due to lack of cranial development.—Jonnesco.

Before Operating it should be discovered whether the patient gives any history of malaria. This may save anxiety when the temperature suddenly goes up afterward.

Cancer of the Tongue.—The danger of sepsis, which is the chief cause of mortality after operation, can be lessened by thoroughly cleansing the mouth and teeth for several days before operation.—Cheyne.

Chancroids should be washed twice a day for fifteen minutes with a two-per-cent. creolin solution at a temperature of 100° to 108° F.; after drying they should be dusted with salol and a bandage applied.—Grimeperte.

Needles are best kept in a saturated solution of washing-soda. Lysol is good, but the color hides the needles. Albolene is also a good medium, as is likewise absolute alcohol containing calcium chloride.—Dawbarn.

Cyst of the Breast.—There is little evidence that general cystic disease of the breast degenerates into cancer. The cysts which occasionally develop at the menopause during the process of involution need not be interfered with.—W. T. Bull.

Vaginal Antepartum Douches should be employed only if there is any purulent or putrid discharge, such as caused by gonorrhœa or cancer; and if any operation is to be performed in which the hand or instruments have to be introduced into the uterus.—Jardine.

Laminectomy should not require more than half an hour's time, diminishing shock. Sepsis is the only danger. There should be a single median incision. Operation should not be done till the shock of the accident has passed, and not at all if the cord is known to be completely crushed or divided.—J. C. Munro.

Cancer of the Breast.—The disease is more frequent in the upper and outer quadrant. Medullary cancer is far more apt to recur than scirrhous.—Warren.

The pectoral fascia must invariably be removed, and if the whole great pectoral is not taken away, at least a superficial layer must be dissected off.—Cheyne.

It seems impossible to doubt that in certain instances oöphorectomy causes the cancer to disappear. It may be of value as a palliative operation.—Stanley Boyd.

The supraclavicular region should almost invariably be cleared out.—Halsted.

A mask should be worn by the operator to prevent wound infection from the mouth and nose.—Huebener.

Rubber gloves are the only effective kind for surgeons' use. The hands must be as carefully sterilized as though the gloves were not to be worn.—Lockett.

Society Reports.

THE PRACTITIONERS' SOCIETY.

One Hundred and Fifty-fifth Regular Meeting, Held on Friday, April 6, 1900.

A. Alexander Smith, M.D., President, in the Chair.

Two Cases of Hypertrophy of the Spleen of Difficult Explanation.—These were presented by Dr. Andrew H. Smith.

Case I.—Male, aged twenty-six years, was admitted to the Presbyterian Hospital on November 28. 1899. His family history was negative. When the patient was eleven years old he had an attack of typhoid fever. Ten years ago he had an irregular fever which lasted for ten or twelve days; at that time he had no chills, but he was greatly prostrated with nausea and vomiting. He was treated at a hospital in Savannah, Ga., and cured by the administration of quinine. He had never had a similar attack since. Six years ago he had an attack of rheumatism which lasted two months; during this attack he suffered much from palpitation of the heart and dyspnœa. He was only a moderate user of alcohol, and denied syphilis. About a year ago the patient began to have a sense of oppression over the chest, with slight dyspnœa on exertion. He also had rheumatic pains in the joints. These continued with more or less intensity for four months. He also had some cough and several slight hæmoptyses, and lost considerable strength but no flesh. His appetite was poor; the bowels were regular. He paid a visit to his home in Sweden, and returned to this country two months ago, slightly improved. Examination showed a man of large frame, well nourished but somewhat anæmic. The lungs were normal. The heart's action was regular; the apex impulse was in the fifth intercostal space, three and one-half inches to the left of the median line. Over the third right space was heard a faint systolic and a louder diastolic murmur, the latter being transmitted up and down the sternum and heard loudest over the third right space at the sternal margin. The pulmonary second sound was somewhat accentuated. The liver was percussed from the fifth space to the free margin of the ribs; its edge could not be felt. The spleen was enormously enlarged, being percussed as low as the umbilicus; its surface was distinctly felt, but its edge could not be made out. The pulse was soft and regular. The urine was negative. An examination of the blood on December 5th showed sixty-five per cent. of hæmoglobin; red cells, 4,396,000; leucocytes, 7,000; there was marked relative lymphocytosis. On December 6th a blood culture was made with negative results.

Case II.—J. H——, male, aged twenty-five years; a native of the United States; a cook by occupation. He was admitted to the Presbyterian Hospital on October 17, 1899. His mother had died of cancer of the breast; the other members of his family were alive and well. There was no history of leukæmia. The patient stated that he had always had a sallow, yellowish color, and had never been very robust. As a boy, while living on the Delaware River, he had repeated attacks of chills and fever, recurring every summer until he was seventeen years of age, when he went to sea; this was eight years ago. Fourteen years ago he first knew of any trouble with his spleen. At that time he had an attack of intestinal obstruction, and was very ill for two weeks, recovering without operation. For some time after that his abdomen was increased in size, but gradually it resumed its normal dimensions. Two years later he had typhoid fever and was ill for two months. Three years after that he had a second attack of typhoid fever, which was treated at the German Hospital in this city. The following year he had an attack of what was pronounced to be "typho-malarial fever." Six years ago, while in Australia, he had scurvy; at that time his teeth became so loose that he could easily have pulled them out. He recovered, however, but some months later an ulcer formed on his leg which failed to heal until his return to America, three years ago; recently this ulcer broke out again. Four years ago he had pneumonia at Bellevue Hospital. During the past five or six years, whenever the patient visited his home on the Delaware River he had repeated attacks of chills and fever, the last one about a year ago. The patient denies venereal disease. He had at times used alcohol to excess, but drinks infrequently. He had never had any vomiting to speak of, nor hemorrhages from the mucous membranes; he had never noticed any glandular enlargements. Examination showed the impulse of the apex of the heart to be in the fourth space, two and one-half inches from the median line. The heart's action was regular. There was a blowing systolic murmur, heard at the apex and upward along the left sternal margin to the pulmonic area. There was also a loud systolic murmur heard over the aortic area. The area of cardiac dulness was apparently not increased. The lungs were normal. The liver was percussed from the fifth space to an inch and one-half below the free margin, where its edge was felt. It was tender to the touch. The spleen was very much enlarged, extending about an inch to the right of the umbilicus, and three inches below that point it was distinctly felt. Its surface was smooth, hard, and not tender. The organ was so large that it could be grasped between the two hands. The abdomen was prominent over the splenic region; otherwise it was normal. While the patient was in the hospital he had an attack of acute pleurisy, without effusion, from which he made an uneventful recovery. A blood count, made on October 24th, showed 3,056,000 red cells and 17,000 leucocytes, with thirty-eight per cent. of hæmoglobin. The blood was carefully examined for malarial organisms, but none was found. The urine was negative throughout. On February 14, 1900, the patient was readmitted to the hospital for an attack of lobar pneumonia. Three days later an examination of his blood showed 4,120,000 red cells, 17,000 leucocytes, and forty-five per cent. of hæmoglobin. He made an uneventful recovery from his pneumonia.

In both of the preceding cases, Dr. Smith said, the point to which he desired to direct particular attention was the enormous chronic enlargement of the spleen, to which no adequate cause could be assigned.

Dr. George L. Peabody said that in the second case shown by Dr. Smith the enlarged spleen was probably attributable to chronic malarial infection, of which disease the patient gave a history dating back many years. He also gave a history of having had three attacks of typhoid fever, and it was possible that one or more of these were really malaria instead of typhoid.

Dr. E. G. Janeway said he thought the second patient shown by Dr. Smith could be put down as one of the old-fashioned ague cases. In the first case he did not care to venture a positive opinion as to the cause of the enlarged spleen. There was possibly some obstruction to the portal circulation, without dropsy. The possibility of a cirrhosis of the liver, with irregular manifestations, should always be borne in mind, and further developments awaited. The speaker said he had frequently seen cases of supposed pseudo-leukæmia at Bellevue Hospital turn out to be cases of cirrhosis of the liver, in spite of the fact that the patients absolutely denied an alcoholic habit.

Dr. Beverley Robinson expressed the opinion that the use of the microscope could not be relied upon in the diagnosis of chronic malaria, nor, in many instances, could the usual anti-malarial remedies be depended upon.

A Case of Heart Disease with Some Unusual Features.—This case was presented by Dr. J. W. Brannan. A. J——, a colored boy, aged sixteen years, was admitted to Bellevue Hospital on March 21, 1900. His father died of pneumonia; his mother was alive and well. His sister and grandmother had suffered from rheumatism. According to the statement made by the boy's aunt, he had been a healthy baby, but at the age of five years he had had an attack of acute articular rheumatism, and again two years later. In both of these attacks his heart was affected, and since his second attack he had always suffered more or less from dyspnœa, with cardiac pain and palpitation. Five years ago he had an attack of dizziness and fell to the floor, but did not lose consciousness. He was put to bed and remained there for five weeks. His present illness began about March 1st. He had a severe cough, with muco-purulent expectoration and pains in the chest. No blood was raised. His ankles and knees became swollen, painful, and tender, and he was unable to walk. His dyspnœa at times became so severe that he could not breathe comfortably in the recumbent position. No ascites was found. On examination the heart apex was difficult to locate. Its impulse was made out with the greatest distinctness in the fifth space in the nipple line, two and three-quarter inches from the mid-line of the sternum. It varied in force. The impulse at the base was stronger than at the apex. Over the whole precordium there was a systolic thrill, with its maximum intensity in the second left intercostal space. Over this same area was also heard a loud, long, rough systolic murmur, with its maximum intensity in the second left space, close to the sternum. The murmur was heard with great distinctness over the entire chest in front and behind, most distinctly on the left side. The heart's action was rapid and irregular. The second aortic sound was absent and the second pulmonic accentuated. The left border of the heart was three inches outside the median line; its upper border was at the third rib; the right border was three-quarters of an inch to the right of the edge of the sternum. Examination on April 1st showed the apex impulse to be fairly well localized in the fifth space, two and three-quarter inches from the median line. The heart's action was more regular and the dyspnœa had disappeared. The murmur was heard as at the first examination, with its maximum intensity in the second space to the left of the sternum. There were marked pulsation coincident with the murmur and thrills in the second and third left spaces. The murmur was heard loudest posteriorly higher up than usual, about the level of the spine of the scapula. It was also apparently transmitted into the great vessels of the neck and axilla. The patient had been up and about the ward during the past few days doing light work. Dr. Brannan said he was in doubt as to the nature of the cardiac lesion in this case. The possibility of a pulmonary lesion had been considered, but in the absence of any signs of venous congestion and the fact that the patient had not been a "blue baby," that diagnosis was rather doubtful. On the other hand, it was the right side of the heart that was mostly enlarged. The aortic second sound was lost, or at all events was very indistinct. The pulmonary second sound was markedly accentuated. There was nothing abnormal in the sphygmographic tracings. They certainly did not indicate stenosis of the aortic orifice. There was no change in the murmur when the patient was in a recumbent position, nor when the lung was inflated and fixed or held in the position of complete expiration. The possibility of aneurism of the descending portion of the arch of the aorta and pressing upon the pulmonary artery had been suggested. The similarity of the sphygmographic tracings in the two radials was opposed to this diagnosis.

Dr. Peabody said the case presented by Dr. Brannan was certainly an unusual one. The murmur was a very loud one, with its point of maximum intensity over the pulmonary area. The fact should be borne in mind that the loudness of a murmur was not always an indication of its seriousness. Dr. Peabody said he was inclined to think that the murmur in this case was a mitral one. The absence of certain symptoms which one would expect to find in a pulmonary cardiac lesion should be taken into consideration in making the diagnosis.

Dr. Janeway said that a case of this kind would require repeated examinations before a definite opinion as to the nature of the cardiac lesion could be arrived at. The right ventricle did not appear to be particularly enlarged. Mitral stenosis, in rare instances, gave rise to some of the phenomena observed in this case, or possibly its unusual features were due to some anatomical abnormality. The speaker said that some years ago he saw a boy who had a loud heart murmur which was abnormally situated. At the autopsy it was found that the aorta sprang from the right ventricle and the pulmonary artery from the left. He said he did not think the case shown by Dr. Brannan was one of mitral insufficiency, because the murmur was so loud above and less distinct in the area where it was usually heard when the mitral valves were insufficient.

Dr. Andrew H. Smith said he agreed with Dr. Janeway that Dr. Brannan's case required more prolonged study before an explanation of its unusual phenomena could be given. The speaker said he was struck by the fact that the murmur could be heard very distinctly posteriorly and along the dorsal spine. He was inclined to believe that the case was one of mitral regurgitation, and that the thrill and the unusual location of the sounds were the result of some abnormality existing in the auricle by which the backward current from the ventricle was made to form an eddy.

Dr. Robinson said that, in considering a case of this kind, the symptoms and general condition of the patient should be borne in mind. The diagnosis probably lay between mitral stenosis and mitral regurgitation, as it was highly improbable that a pulmonary lesion was the cause of the murmur. That the location of the bruit would not always enable us to distinguish positively between a mitral stenosis and regurgitation was proven by the late Dr. J. West Roosevelt in a paper on this subject which was based upon the post-mortem records at Roosevelt Hospital. In obscure cases like the one shown by Dr. Brannan, repeated examinations might perhaps enable us to make out the cause of the trouble, but our diagnosis could only be verified on the post-mortem table.

A Case of Bullet-Wound of the Brain.—This case was presented by Dr. Robert Abbe. The patient was a man forty years old, who was shot in the head sixteen years ago. The missile, which was a small rifle bullet, entered the forehead near the hair-line an inch to the left of the centre, and became embedded in the brain. The bullet gave rise to no trouble until four years ago, when the man had an epileptic convulsion which was repeated in six months and gradually came more frequently. Now it recurred every two weeks. An *x*-ray picture was taken, which located the bullet in the brain, about one-third the distance between the frontal and occipital bones, and about an inch and one-quarter below the vertex. Dr. Abbe said he intended to operate on this patient, as the convulsions were possibly due to pressure from an indurated scar or to the presence of bony spicules. The bullet was a small one and probably could be removed.

Dr. Charles L. Dana said he had seen a number of cases like the one shown by Dr. Abbe, and in one instance he had had an opportunity to examine the brain after death. It was not particularly rare to have epilepsy develop some years after the receipt of an injury of the brain. In the case which the speaker had in mind the patient developed generalized epileptic attacks and subsequently died of alcoholism. The brain showed a certain amount of cortical cellular degeneration, such as was seen in degenerative epilepsy. This cellular degeneration was usually at the bottom of the epilepsy, and it continued whether operation was done or not. In the case shown by Dr. Abbe the convulsions set in so long after the accident that an operation could hardly be expected to do much good. At the same time, it could be done with comparative safety.

Dr. Janeway said the man admitted having had syphilis twenty years ago.

Dr. H. M. Biggs said that some time ago he performed an autopsy on a man who had committed suicide. In addition to the bullet which had caused his death, an old, encysted bullet was found in the frontal lobe of the brain, and it was afterward learned from the man's relatives that he had made an attempt at suicide by shooting himself in the head ten years before. The bullet had apparently remained embedded there for ten years without giving rise to any symptoms.

Dr. Abbe said that if any improvement would result from the operation in the case he had shown, he thought it would be due more to the removal of scar tissue, cortical adhesions, or cyst, or, probably, of osteophytes, than from the removal of the bullet itself. The speaker recited cases of severe epilepsy which he had relieved for varying periods by the release of adhesions.

Remarks on Some of the Conditions Simulating Appendicitis and Peri-Appendicular Inflammation. —This paper was read by Dr. E. G. Janeway (see p. 897).

Dr. Robert F. Weir said that surgeons were well aware of the difficulties occasionally encountered in the diagnosis of appendicitis. Many of the rarer conditions simulating this disease could be recognized only after much study and observation, and not infrequently an exploratory incision was necessary in order to clear up the diagnosis. Probably three of the most common conditions which were mistaken for appendicitis were those associated with a displaced kidney, or with perforation of the gall bladder, or with perforation of the stomach or duodenum. The speaker said he had recently collected fifty-one cases of duodenal perforation, three-fourths of which had been regarded as cases of appendicitis and operated on as such.

Dr. Joseph D. Bryant said that a mistaken diagnosis of appendicitis was probably often due to the fact that the anatomical relationship of the appendix to other contiguous organs was an uncertain one: it was not always found in one particular region. Hence, any derangement of that appendage might easily be confounded with a diseased condition of the ovary, or kidney, or gall bladder, and *vice versa.* The speaker recalled the case of a man who suffered from neuralgia, associated with symptoms of gastric and intestinal trouble due to the excessive use of alcohol; his neuralgic pain simulated appendicitis, and he was twice operated on under the supposition that he was suffering from that disease, and subsequently he was refused operation at two hospitals where he applied for relief from the same trouble. Dr. Bryant said that another case which came under his observation was that of a girl aged seventeen years, with an hysterical tendency, who complained of excessive pain in the region of the appendix. There was a slight increase of temperature and a small tumor could be made out. An operation cured her, but it also revealed the fact that she had no appendix at all, the usual site of the appendix being occupied by a small elevation, scarcely half an inch in height. He said he had seen cases of perforation of the stomach and duodenum which were regarded as examples of appendicitis. In one instance of the former there was a perforation, and the escape into the peritoneal cavity of gastric contents had set up an extensive circumscribed peritonitis, which after much suffering gave rise to the formation of an abscess pointing to the left of the median line and just above the umbilicus, when the patient came to his attention. A free incision at that point permitted the discharge of the collection and established a diagnosis through the presence of gastric juice a few hours later. This patient made a prompt and complete recovery. A perforation at the posterior surface of the duodenum, complicating a pronounced and long-extended alcoholic debauch, was mistaken for an attack of acute appendicitis with perforation, in an instance coming beneath his observation. Another source of error in the diagnosis of pathological conditions in the appendicular region lay in confounding the fibrous exudation of chronic appendicitis with malignant disease of the cæcum. Such a case was recently reported at the New York Surgical Society. A similar one not long since came under the speaker's observation. The patient was supposed to have appendicitis. The surgeon upon opening the abdomen found a large mass which he then regarded as inoperable sarcoma of the cæcum, whereupon he abandoned the operation and closed the wound. Subsequently the patient came under the speaker's care, who found a large, compact tumor composed of fibrous exudate, from the centre of which the appendix was removed and submitted to Dr. Dunham for microscopical examination. The walls of the appendix were greatly thickened from chronic inflammation. No evidence of perforation or ulceration was noted. After removal of the appendix, the exudation was rapidly and completely absorbed, and the patient had remained entirely well since the operation. Another case, presumptively of the same character, had lately come to his attention. There was slight elevation of temperature, attended with the presence of a large fibrinous deposit involving the cæcum, and other manifestations indicative of chronic fibrous appendicitis. The abdomen was opened and revealed peritoneal surfaces which were perfectly smooth, presenting no evidence of any inflammatory action except at one point about the size of a head of a pin, to which omentum was adherent; also numerous enlarged mesenteric glands were found. The new formation was extensive and fixed to the deep underlying bony tissues. It was highly vascular, presenting other physical characteristics of inoperable sarcoma, which the tumor was considered to be, and the wound was closed. Subsequently the growth began to diminish in size and finally disappeared entirely. Not infrequently in the current medical literature of the day apparently similar examples were noted, for which excision of the cæcum was practised, when possibly the removal of the appendix might have sufficed.

Dr. Walter B. James said he had often been impressed with the fact that although in the majority of cases of appendicitis the diagnosis was easy, yet in a certain number of cases the true state of affairs remained in doubt in spite of the most careful observation. In some instances an absolute diagnosis was impossible. Such an example recently came under his observation. The patient was a physician, the house surgeon in one of the hospitals in this city, who developed an agonizing pain in the right iliac region. He had a sharp chill, followed by a rising temperature, and in the course of a few hours there was intense tenderness over the lower abdomen. The symptoms were typical of a ruptured gangrenous appendix, with the rapid effusion of serum into the lower peritoneal cavity. He was operated on four or five hours later; the appendix was found to be inflamed, but there were no evidences of peritonitis, no rupture, and no fluid in the peritoneal cavity.

Dr. William T. Bull said that he could recall quite a number of instances in which a wrong diagnosis of appendicitis had been made by both physician and surgeon—cases of right-sided pleurisy and pneumonia and inflammations of the gall bladder. In order to avoid such errors, one or two factors should be borne in mind. In arriving at a diagnosis of appendicitis, considerable weight should be attached to the presence of an actual inflammatory exudate in the appendical region. If this could not be detected, and there was simply local tenderness in the iliac region, with some fever, Dr. Bull said he was rather disposed to wait. In certain doubtful cases, the use of an anæsthetic was of the greatest service, both to the physician and to the surgeon, in order to overcome the muscular rigidity which often existed. In more than one instance this had helped him to clear up the diagnosis. With reference to chronic cases of appendicitis, Dr. Bull said he had no doubt that many errors had been made. Still, the fact should be borne in mind that in operating for chronic appendicitis an appendix might be removed which was apparently perfectly healthy, and which still might have been the seat of disease. Many such attacks cleared up and left a fairly normal appendix; yet its removal might be desirable on account of the repeated attacks which it had given rise to. The recognition of chronic appendicitis by palpation, Dr. Bull said, seemed to him a rather uncertain procedure, in spite of the fact that some surgeons had made the assertion that they could feel such an appendix distinctly. The speaker said he had often found that what he supposed to be the thickened appendix proved, upon operation, to be the edge of the psoas muscle, or a thickened mesentery or wall of the colon. The diagnosis of chronic appendicitis by palpation had been strongly insisted upon by some rather persistent writers on this subject, and one writer had found the condition very frequently associated with floating kidney. Dr. Bull said he had good reason to believe that in many of these cases the diagnosis rested upon a false bottom. He had seen a number of cases in which small neoplasms of the ileocæcal region were confused with appendicitis; such were very difficult to recognize. This was also true of cases in which peritonitis had already set in. It might be due to a perforating appendicitis, or to a perforation of the stomach, duodenum, or gall bladder, and an exploratory incision was necessary to reveal its starting-point.

Dr. Peabody said he did not think that cases of abdominal neuralgia, to which reference had been made, were often confused with appendicitis. The intermittence of the symptoms in neuralgia was far more marked than in cases of appendicitis; besides, the thermometer would help clear up the diagnosis. Dr. Peabody said he had seen a number of cases of typhoid fever which had been operated on for supposed appendicitis. In those cases, the wound interfered materially with the hydrotherapeutic treatment of the fever. In one case, the speaker said, he mistook a ruptured gall bladder, with tenderness, pain, and fever, for appendicitis. An operation revealed the true state of affairs. In any case of supposed acute appendicitis, in which an exudate or some foreign mass could be felt, we were not likely to go far astray by advising an exploratory operation.

Dr. Robinson said he had seen a certain number of cases of supposed appendicitis, both in children and adults, with localized pain in the appendical region, with a certain amount of fever, and perhaps more or less resistance in that region, in which the patients recovered without operative interference, and the true nature of the lesion was therefore left in doubt. On the other hand, there were undoubted cases of appendicitis which resulted in recovery without operation, and the general practitioner was often placed in a very uncertain state of mind as to whether the gravity of the case demanded the aid of a surgeon or not.

Dr. Abbe said that his most troublesome cases of doubtful appendicitis had been in women, in whom the question of ovarian or tubal trouble became a factor. In a number of such cases in which he had operated, he found that the inflamed appendix had attached itself to the pelvic organs, and thus helped to confuse the diagnosis. He said he had very rarely been able to palpate the appendix in cases of chronic appendicitis. What he regarded as the appendix had usually proved to be the border of the external oblique muscle. Although the gross appearance of the appendix in cases of chronic latent appendicitis might be fairly normal, its interior would almost invariably be found to be diseased. This, the speaker said, he had proved by distending and hardening hundreds of such specimens in alcohol, and then, upon section, the diseased condition of the interior could be plainly made out (see Medical Record, July 10, 1897). After a very severe, or even a fairly severe, attack of appendicitis, the lumen of the tube might become entirely obliterated by the hypertrophy of the mucosa, and adhesion of its inflamed and denuded lining. No future attacks would occur. This explained the occasional spontaneous cures after one severe attack. It was so rare to have this occur, however, that much stress should not be laid upon it.

Dr. Peabody said that on one occasion, at a meeting of this society, during a discussion of this subject, the late Dr. —— related at length the history of a very severe attack of what was probably appendicitis—although it occurred long before that name was given to the disease—which he passed through while a student at Harvard twenty years previously. After his death Dr. Peabody made an autopsy and failed to find any trace of the appendix, not even a fibrous cord. It had probably been destroyed by the inflammatory process years before.

Dr. Biggs said that one was impressed very much by the frequency with which evidence of disease in the appendix was met with at autopsy. Sometimes very extensive changes in the appendix were observed in cases in which the patient had given no history of ever having had trouble in that region.

Dr. A. H. Smith said he recently saw a patient with right-sided pneumonia, who complained of a great deal of pain and tenderness in the region of the appendix, although his trouble was clearly confined to the lungs. He also recalled a similar case which he saw some years ago. That patient complained of pain in the right side of the abdomen, and gave a history of having eaten a heavy, indigestible meal and afterward exposed himself to the cold: all the symptoms pointed to the abdomen as the seat of the trouble, but shortly afterward he developed a right-sided pneumonia which proved fatal. It was a recognized fact, Dr. Smith said, that the pain of pneumonia might be referred to a region distant from the seat of the trouble.

Dr. Weir said he wished to corroborate the statements made by Drs. Bull and Abbe with reference to the unreliability of palpating the appendix in cases of chronic appendicitis. When the appendix was enlarged it could at times be felt, but an appendix of the ordinary size could not always be palpated satisfactorily; at least that had been his experience.

Dr. Bryant said he wished to add his evidence to the confirmation of the statement just made by Dr. Weir. The speaker said that in probably one-half the cases in which he had been called upon to operate he had been unable to locate the appendix correctly, as proved by the operation. In many cases in which he thought he had located the organ, it proved to be something else that he had felt; in one case it was the psoas muscle.

Dr. F. P. Kinnicutt expressed the belief that oftentimes in these cases the induration which was palpable, and which was regarded as an inflammatory exudate, was in reality the resistance due to the rigidity of the muscles. The speaker said he entirely agreed with the previous speakers regarding the unreliability of palpating the appendix in cases of chronic appendicitis. The case reported by Dr. James was supposed to be one of chronic appendicitis, the patient having had six or seven attacks during the past two years: in spite of this, frequent examinations made during this period failed to elicit any positive signs of an enlarged appendix. Operation demonstrated the existence of a chronic appendicitis.

Dr. Janeway, in closing, said it had not been his intention, in his paper, to speak of all the conditions which might be or which had been mistaken for appendicitis. He mainly wished to emphasize the fact that the diagnosis of appendicitis was often jumped at too quickly, and too much import placed upon the pain, tenderness, and muscular rigidity. He said he agreed with the previous speakers that, as a rule, the appendix was not palpable with certainty in chronic appendicitis.

RADICAL CURE OF EPITHELIAL CANCER BY ARSENIC.

BY C. TRUNEČEK, M.D.,

PRAGUE, AUSTRIA.

ARSENIOUS acid is one of the oldest remedies used in the treatment of epithelial cancer. This fact alone would not justify the conclusion that it is a specific in this disease, for nearly the whole materia medica has been used at various times, and often with apparent success, in its treatment. But considering the ease with which certain kinds of cancer are cured by arsenic, it is almost certain that some cases of epithelioma have been cured by arsenious acid. As it is not within the scope of this article to enter into the history of this department of medicine and surgery, it will suffice to say that arsenic has been repeatedly recommended for this special disease. Various have been the reasons why it has failed of universal adoption, and has fallen into disuse. In some cases the diagnosis of cancer cured by arsenical treatment was not convincing, and in other cases there was a prejudice against the treatment, more or less justified by its many failures. A third reason appears to consist in the fact that the different varieties of epithelial cancer have not been sufficiently taken into account. For although the arsenical preparations, such as the paste made by the Brothers Côme, contained many useless substances and altogether too much arsenic, still they did cure some varieties of cancer. They also destroyed normal tissue, a disadvantage which they shared with all methods.

Within the past ten years experiments have again been made with arsenic as a remedy against cancer. Lassar claims a rapid cure in several cases of cancerous ulcers by the internal administration of Fowler's solution, but they were merely small ulcers which had never been operated upon. Since in other analogous cases this method was a total failure, it cannot be said to have greatly enriched our knowledge of the therapeutics of cancer. A real step in advance, however, was made by Hue, who injected an aqueous solution of arsenic into the midst of the cancerous masses (0.20 gm. arsenious acid, 100 gm. distilled water [gr. iii$\frac{1}{3}$ to fl. ℥ iii$\frac{2}{5}$]). His method, however, has not become widely known, partly because he brought forward no proof of its value, and partly because it is of such difficult application. Von Esmarch used arsenious acid in the treatment of cancer some time before the authors mentioned above, and according to Momburg[1] he used a mixture of 0.25 gm. (gr. iv$\frac{1}{6}$), 0.25 gm. morphine, 2 gm. (gr. xxx.) calomel, 12 gm. (ʒ iii.) gum arabic; the result is not given. The treatment of Félix* consists in the application of a paste, one-half zinc chloride, the other half mostly of indifferent substances, but containing arsenic. This method is a combination of ancient arsenical treatment and of treatment by simple caustics, that is to say, chemical agents capable of destroying any part of the body, whether normal or diseased. It scarcely deserves mention, since the same effects are more rapidly and easily attained by operation, but the author claims that in his experience relapses do not occur.

With the exception of the above-mentioned rare modes of treatment, which never became general, arsenic fell into absolute disuse as a remedy against cancer. It was, however, given internally to improve the general condition of patients suffering from cancer. The experiments of Billroth and von Esmarch in this line are well known, yet these authorities state that they have never seen a single case of cancer cured by arsenic.

In 1897, together with my collaborator, Dr. S. Cerny, I published a work[2] in which I tried to show that under certain conditions arsenious acid gives a constant reaction with cancerous tissue, and that by its aid we may radically cure some varieties of epithelioma. Since that time the method has been tried in several clinics and hospitals, and with good success to judge by the reports published.[3, 4]

I will first give a detailed description of the method itself, and then the indications, and, after having described two typical cases in which a cure was obtained, will briefly describe the mechanism of the cure of cancer by means of arsenious acid.

I.

℞ Acid. arsenios. pulver....... 1 gm. (gr. xv.)
Alcohol. ethyl. absol.,
Aq. destillat ....āā 75 gm. (℥ ii. ʒ ivss.)
M. S. For external use.

The remedy as prescribed in the works quoted above is a mixture of arsenious acid (As_2O_3) and of 75 gm. of ethylic alcohol (C_2H_6O) with an equal amount of distilled water. It is applied as follows: The ulcer is cleansed and dried; we must not be afraid of causing a slight flow of blood; indeed, it may even be necessary to scrape and denude a portion of the neoplastic tissue. The arsenical mixture is then stirred and spread with a brush over the whole surface of the tumor. Without covering it, it is left to dry, and if at the end of five minutes the patient feels no pain, another layer of the mixture may be spread over the cancer. No dressing is placed upon it.

The patient sometimes has pain after the application, but not of an unbearable nature. The next day, or perhaps not until the day after that, the neoplasm will be found to be covered with an eschar (especially in the denuded or scraped portions), which is not removed, but treated daily with the preparation of arsenic. Acute œdema of surrounding parts may be caused by the application, in which case the treatment is suspended until the œdema has completely disappeared, after which the remedy is used in lessened amount. The crust, thin and yellowish at first, becomes gradually brown, and finally black. The first day its base is firmly adherent to the subjacent tissue, and its removal would bring away a large amount of cancer substance. By degrees it thickens and invades the whole surface of the neoplasm. After a while its edges become less adherent and begin to be detached; the fissure thus formed becomes daily more marked, and a greenish fluid oozes out from the edges of the ulcer. Treatment is continued regularly until the eschar is freely movable, non-adherent to the subjacent tissue, and is easily removed, or falls of itself. This eschar is of variable thickness, is hard in consistency, and is essentially formed of cancerous tissue which has mortified under the influence of arsenic. The scab being removed, another application of the arsenical mixture is made to the bottom of the ulcer, but only once. If by the next day I find merely a yellowish crust which can be easily removed without causing any hemorrhage, I may be sure that no cancerous tissue remains in the wound. If, on the other hand, there is a dark crust adherent to the subjacent tissue, the treatment is continued until the last cancerous cell has disappeared.

---

* "Des caustiques dans le traitement du cancer." Brussels, 1892, Manceaux, publisher.

During the course of the treatment, as the eschar thickens, the amount of arsenic should be increased. Instead of the 1 : 150 solution used in the beginning, a 1 : 100 or even a 1 : 80 is used, according to this formula:

℞ Acid. arsenios. pulver.......... 1 gm. (gr. xv.)
Alcohol. æthyl. abs.,
Aq. destill....................āā 40 gm. (℥ i. ʒ ii¾)
M. S. For external use.

When no vestige of cancerous tissue remains, the neoplastic ulcer is transformed into a granulating wound, covered with a fine whitish membrane, and possessing no induration anywhere. It should now be treated as an ordinary suppurating surface which is beginning to be covered with granulations. For the stimulation of the regenerating tissues an ointment consisting of one part boric acid to ten parts vaseline should be applied, especially to the edges of the wound. Even when every vestige of cancer seems to have disappeared, it is well to make assurance doubly sure by occasionally making a light application of the 1 : 150 mixture until a cure is attained. When the neoplasm has been entirely destroyed, the applications no longer produce a black, adherent crust, and the alcohol contained in the remedy merely helps to cleanse the wound.

For superficial, non-ulcerating cancers, in which mere surface applications give no result because the remedy does not destroy normal epithelial and epidermal cells, we should proceed as follows: if the integument is very thin and adherent to the tumor, it will usually be all-sufficient to scarify slightly the adherent portion, and to apply the remedy in such a way that some of the arsenic will penetrate to the cancerous tissue. If the skin has not yet been invaded by the neoplasm, it will be found best to excise a small cutaneous flap with the scissors, and then to make an application of the remedy, leaving it as usual without dressing. The applications are repeated daily, and after three or four of them we see the tumor diminish in size and become dried. Treatment is continued up to complete cicatrization. The same method of procedure is indicated in the case of the cancerous nodules sometimes found under the adjacent skin during treatment or subsequent to the cure of a neoplastic ulcer.

Instead of using a brush, we may, if we prefer, fix a pledget of wadding on forceps, or wrap cotton around a probe, as I did in an undoubted case of cancer of the larynx, in which cure was obtained and has been maintained for two years. However, although the use of hair brushes is not in strict accordance with the laws of modern surgery and of asepsis, it must be acknowledged that a brush distributes the solution more regularly than anything else and possesses the advantage of not irritating the granulating tissue.

II.

The curability of cancer by the above-described method depends in part upon the stage of development of the neoplasm, and in part upon its location. In regard to the first, a necessary condition is that the ganglia be not indurated; in regard to the second, the tumor must be where it can be reached by the medicament. This can be done in the case of all non-relapsing cancers of the skin, no matter what their extent; cancers of the external auditory meatus, of the lips and the buccal mucous membrane wherever it can be reached, and cancerous lesions of the larynx in an early stage.

In order to specify more exactly the indications for this treatment we will compare the results which it has given with those given by operation.

With the exception of incurable cancers, such as those of the pancreas for instance, we may from a therapeutic point of view divide malignant neoplasms into three groups: The first, and by far the largest, those in which an operation constitutes the only method of relieving the patient, although in truth a permanent cure is the exception rather than the rule (for instance, cancers of the stomach, and all cancerous lesions accompanied by infiltrations of the ganglia); the second, those in which the method described above is the only one applicable,[5] as, for example, large cancers of the skin whose extirpation would leave an enormous wound, some neoplastic lesions of the head where a bloody operation would necessitate too extensive impairment and might even risk the patient's life; finally the third, those in which either method might be used with probable success, and in which the choice may be left to the patient or to the physician. This last group is worthy of a closer study.

In cases in which either procedure is capable of giving good results, and in which we are certain that there is no induration of the ganglia, the method under discussion seems preferable for the following reasons: during the course of treatment we can always ascertain whether any cancerous tissue remains in the wound, a thing which is almost impossible during surgical intervention, owing to the fact that the operative field is hidden by the flow of blood; again, auto-inoculation, which is of easy occurrence during operation, cannot take place when we apply the arsenical mixture, and finally, the latter does not destroy neighboring healthy tissues, whereas operative intervention always does to some extent. This method should be used, whenever possible, in the treatment of cancer of the face, especially of the eyelids, nose, ears, lips, in which surgical measures, even when successful, usually cause frightful deformity. I must not be understood as saying that it is not indicated for other parts of the body, for the prognosis does not seem to be less favorable than in regard to lesions of the lower lip. The great advantage of this procedure, as I have already said, consists in the fact that it destroys every vestige of cancerous tissue without injury to normal tissues. Moreover, in no case have I ever been obliged to apply a ligature, for the cancer was always eliminated without loss of blood, although several of the patients before treatment had had hemorrhages that were difficult to arrest. This is certainly an important advantage.

Cancers of the nipple can be successfully treated by arsenic, and the cure, according to my experience, is permanent. The same may be said for some cases of cancer of the mammary gland, but at present I am unable to give exact statistics. As to neoplasms of the internal organs and of all those accompanied by induration of the ganglia, they are best treated by surgical measures. The same statement applies to relapsed cancers, which I have often succeeded in curing, as we shall see later in the report of a case, yet in regard to which I have not had a sufficient number of cases to establish absolute conclusions.

As to the action of arsenious acid upon the organism, it has been *nil*, even when the lesion was situated in the mouth, and when treatment extended over several months. It may therefore be used in all cases and for as long a time as necessary, without fear of arsenical intoxication. All investigators have recognized this advantage possessed by this treatment.

From what has been said, it is evident that the procedure is especially indicated in the treatment of cancer in its early stages. The therapeutic value of the method may appear to be somewhat limited, but I would call attention to the fact that every cancer has an early stage, and that uncertain diagnosis, and, more frequently still, fear of operation, are what usually aggravate the lesion and cause it to become inveterate. With the possession of a harmless method of treatment, it is to be hoped that cancers with indurated ganglia (that might have been cured in the early stages) will become rare exceptions. Taken in the beginning, a cancer is amenable to treatment by arsenic, and when we find an ulcer we need no longer resort to expectant treatment, as was the case when an operation was the only treatment possible to recommend. This is one reason why the argument that a radical cure can be more quickly obtained by operation falls to the ground. This would be an incontestable fact if the physician was able to make a positive diagnosis at once, or if the patient was willing to submit immediately to an operation. But very frequently even surgeons advise patients having a small ulcer on the lower lip, for instance, to wait awhile, and should the ulcer not heal after some simple antiseptic treatment to have it removed. But by the proper application of our remedy we are enabled to ascertain at once whether we have to do with cancer or not, and in the time usually devoted to expectant treatment, before operation is resolved on, we have cured the cancer by arsenic. If, on the other hand, we are dealing simply with a non-cancerous ulcer, no characteristic eschar is formed, and the ulcer heals of itself.

This method is the only one possible in patients suffering from diabetes, hæmophilia, etc., in whom even a slight operation might cause dangerous or even fatal hemorrhage.

As to the duration of treatment, it would appear that the greater the ulceration the more rapidly the remedy acts. Moreover, in cases in which the cancerous tissue has the characteristics of embryonal tissue, its action is more prompt than in cancroids, in which the cells are corneous. This is the reason why the remedy sometimes acts very slowly upon the superficial layers of a tumor, but when the first eschar, composed of horny cells, has been detached, acts more quickly upon the layers formed of young cells. Small cancerous ulcers which have not been operated upon require three or four weeks for a complete cure, while extensive cancers take much longer; but the physician as a rule does not need to see the patient more than twice or even once a week. On the other days the patient himself applies the solution, and goes on with the daily routine of life as usual. The cure of cancers situated in parts of the body where subcutaneously there is a hard base is much easier, for bone and cartilage are so resistant to the invasion of cancerous granulations that the process extends superficially rather than deeply, which permits of thorough applications of the remedy, even in inveterate cases. In some cases no opinion can be given as to the probable duration of treatment, unless we can tell the depth to which the neoplasm penetrates, for the deeper it goes the more difficult the treatment, and the longer will it last.

This method is, moreover, of value in cases in which the patient absolutely refuses operation, in spite of the fact that it would undoubtedly effect a cure; examples of this condition are described by Hermet and Couraux, in which non-operative treatment, no matter what its duration, was preferred to surgical measures.

III.

Having described the method of application of the medicament, and the indications for its use, I will, to make the treatment more comprehensible, give the history of two cases in which it effected a cure. The first case was one of relatively benign cancer of the face, which had never been operated upon; the second, one of cancer of the lower lip, which had returned after a radical operation, and in which the cancerous masses were found deeply situated in the lip, having either penetrated it in the form of bundles and, finding little resistance in the soft tissues, having grown there with rapidity, or begun there after autoinoculation in the depths of the wound, following operation.

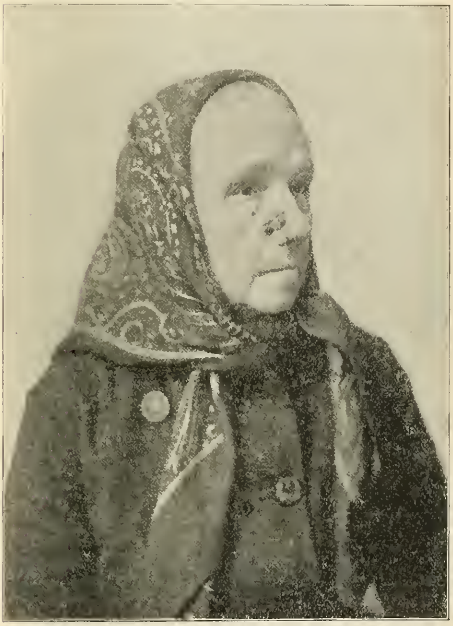

Fig. 1.

The patient, a woman seventy-seven years old, had never been seriously ill, and had never had syphilis. Until the present illness she had never observed any abnormality in the part of the face where the cancer is situated. Eleven years ago a small pimple appeared on the cheek and increased progressively until it had reached the dimensions seen in Fig. 1, from a photograph taken before treatment. Microscopical examination showed cancroid.

On March 6, 1898, I began treatment. I cleansed the ulcer with boric acid, freshened a small portion, applied the mixture 1 : 150, and left it without dressing. The next day a black crust appeared on the scraped portion, and was painted over with the mixture daily. After the third application œdema of the neighboring parts obliged me to suspend treatment for two days. Ten days later moderate pressure on the crust forced out a purulent fluid from the edges, a sign that it was beginning to be detached; on the fourth day thereafter detachment was complete. In the wound, which was treated every other day with the

1:150 solution, another eschar formed and was detached in three weeks, leaving only the débris of cancerous tissue. These having been destroyed by arsenic, the wound was treated as an ordinary granulating surface, but treatment in general was prolonged because of my finding three nodules in the vicinity of the lesion. I pierced these with a pincette à hameaux, and applied the mixture. After three treatments they were dried and transformed into an eschar which healed in the usual way.

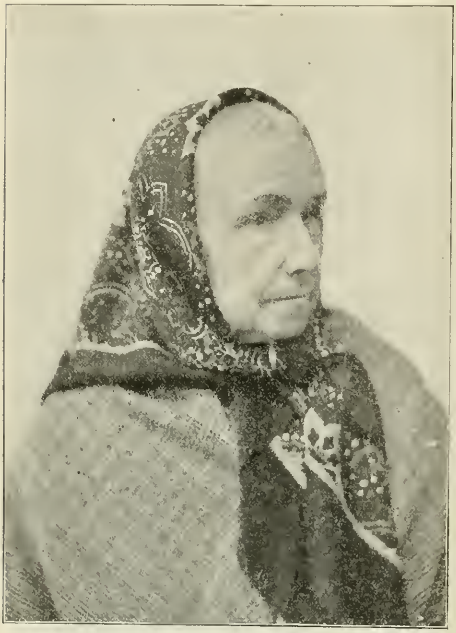

FIG. 2.

The treatment lasted more than three months, partly because toward the last I saw the patient only once a week. As we can see by the photograph of the patient taken after treatment, it is impossible even to tell where the cancer was situated. The result of a successful bloody operation would not have been so good, for there would have remained a deformity of the nose. The patient is cured, and no change has occurred in the cicatrized portion of the face. It is eighteen months since the treatment ended.

Similar cancers in other parts of the body where bone or cartilage form a hard base are more easily cured, and the prognosis is good even in moderate cases. We must always ascertain whether there is any induration in the vicinity of the ulcer, and moreover the granulating wound itself should often be treated with the arsenic so that not the smallest cancerous tissue may remain within it. European medical literature[8-22] contains many reports of cancers cured by this method, and there is a consensus of opinion that it is the best form of treatment for cancer of the face.

The second case is that of a man aged forty-nine years, who has never been ill, and has never had syphilis; until the beginning of the present trouble he never noticed anything abnormal on his lower lip. Three years ago a fissure on the lip was followed by a small excrescence, which kept increasing in size; to get rid of it he had it removed in the Bohemian surgical clinic of Prof. Mayde in Prague. Judging from the cicatrix, which is still visible, a cuneiform excision was made, and in addition the right submaxillary ganglia were removed. A year ago a new excrescence formed, the growth of which was more rapid than the first, and which gradually invaded the whole middle third of the lip. In this condition he came under my care the 18th of December, 1898. In the inside of the lip were indurations connected with the tumor. The lymphatic ganglia were not indurated. Microscopical examination showed carcinoma simplex (not cancroid).

On December 18th I began treatment. The tumor was nowhere ulcerated, and I had to freshen it, which I did, removing a small portion of the epithelium with the forceps. The day after the arsenic was applied, the characteristic eschar was formed, and I removed a portion of it to use in the microscopical examinations which I describe below. Under daily treatments the eschar grew to such an extent that on one side it overlapped the tumor. This phenomenon frequently occurs, especially in cancers in which there is much stroma, and physicians who have not had much experience in this method are easily deceived by it and think that the tumor has increased in size under the influence of the treatment. This is seen in a work published from the clinic of Prof. Bruns,[23] of Tübingen. After the spontaneous detachment of the eschar, which occurred after eight days of treatment, there was found a dark red tissue, which upon contact with the air became black; the following day it had the aspect of the characteristic eschar, and under daily treatment with the 1:80 solution grew to the extent shown in the photograph (Fig. 4). It was firmly adherent by its base to the subjacent tissues, and five weeks later it began to become detached. It was only three weeks after this, however, that it could be removed, and even then not entirely, a small, pimple-shaped, adherent portion having to be left *in situ*. Antiseptic treatment of the wound and arsenic applications to the débris of the eschar succeeded in five days more in

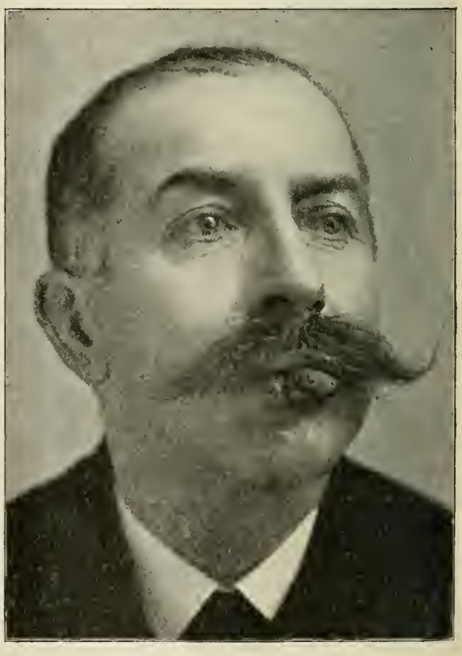

FIG. 3.

completely loosening the eschar, and cicatrization was perfect on March 20, 1899. As we can see in the illustration (Fig. 5) the cure is more complete than would have been the case after a bloody operation, for although a third of the lip was affected both superficially and deeply, scarcely a trace remains.

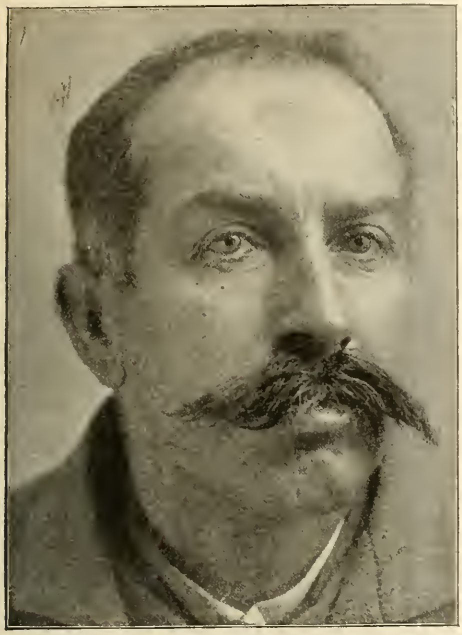

Fig. 4

In cases like this it is of the greatest importance to leave the eschar in place until it is entirely detached; even when it is of large size, only the free portions must be removed, and while this is being done, care must be taken not to pull or tear the parts adherent to the crust, for if the crust is pulled off forcibly, portions of the cancer usually remain in the depths of the wound and grow there, it being especially difficult to apply the treatment to them. Those beginning to use this treatment would best commence with cases of the first class, in which a slight mistake would not be dangerous to the patient.

In the medical literature of the subject I have been able to find only two cases of cancer of the lower lip cured by this method. The first, in which the cure has been maintained for more than a year, was seen in the surgical clinic of Professor Eslar of the faculty of Montpellier,[24] and the second in the surgical clinic of Toulouse.[25] I would add that for relief of the pain which is occasionally caused by the application of the remedy, some have recommended the addition of orthoform to the original prescription,[26] while others combine the treatment with the internal administration of Fowler's solution of arsenic.[27] This I do only in cases in which the cancer is situated in some part of the body where arsenic might be absorbed, and I administer it for a few days before beginning treatment. By this means the organism gradually becomes accustomed to arsenic, and its absorption later will not injure the patient.

IV.

The mechanism of the cure of cancer by the above-described method remains to be explained. The chief agent is the arsenious acid, which constitutes the essential element of the remedy. The presence of alcohol is not absolutely necessary, for I have cured a case of cancroid by a simple mixture of water and arsenious acid. The pain following the application was less than when the alcoholic mixture was used. In the case of encephaloid (medullary) cancer, alcohol plays an important part by determining dehydration of the neoplastic tissues, and it would therefore be a mistake to leave it out.

The first symptom after application of the remedy is the flow of a liquid so irritating to the surrounding parts that if it is very abundant these will have to be protected by means of borated vaseline. In the encephaloid forms this flow may last for several days, and when it stops reddish or purplish spots appear on the surface treated; when they come in contact with the air, they are changed to a black crust. For the arsenic to act it appears to be necessary that the cancerous tissue should lose some of its water. The water remaining in the mortified tissue simply evaporates as from dead matter in which arsenic prevents putrefaction, and a true mummification is the result. A microscopical examination of the crusts which have separated of themselves shows merely a necrosis of cancerous cells; we see a granular mass in the midst of which may still be distinguished infiltration and thrombosis of the vessels, with hemorrhages; we also see in the midst of this débris nuclei similar to those of cancer cells.

For a better study of the processes I cut out small fragments of crusts which had formed as the result of several applications of the remedy, and which had not yet become detached. The preparations, of which I present drawings, are from a fragment of the cancer of the lower lip which I have described in detail—a fragment removed after the first arsenical application; and from a crust produced by four applications in another case of cancer of the lower lip which I cured fif-

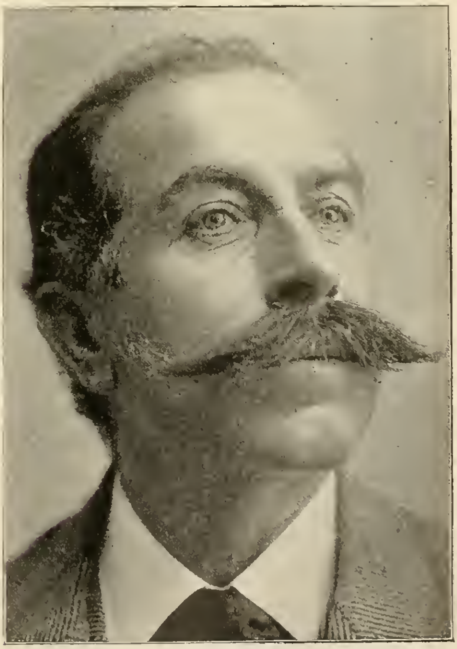

Fig. 5.

teen months ago, and in which there has been no relapse.

The preparation made from the crust caused by one application of arsenic upon the cancer previously described, will be seen to be torn. This is due partly to a mechanical cause, partly to lesions of the cancerous stroma, especially its increase in size. The cells have the appearance of being in hyaline degeneration. They are increased in size, their outlines are pale, and the nuclei present no visible alteration. There are, moreover, lacunæ between the cells of the stroma, near which is found a small-cell infiltration and even hemorrhages infiltrating the cancerous tissue. These cells, and more especially their nuclei, have undergone no change.

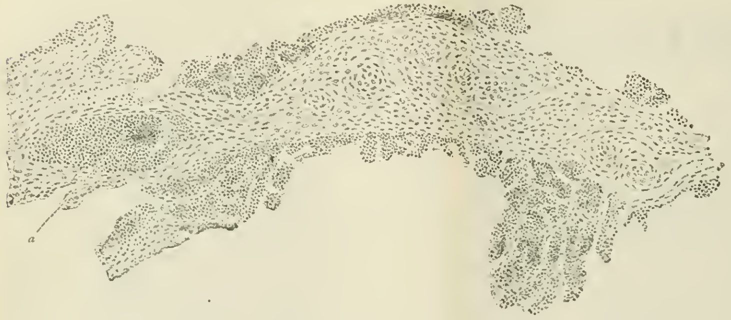

FIG. 6.—Section of Scab, after four applications of arsenic on epithelioma of the lower leg. *a*, Lymphatic infiltration pushing through the scab.

An examination of the crust from cancer of the lower lip, produced by four applications of the remedy, shows that this crust consists of a lamella covered with a thin layer of lymphatic exudate, and that it is composed exclusively of cancer cells possessing the same characteristics as those in an actively developing neoplasm. These cells show no sign of degeneration; their nuclei appear to be normal, and stain as usual. In one portion of the preparation the crust is torn by the lymphatic infiltrate. In the interior part of the crust the cells are either isolated or disposed in rows, but always interrupted by lacunæ filled with the lymphatic infiltrate and a few red corpuscles. Here the cancer cells show various degrees of necrosis. As a rule the nucleus becomes paler, swells, and finally disappears, so that we find here and there a mass of cells with well-marked outlines but without nuclei. Farther along outlines of the cells have also disappeared, and there remains merely a granular mass formed not only of cancerous tissue but of the exudate and blood as well.

It was not possible to ascertain when the arsenic had become fixed in the tissues, because there is no characteristic arsenic reaction that can be seen under the microscope; with our ordinary chemical methods the red blood cells give nearly the same reaction as arsenic.

From all these microscopical examinations we find that the cancer cells are directly mortified by the arsenic without the production of any visible phenomenon, while the action upon the stroma causes degeneration of its cells and a small-celled infiltration in its vicinity. Gaston and Haury, who have especially studied this question, state that the more abundant the infiltration, the better the action of the remedy and the more prompt the cure.

In order to understand the mechanism of the action of arsenious acid, I have made a number of experiments, applying the remedy to various wounds, to epithelium of the mouth and nose, and to suppurating surfaces. But in no case have I been able to cause the formation of the characteristic adherent crust, even when the mixture contained ten times the amount of arsenic, and was made with absolute alcohol. Violent inflammation of the tissues has followed, but not the black, adherent eschar. This is in harmony with the results obtained by Binz, who has never yet succeeded in causing a combination of albumin with arsenious acid. Such also has been my experience with albumin, or rather with the protoplasm of normal cells, whether of epithelial or connective tissue. As to cancer, everything leads us to believe that arsenic enters into combination with some substance contained in the protoplasm. At least, in all cases in which the application of arsenic caused an inflammation of normal tissues, the same application caused in cancer the formation of a black and adherent crust. Moreover, this crust cannot be removed from the rest of the cancerous tissue without causing a wound and abundant hemorrhage, while it separates of itself from normal tissue without hemorrhage. The formation of crusts always ceases after a certain time, no matter whether the applications are continued or not. Finally, the application to the surface of the arsenic which is contained in the remedy as a powder determines mortification of the cancerous tissue, even to the depth of 2 to 3 cm. (0.8 to 1.2 inches), which proves that arsenious acid penetrates into the cancerous tissue probably in the form of a soluble combination. If repeated applications are made to one special portion of an ulcer, the mortification of the whole cancer follows; as was shown in the description of treatment of cancer of the lower lip, given above. But on account of the absence of direct proof, the theory that arsenic enters into combination with one or several substances of the cancerous protoplasm remains an hypothesis awaiting confirmation.

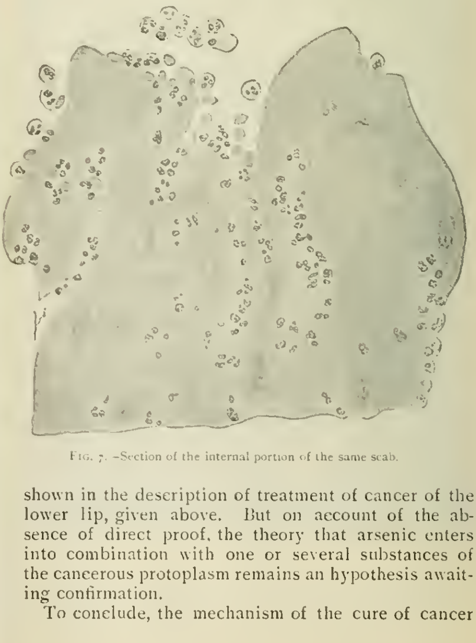

FIG. 7.—Section of the internal portion of the same scab.

To conclude, the mechanism of the cure of cancer by the application of the hydro-alcoholic mixture of arsenious acid may be explained as follows:

1. The cancer cells are first of all dehydrated by the alcohol, and then their protoplasm coagulates in the presence of arsenic.

2. The cells of cancerous connective tissue—cancerous stroma—degenerate, and provoke a serous exudation, which in its turn determines alterations in the cells mummified by the arsenic.

3. In the surrounding healthy tissues a circumscribed inflammation is set up by the remedy, which always goes on to suppuration, and by means of which the neoplasm is first cut off from the circulation, and is finally eliminated from the organism as a foreign body.

CYSTIC TUMORS OF THE TESTIS AND EPIDIDYMIS.[1]

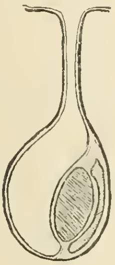
By JAMES B. BULLITT, M.D.,

LOUISVILLE, KY.

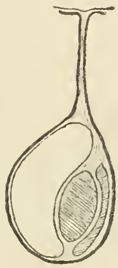
Cysts of this character are usually spoken of as encysted hydroceles; but the above classification is believed to be more correct and therefore preferable.

Before coming to the subject proper of this paper it will be useful to review briefly the various forms of hydrocele with the help of the accompanying diagrams.

It will be borne in mind that the testis at an early period of fœtal life is placed at the back part of the abdominal cavity behind the peritoneum, in front of and a little below the kidney. Its descent into the scrotum takes place gradually during the progress of fœtal growth through the agency of the gubernaculum testis, reaching the scrotum in ordinary development by the eighth month. The pouch of peritoneum extending from the peritoneum proper into the bottom of the scrotum is termed the processus vaginalis; this is blind at its lower extremity, open and continuous at its upper extremity with the parietal peritoneum of the abdominal cavity. The testicle finally comes to occupy a position at the lower and back part of the scrotum, the epididymis being placed to its outer side and the vas deferens to the inner side. It will be borne in mind that the testicle is not completely invested by the peritoneal coat of the processus vaginalis, but that it lies really outside of the peritoneal prolongation, and is only partially invested by it, just as the kidney lies behind the peritoneum and is only partially covered by it. Just before birth the upper part of the pouch, the processus vaginalis, usually becomes closed, and this obliteration extends ordinarily from the site of the internal ring to within a short distance of the testis. The peritoneal process surrounding the testis is in this way entirely cut off from the general peritoneal cavity and is termed the tunica vaginalis.



1.

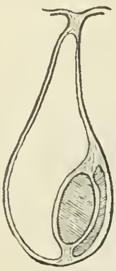


2.

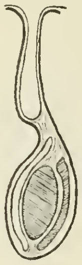
The ordinary form of hydrocele consists in the distention with serous fluid of this space enclosed by the tunica vaginalis, and represented by Fig. 2. It is contended by some authors that it is incorrect to speak of the cavity of the tunica vaginalis, or of the pleural cavity, or of the peritoneal cavity, as these cavities do not exist, the serous surfaces normally lying in contact. Such contention, however, seems somewhat hypercritical; certainly for purposes of convenience it is desirable to speak of all three as cavities. We know that a rubber bag with a capacity of four quarts has its walls lying against each other in apposition when empty, and it might be just as fairly contended that it would be improper to speak of the cavity of a four-quart rubber bag.

---

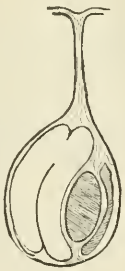
[1] Read before the Falls City Medical Society, Louisville, Ky., in March, 1900.



3.



4.

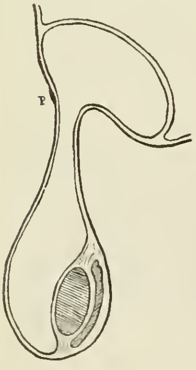


5.

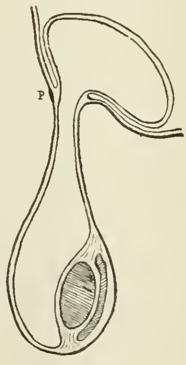
In Fig. 4, the cavity of the tunica vaginalis is seen in its normal relation to the testis and epididymis, its serous lining membrane being indicated by the single light line. Throughout these diagrams the single light line will indicate the tunica vaginalis on the one hand and the abdominal parietal peritoneum on the other. We observe, therefore, that the ordinary hydrocele is a simple distention of the cavity of the tunica vaginalis with serous fluid.

Fig. 1 represents the congenital variety of hydrocele. The cavity of the tunica vaginalis is again distended with serous fluid, but it connects with the general abdominal cavity through failure to close of the funicular process, which is that portion of the processus vaginalis lying between the testicle and the internal abdominal ring. This communicating opening is here represented as very wide, but in reality it is usually very small, from the size of a goose-quill to a straw.

The infantile variety of hydrocele is represented by Fig. 3. It will be observed that the cavity of the tunica vaginalis is distended with fluid and connects with the open funicular process, the latter being closed off at its upper end from the abdominal cavity. This closure generally is at the external abdominal ring, although it may be at the internal abdominal ring, or between these two.



6.

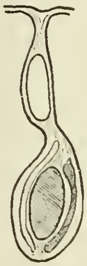


7.

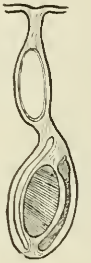
Fig. 4 represents the converse of this condition. The funicular process is closed at its lower end toward the testis, but remains open above in communication with the abdominal cavity. This condition is termed by some authors congenital hydrocele of the cord, or congenital funicular hydrocele, and is the form which not infrequently accompanies undescended testicle.

Fig. 5 represents the rare form of hydrocele known as bilocular. It will be observed that there is a second cavity communicating by means of a small opening with the cavity of the tunica vaginalis, and that both of these cavities are lined with the serous membrane characteristic of the tunica vaginalis. This second cavity may occupy the position of the funicular hydrocele. In still rarer instances the bilocular form of hydrocele may be intra-abdominal; in such event the second arm may be either intra-peritoneal or extra-peritoneal.

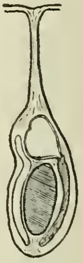
Fig. 7 shows the first of these varieties. The tunica vaginalis and funicular process are distended and connect through the internal abdominal ring with the intra-abdominal arm. The peritoneum covers this pouch in the same way that it is carried ahead of and covers an advancing inguinal hernia, so that if an incision were made above Poupart's ligament into this pouch two layers of peritoneum would have to be divided before the pouch could be reached.



8.



9



10

Fig. 6 represents the intra-abdominal and extraperitoneal variety. The advancing arm of the hydrocele has pushed the peritoneum before it and bears about the same relation to it as the urinary bladder does.

This brings us to the consideration of the subject proper of this paper, namely, encysted hydrocele, or, more properly, cystic tumors of the testis and epididymis.

Encysted hydrocele of the cord will occupy us only for a moment. Fig. 8 represents an encysted hydrocele of the cord due to the distention with fluid of an unobliterated portion of the funicular process. It will be observed that it is lined with the same serous coat which lines the tunica vaginalis.

Fig. 9 represents another variety of encysted funicular hydrocele which has had its origin in another way, either as the result of the extravasation of blood into the cellular tissue of the cord after a strain, the resulting fluid afterward becoming encysted and its coloring matter absorbed; or it is possible for a funicular hydrocele situated low down to have its origin by the distention of a tubule of the organ of Giraldés, of which we will have occasion to speak further along.

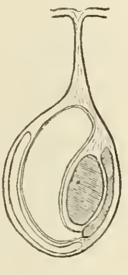
The cystic tumors having their origin in or near the epididymis are of much greater frequency, and hence much more importance, than the cystic tumors of the testis proper. These latter are in fact very rare; in them the fluid is described as "encysted between the tunica albuginea and the inner surface of the visceral tunica vaginalis."[1] The language of this description would apparently indicate that such cysts have no wall or sac proper, but consist of really free fluid lying between the tunica albuginea and the visceral tunica vaginalis, these two tunics supplying the cyst walls in the same way that the visceral and parietal pleura furnish the enclosing walls of an encysted empyema. On the other hand, some of these testicular cysts certainly lie beneath the tunica albuginea, as shown in the illustration in Jacobson, p. 202, and represented by diagram 13. The cyst here was supposed to have resulted from an interstitial hemorrhage into the tunica albuginea as a result of puncture of the testis by tapping with a needle some years before. The testicular cysts are usually situated in front of the testicle, are small in size, and are very hard in consistence, owing to the intra-cystic tension due to the resistance of their surroundings. This peculiarity of these cysts would seem to indicate that most of them, at least, have more than the tunica vaginalis as a wall on one side. This tunica yields readily, as is attested by the large size which the ordinary form of the hydrocele attains; and further by the ease with which the tunica vaginalis can be displaced and pushed to one side by the cystic tumors of the epididymis. If this tunic ordinarily formed part of the wall of such cysts, therefore, it would scarcely be expected that the cystic contents would exist under such pressure; and there would further be no reason, in so far as limitation by pressure is concerned, why such cysts might not attain a respectably large size, instead of remaining very small, as they practically always do. The conclusion is therefore reached that cysts in this situation in all probability have other coverings and are not, properly speaking, encysted collections of fluid.

---

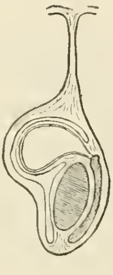
[1] Jacobson, and White and Martin.

Cysts of the épididymis are much more important clinically, on account both of their greater frequency and greater size. All such tumors are provided with proper walls of their own, and therefore are not properly described as "encysted hydroceles." According to Jacobson, they are conveniently divided into two classes: (1) Small subserous cysts, usually appearing external to the epididymis, unimportant clinically, and very rarely containing spermatozoa. After the age of forty about two-thirds of the testicles examined have shown these small cysts from the size of a pin's head to that of a pea, projecting upon the convex free surface of the head of the epididymis, and more rarely upon its body or near its tail. They are usually multiple, four or five in number; sometimes they are pedunculated and may become one source of the loose bodies sometimes found in the tunica vaginalis. The contained fluid is usually clear and limpid, sometimes turbid; it rarely contains spermatozoa. They possibly develop from remnants of fœtal structures, but more probably are involution cysts originating in the tissue of the epididymis but becoming subserous. (2) Larger cysts, originating within the tissue of the epididymis, and therefore important clinically and often containing spermatozoa.

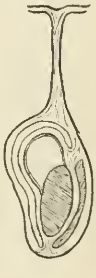
These cysts are usually single, but may be multiple or multilocular. The contained fluid may be perfectly clear, but is frequently milky from the spermatozoa contained. In size they vary from that of a hazelnut to that of a goose egg, or even an ostrich egg, containing on an average not more than two or three ounces of fluid. They are represented diagrammatically by Figs. 10, 11, and 12. Fig. 10 shows the tumor originating about the head of the epididymis, small and extra-vaginal. As the cyst grew and developed the vaginal tunic was pushed before it, and it remained outside of it. I possess a pathological specimen of such a cyst. It was removed by Dr. W. C. Dugan, and kindly entrusted to me for preservation. In its removal the operation was made entirely outside of the tunica vaginalis, which was accidentally opened, however, in one place. Fig. 11 represents a similar extra-vaginal cyst having its origin near the tail of the epididymis and pushing its way between the testicle and the tunica vaginalis. Another pathological specimen in my possession is of this nature. It was removed by the writer from a man at the City Hospital during last summer's service. It is much larger than the other specimen, about the size of a goose egg. These two cases illustrated very well the different relations which these cysts can bear to the testicle proper. In the ordinary intra-vaginal hydrocele the testicle is situated at the lower and back part of the tumor. In the ordinary epididymal cysts the testicle is immediately beneath the cyst, the cyst being unmistakably superimposed on the testicle. This was the case with the smaller of the specimens. But if the cyst has its growth from the tail of the epididymis, and attains a large size, almost the exact relations of ordinary hydrocele are presented; the testicle appears at the lower and postérior aspect of the tumor, and the latter may assume the even, pyriform shape and appearance characteristic of intravaginal hydrocele. Such was the case with the larger specimen. Indeed, the diagnosis was not made until the incision showed that the fluid was contained in a sac outside of the tunica vaginalis. Unquestionably cysts of this kind have often been operated on as ordinary hydroceles, the true condition never being recognized.



11.



12.



13.

Fig. 12 represents another possible relation of these cysts to the tunica vaginalis. The cyst has its own proper wall but projects into the cavity of the tunica vaginalis.

These larger cysts are believed to originate in several ways: (1) as a retention cyst due to dilatation of a seminal tubule, and the final severance of connection of the dilated portion, just as other retention cysts are formed. (2) Morris[1] states they may also occur as a new formation in the connective tissue consequent upon the rupture of a seminal tubule and the escape of some drops of seminal fluid. (3) The cyst may originate in certain fœtal relics, as follows: (*a*) The parepididymis, or organ of Giraldés, a little body which lies in front of the cord immediately above the head of the epididymis, and beneath the upper part of the tunica vaginalis. The tubules constituting this organ are the relics of the urinary part of the Wolffian body, as the tubules of the parovarium, or organ of Rosenmueller in the female, are of the sexual part. Cysts having this origin, therefore, would be analogous to the parovarian cysts of the female. It will be remembered that parovarian cysts in the female usually contain a clear and limpid fluid of low specific gravity. (*b*) Vestiges of the duct of Mueller. In the female this duct forms the Fallopian tube, the uterus, and vagina. Abortive in the male, its remains are to be found constantly in the hydatid of Morgagni, and sometimes it can be traced from the globus major between the testis and epididymis to the globus minor, reappearing again as the sinus pocularis in the prostatic urethra. The hydatid of Morgagni is normally cystic, and by its growth may develop into a good-sized cyst. Owing to its pedunculation it would be of the variety represented by Fig. 8 of the diagrams. (*c*) The vas aberrans of Haller, which is a diverticulum of, or a convoluted cæcal tube opening into, the vas deferens close to the tail of the epididymis. This structure, usually single, is a part of the remains of one of the tubes of the Wolffian body, still connecting with the representative of the excretory duct of that body, the vas deferens. This is the probable origin of the larger of these cysts above mentioned, which had its chief attachment, and hence origin, in the tail of the epididymis.

---

[1] White and Martin, p. 926.

As has been stated, in a large proportion of these larger cysts spermatozoa are found in the fluid. Several theories have been advanced to explain their presence. A communication may remain unobliterated between the fœtal remains and the seminal tubule, as has been proven to exist between the vas aberrans and the vas deferens.

The fact that seminal fluid is generally not found in these cysts when they are small suggests the probability that the semen gains entrance by the rupture of a seminal tubule as a result of the distention from the larger growths.

These cystic tumors are very slow in developing. What has been said of their characteristics and illustrated by these diagrams gives the clew to diagnosis. The small cysts in any event are recognized with difficulty; and in some of the largest cysts the differentiation from ordinary hydrocele will scarcely be made without incision or puncture. If the trocar is used the character of the fluid may be determinative.

Many of these cysts cause so little discomfort that relief is scarcely demanded. Simple evacuation may produce a cure; or evacuation with injection of iodine or carbolic acid may be practised. But, best of all, the scrotum should be opened and the cyst dissected out.

HEALTH CONDITIONS IN THE HAWAIIAN ISLANDS.

By CHARLES E. DAVIS, M.D.,

LATE MAJOR SURGEON OF FIRST NEW YORK VOLUNTEER INFANTRY; FORMERLY IN CHARGE OF THE MILITARY HOSPITAL AT HONOLULU.

THE Hawaiian islands are in an ideal location, being just inside the tropics. There is never danger of frost (except upon the mountain tops), and as they lie in the line of the trade winds extremes of heat are unknown; although the humidity, at times, is quite unbearable.

The group consists of eight inhabited and four uninhabited islands, lying between parallels 18° 50′ and 23° 5′ north latitude, and meridians 154° 40′ and 161° 50′ west from Greenwich. A straight line drawn, connecting the two most distant points on the islands, would measure about four hundred miles. Honolulu, the chief seaport town, is situated twenty-one hundred miles from San Francisco and forty-eight hundred miles from Hong Kong.

	Area in flat sq. miles.	Acres.	Height in feet.
Hawaii	4,210	2,000,000	13,800
Maui	760	400,000	10,032
Oahu	600	360,000	4.030
Kauai	590	350,000	4.800
Molokai	270	200,000	3,000
Lauai	150	100,000	3,000
Niihau	97	70,000	800
Kahoolaue	63	30,000	1,450
Total	6,740	3,510,000	

The accompanying table gives the area and highest elevation of the eight inhabited islands. The four others are small and unimportant. All these islands are of volcanic and coral origin. Upon the largest of the group, Hawaii, stands Mauna Loa, the greatest active volcano in the world. Upon the island of Oahu, where is situated Honolulu, the United States troops were, and still are, located at Camp McKinley. Here are to be found no less than seven extinct craters. The city lies at the foot of one crater (Punch Bowl), and the camp at the base of another (Diamond Head), and are four miles apart. These craters are distinctly defined. The cones have been built up of successive layers of lava. Eruptions occurring at intervals give to the sides of these mountains a stratified appearance, which is easily confounded with a like appearance produced by water.

None of the seven craters on Oahu has been active within the memory of man. Upon the island of Hawaii, Mauna Loa, or Great Mountain, is at present active, and a few weeks ago threatened, in its immense flow of lava, to destroy much valuable coffee and sugar land on the "koua" or southwest side.

The soil of the islands is very fertile, and is composed of volcanic lava, disintegrated by atmospheric agencies. The climate and rank vegetation favor the decomposition of lava and rapid formation of soil. The "coral insect" or animal—Professor Agassiz calls it a species of jelly fish—by its industry has added acres to the territory that fringes the shores of these islands.

The mountainous character of this country gives a great variety of temperature. Torrid heat can be found at times in some spots sheltered from the trade winds; frost and snow exist upon the tops of the highest mountains. The invalid in search of a change of climate has but to travel a few miles to find any temperature the physician may prescribe. The air, coming over so many thousand miles of sea, is remarkably pure. The average temperature is about 74° F. In observations made by Prof. A. B. Lyons from 6 A.M. to 2 P.M. and 9 P.M. each day throughout the year, for seven years, the minimum in Honolulu has been 54°, the maximum 90°. These islands lie in the track of the Japanese gulf stream called "Kuroshiwo," which has much to do in preventing extremes of heat and cold. The contrast between the windward and leeward sides of the island is very marked. The eastern sides are windy, rainy, and heavily wooded, while the western coast possesses a warm, dry climate, with scanty vegetation.

Trade winds blow constantly from the northeast for nine months of the year, and have an average velocity of twenty miles an hour, keeping the temperature cool and invigorating. During the rainy season, the wind often shifts to the south, bringing intense humidity. The natives call this the "koua" or sick wind; it often lasts twelve or fourteen days and is very unhealthful and depressing, also blighting temporarily the vegetation near the shores.

The ethnological problem exhibited in these group of islands, though a complex one, has never, from the first, been difficult of solution. It is but another demonstration of the old hypothesis, "the survival of the fittest," where the unconquered Anglo-Saxon rules every other people with whom he mingles. The accompanying census enumeration shows, for the year 1896, a total population of 109,020 souls, made up from the representatives of ten different people, and no less than six different races: native Hawaiians, 31,019; part native, 8,485; Hawaiian-born foreigners, 13,733; Americans, 2,266; British, 1,538; German, 912; French, 75; Portuguese, 8,232; Norwegians, 216; Chinese, 19,382; Japanese, 22,329; Polynesian, 409; other nationalities, 424; total, 109,020.

Added to this already cosmopolitan population is found a combination, or mixture of white and dark blood, which, of frequent occurrence, is found to possess in the offspring in a marked degree the color of the dark parent, with the tastes, ambition, and often the refinement of the white parent. Of this cosmopolitan population, it is especially to be noticed that only 3,804 persons can properly be classed as Anglo-Saxons, and that the curious fact exists, explained only by the indomitable courage and persistence of the race, that these 3,804 Anglo-Saxons, constituting as they do but a small fraction of the population, have taken in their hands the control of affairs, political and governmental. That this should be the racial condition that would finally be established has never been a question of much speculation, since the time that the great natural resources of the islands became known and tempted with the promise of wealth the adventurous Briton and the practical American.

The preceding enumeration shows a large population of Chinese and Japanese. This element never has, and probably never will, seriously figure in the political history of these islands, since nearly all were brought here from their native countries by the Anglo-Saxon, who had already acquired possession of the richest portions of the islands. They were brought, too, under the contract labor system, by which they were little better than the white man's slave, whose lot it is to bear the heat and burden of the day.

The Portuguese, of whom there are more than eight thousand, are a quiet, unobtrusive people, content to live simply and work industriously for their day's wage. Very few Portuguese are progressive and independent enough to establish their own business. They segregate in the parts of the city that are given up almost exclusively to them. They marry young (seldom outside their own people), raise large families, and are not, to any marked degree, assimilated by any other race. The native Hawaiian is undoubtedly of Malay-Polynesian origin. This philologists have established through a study of the language, which they declare to be directly derived from that spoken by the Polynesians. They probably emigrated to these islands in canoes via Samoa. Their skin is dark, resembling that of a half-white in the States. Their hair is raven black, very luxuriant, and straight or slightly waving. Their faces are broad, noses rather flat, and lips thick. They are of moderate height.

When in 1778 Captain Cook discovered, explored, and named the islands after an Englishman, the Earl of Sandwich, he estimated the population at 400,000, which, most likely, was too great. In 1828, when the missionaries arrived, 120,000 was the estimate. To-day the natives number about 31,000. They are becoming extinct as a race, and a few more generations will see the last of them and of the Hawaiian language. However, no small fraction is by inter-marriage becoming assimilated by the white races, especially the Anglo-Saxon, that have settled here. Under the rule of Kamehameha I., who consolidated all the petty chiefs of the eight islands under one monarchical government, they were warlike and prosperous. But with the advent of the white man the extinction began. They are immoral, and because of improper medical attention (a necessity which they do not understand) they are diseased. Syphilis and leprosy have made sad inroads on their general health and fertility. The missionaries reduced their language to a written form, which was gratefully received and quickly acquired. Many of the natives show an aptitude for languages, and usually acquire English, and often Japanese and Chinese, in addition to their own. An interesting item to notice is, that there is no word for virtue—and for their omission the people are paying the penalty.

The health problem in the Hawaiian islands is almost as serious a question for the United States to deal with as it is in Cuba or Porto Rico. In some respects it is greater, in proportion to the population; the conditions existing in the two large cities (Honolulu and Hilo) are identical with that which confronted the military commanders of Santiago and Havana. If, added to the general unsanitary condition of these two cities, there should be placed in them a certain number of reconcentrados, starving and afflicted with all kinds of diseases, the problem here presented would be the same. That some radical action must be taken at once is most apparent to any one who has had anything to do with matters pertaining to public health, or who has given the subject a moment's consideration.

Honolulu offers the best example of life in these islands from a health point of view, because it is the largest city, and said by the inhabitants to be the healthiest. It is located, as mentioned above, on the island of Oahu, which is about thirty miles long, with many hills and mountains, rising to the height of several thousand feet, between which are many fertile vales and plains. But, owing to its general formation, the coast lines are most available for habitation and cultivation. It is on one of the level tracts of land, between the mountains and the sea, that Honolulu is situated. In early days the plain was the remnant of a lava-flow, or perhaps the bottom of an extinct crater, with the side fallen out. It is within the memory of the earliest inhabitants when it was nothing but beach sand and lava-dust. The subsoil is black sand, very porous, and quickly absorbs all fluids cast upon it. The general drainage is bad, because of the fact that the hills rise somewhat abruptly from the sea, leaving a great tract of land but a few feet above sea-level.

The transformation of Honolulu from grass huts and cocoa-palms to modern houses, parks, and streets has been very rapid. Good roadways of coral blocks have been laid; palaces and fine public buildings have been constructed, also mansions large and small, elegant detached houses, modern schools, churches, and museums. Tram-cars, water-works, and electric lights are enjoyed. Parks filled with beautiful tropical foliage dot the city here and there. Streets and driveways are nicely shaded with royal and cocoanut palms. And yet, with all this seeming love and beauty and show of intelligence and refinement, Honolulu might almost be considered filthy, and a spot full of danger to its inhabitants. In what might otherwise be the garden city of the world, certain classes have disregarded the laws of nature and hygiene, and actually defiled their own habitations.

The chief part of the city trade is carried on in a space of about half a mile square, closely built, densely populated, and largely made up of one- and two-story houses, the sort usually found in tropical countries. Of late years, modern stone and brick structures are taking their places. In this part of the city, Chinese, Japanese, and some natives are found in great numbers; they generally live and sleep in one room, and the small yards in the rear of their houses are entirely taken up with cesspool and vault. On one or two of the principal streets it is impossible for pedestrians to travel without being met everywhere by the most obnoxious odors. No part of this city has had a sewerage system until the present time, when one is being constructed through the main thoroughfares. If the history of other cities repeats itself here, it will be some years before this comes into general use. At present, all refuse matter is disposed of in cesspools. In many cases they are properly built and regularly pumped out by scavengers, but in the majority of cases they consist of holes in the ground, with wooden boxes sunk into them. In many cases refuse is cast upon the ground to decay and rot in the tropical sun.

This condition of affairs has continued for the past fifty years. The city is honeycombed with cesspools and privy vaults. The outlying districts, which are not so closely built, have added to this the pestilential nuisance of rice, taro, and banana patches which are constantly flooded with water. Interspersed here and there will be seen duck-ponds and pig-styes; so that from any height overlooking the city the picture is not unlike Venice with its many canals. These pools of stagnant water, added to the lakes and lagoons in the public parks, are favorable breeding-grounds for all kinds of disease, especially in this climate. We are told by those who make the subject a study, that a waterlogged tract of land, between mountain and sea, is the best place for the propagation of malaria. Add to these conditions lava-dust, of which the atmosphere is full and which at times covers everything in clouds, and is so fine that it penetrates one's clothing; a water supply which is partly artesian, and partly collected from mountain streams, (admittedly so full of decomposed vegetable matter that it is the rule to boil it before it is drunk); an even temperature which seldom falls below 72° F., with sunshine and rain almost daily during the winter or wet season; with very little attempt at street cleaning—and we have the conditions which are bound to breed disease wherever they exist.

In this city of thirty thousand inhabitants of mixed races, the death rate is thirty-five per thousand, or thereabouts. Typhoid fever has been constantly on the increase, and is always endemic. Pernicious tropical malaria is a common complaint, while rheumatism, catarrh, and bronchitis are very prevalent. The climatic conditions are especially bad for those suffering from rheumatism or lung diseases. The death rate is steadily increasing, as the incomplete records of the board of health show. The causes of death have not been carefully recorded, and, until the last few months, interments were made without permits. The mortality is greatest among the natives. Venereal diseases in the worst forms prevail among the lower classes.

One cannot better illustrate the effect of the conditions in Honolulu, than to recall the recent epidemic of typhoid fever and malaria which prevailed among the United States troops stationed there. To be sure, they lived in tents, and had to contend with the hardships of camp-life, but had not the disease been there they would not have been so afflicted. Now that these islands have been annexed, the people who live there should look at these conditions as they exist, fairly and squarely, and let the United States government know just how badly they need some active health work done.

The island government is doing all it can to improve the sanitary conditions, but necessarily has many local influences to contend with, as well as native prejudice, which leads the inhabitants to conceal their sickness. Late reports from Honolulu show the above statement to be true among the Chinese, who evade the authorities, and will not report cases of bubonic plague, fearing cremation.

The question of leprosy alone is international, now that we have adopted twelve hundred lepers in these islands, with many more in Porto Rico and the Philippines. Some national health legislation must be the result, and this disease must be properly segregated and treated in a more complete way. New schools, workhouses, and hospitals should be constructed on the island of Molokai, for these afflicted people to live, work, and be treated in. At present no attempt at classification of cases and treatment on Molokai is made. To be sure the Hawaiian government, through the board of health, with Mr. W. O. Smith, its efficient president, has gone further than any other in the segregation of lepers, and much credit is due them, but this disease being now more than ever a possible factor in the diseases of the United States, it becomes a national question, and one of the greatest importance. A local government will take years to do, in a health and sanitary way, what a proper health commission, not of the country, could accomplish in much less time.

For Honolulu I should heartily recommend the completion, as soon as possible, of the sewerage system, the filling of all stagnant pools, rice, taro, and banana patches; putting an end to the breeding of ducks and pigs in the city limits. Then with the sea-bathing and many natural advantages it would become the garden city of the world.

In conclusion, I should like to add a word in favor of a national health department, with a representative in the Cabinet. I am led to believe that medical societies throughout the United States will make a strong effort in this direction, as the necessity for such a department is daily growing more apparent.

THE ASSOCIATION OF CHRONIC APPENDICITIS WITH DISEASE OF THE RIGHT ADNEXA.

By HIRAM N. VINEBERG, M.D.,

ATTENDING GYNÆCOLOGIST TO ST. MARK'S HOSPITAL, MOUNT SINAI HOSPITAL OUTDOOR DEPARTMENT, ETC.

Considerable has already been written upon the differential diagnosis between appendicitis in women and disease of the right adnexa. The writer himself, in a short paper in the Medical Record, December 21, 1896, drew attention to the close similarity in the clinical picture between acute catarrhal salpingitis and acute catarrhal appendicitis, and related some cases in which the differentiation was wellnigh impossible. But in this communication he desires to draw attention to the not infrequent association of the two diseases in the same patient.

Every operator who has to deal with abdominal and pelvic lesions encounters every now and then in cases of marked disease of the right adnexa a thickened and inflamed appendix adherent to the pelvic mass. Such appendices usually show unmistakable signs that they have become involved secondarily to the tubal disease. They are as a rule considerably enlarged through thickening of the wall of the peritoneal covering, with thickening also of the meso-appendix. They usually lie in the midst of an exudate covering the pyosalpinx, or an ovarian abscess, or ruptured tubal sac. Such a complication seldom gives rise to any characteristic sign or symptom by which it may be suspected prior to operation. It derives its importance chiefly from a technical consideration when, as is the custom nowadays with many operators, to attack tubal and ovarian diseases through the vaginal route. In such a procedure of course the secondarily affected appendix would probably be overlooked, and doubtless would interfere with a satisfactory return to good health.

Within the past few years in my laparotomy cases I must have met with over a dozen presenting the foregoing complication, and of course removed the diseased appendix together with the diseased pelvic structures.

One case[1] last summer was particularly instructive in this connection. The woman had a large pelvic hæmatocele as a result of a ruptured tubal sac some weeks previous. As the collection of blood was very accessible through an incision in the posterior vaginal vault, the temptation was strong to adopt that plan of procedure. But the case presented some features which it was thought demanded an abdominal incision. These proved to be an intraligamentous cyst of the left ovary independent of the hæmatocele. Lying buried in a deep exudate in the upper surface of the hæmatocele was found a very much thickened appendix, the size of one's thumb. Both it and the intraligamentous cyst were removed. The hæmatocele was then evacuated by a free incision in the posterior vaginal vault. The patient made a good recovery from the operation, and has enjoyed the very best health since. Further comment is unnecessary.

---

[1] Published in full in The American Gynæcological and Obstetrical Journal, January, 1900.

The object of this paper, however, is not to dwell at any length upon those cases just referred to, in which, in the presence of marked right adnexal disease, there is a secondarily diseased appendix lying in contiguity to the former; it is rather to call attention to those puzzling cases in which the patient suffers from symptoms vaguely referred to the right lower half of the abdomen, and in which the diagnosis vacillates between chronic catarrhal appendicitis and a mild form of salpingo-oöphoritis. These cases in reality show an association of the two affections in the same patient. The operation will disclose a thickened, inflamed right tube, with some inflammatory changes in the ovary, and an appendix showing more or less disease. At one time the changes will be most marked in the appendix, at another they will be found most pronounced in the right tube or right ovary. It is not always easy to trace the causal relation of the two infections. In many of the cases I have operated upon the distance between the appendix and the tube was too great to assume an extension by contiguity of the inflammatory process from one to the other. In some cases, however, there was general relaxation of the abdominal supports, so that the right kidney was found moderately prolapsed and the uterus in more or less retroversion, with the adnexa hanging rather low in the pelvic cavity. Whether the prolapsed kidney and the appendicitis stood in the relation of cause and effect, as maintained by Edebohls,[1] I am unable to say. I am rather inclined to the view that the same factor—relaxation of the abdominal supports—must be looked upon as contributing equally to the changes in the different organs in the abdominal and pelvic cavities. The subject, however, requires for its elucidation much more extensive investigation than has as yet been accorded to it. The profession owes a debt of gratitude to Edebohls for having called attention to it, and for having stimulated observation and thought in this direction by his publications.

As already hinted, the symptoms from which these patients suffer are rather vague. But there is one feature which stands out rather prominently, and that is, the subjective symptoms and general debility are out of all proportion to the physical signs found. There may be and there usually is indefinite tenderness over the appendicular region, but I must confess that I have seldom been able to determine by palpation the slight changes that are usually found in these forms of chronic appendicitis. I have relied more upon tenderness and pain than upon my ability to detect by palpation a constriction of the appendix or moderate adhesions or an inflammation of the peritoneal covering. On bimanual examination the right tube is found decidedly tender and more or less thickened, and the ovary is usually slightly enlarged and moderately prolapsed. The symptoms usually set in insidiously. The patient cannot tell just when she began to suffer from pain in the right side of the lower abdomen. During the subsequent course of her ailment she may or may not have had one or more acute attacks which at one time may have been diagnosticated as appendicitis, at another as right-side salpingitis or oöphoritis or as pelvic peritonitis. In other cases again there may be an entire absence of any acute attacks. Pain and ill health may be the only prominent symptoms present, and at no time will there have been observed any elevation of temperature or any marked change in the pulse rate.

These patients are sometimes operated upon for supposed appendicitis, and the removed appendix shows some slight lesion. But the pain continues, and a second laparotomy reveals a diseased right tube or ovary, which is excised and the patient is cured.[1] Such an experience must cause the operator very much chagrin, to say nothing of the mental agony and physical suffering which a patient endures who has to undergo a second laparotomy shortly after having been subjected to the first. To avoid such a pitfall one should adopt the rule always to investigate the condition of the right adnexa when operating for appendicitis in female subjects, be they married or single.[2] The youth of the patient should not throw us off our guard, as the following case will illustrate:

Case I.—Chronic catarrhal appendicitis, adherent tube and ovary; operation; recovery. Miss S., aged sixteen years. The menses were established in her twelfth year; they were regular and attended with only moderate pain. She had been well until a year ago, when she had an acute attack of pain in the right side of the abdomen which kept her in bed for a day or two. She had another attack of a more severe nature while in the country during the past summer. The physician there diagnosticated right-sided oöphoritis. The pain, with variable severity, continued until her return to the city, when she consulted her family physician, who made the diagnosis of appendicitis. He kindly referred her to me, and on examination I found decided tenderness over the appendicular region, but could not with certainty palpate the appendix. Bimanual examination was made with a finger in the rectum. Considerable tenderness was detected over the right adnexa, and they seemed adherent. She was operated upon November 30, 1898, by an oblique incision over the usual appendicular site. The appendix was found after considerable search behind the cæcum and pointing downward into the pelvic cavity. It was very firmly and extensively adherent, the distal end lying in a sheath of exudate. After excising the appendix, I introduced two fingers through the incision and explored the right side of the pelvic cavity. The right ovary was found moderately enlarged and adherent. The adhesions were gently broken up and the ovary brought up into its normal position. The abdominal wound was closed with tier sutures. Recovery was uneventful. The patient has remained free from pain since the operation.

In the majority of cases presenting the complex phenomena outlined in this paper, the more desirable and prudent course to pursue is to open the abdomen in the median line, when the appendix, uterus and its adnexa can be treated surgically if their condition requires it. No better illustration can be offered of the wisdom of such a plan of procedure than is presented by the following case:

---

[1] Centralblatt für Gynäkologie, 1898, pp. 1084–1090; Medical Record, 1899, pp. 341–345.

[1] See case reported by Dr. R. F. Weir, in a paper entitled, "An Improved Operation for Acute Appendicitis," in the Medical News, February 17, 1900.

[2] I learned this lesson from an unpleasant experience some five years ago. I had operated upon a woman twenty-four years of age, for acute appendicitis. The appendix was swollen and contained pus. The operation passed off smoothly and the patient made an apparently good recovery. She was up out of bed at the end of two weeks. A couple of days after getting up she was seized with pelvic pain and developed fever. A small pelvic abscess was detected, and being incised through the vagina, convalescence was soon established which now was permanent. I had no doubt afterward that at the time of operation the patient had some trouble with the right adnexa which should have been investigated then.

Case II.—Median laparotomy; excision of appendix; suture of round ligaments to abdominal wall; excision and puncture of cysts in both ovaries. Mrs. W——, twenty-five years of age, married eighteen months, gave birth to a child eight and a half months ago. She has been ailing ever since the confinement, which seemed to be perfectly normal. Before this she had enjoyed excellent health. She resides in a Western town. The physician who attended her last writes that she consulted him November 18, 1899: "She was suffering from pain in the right side of the abdomen, backache, dragging pelvic pains, and from profuse leucorrhœa. I found the cæcal, ascending colon, right inguinal and hypogastric regions extremely tender, almost painful. The epigastric region was tender to painfulness on percussion. The endometrium was exquisitely tender. Temperature was normal. I gave her three local treatments, and advised recumbent position and hot douches. On December 15th she aborted. The products of conception were less than two months (not over). After this accident she kept her bed eight days and her distress almost disappeared. After being on her feet distress returned, disabling her almost." Her husband took her then to a large city in the vicinity and consulted two of the most prominent operators there. One diagnosticated appendicitis, the other inflammation of the right ovary. Both urged immediate operation. The diametrically opposed opinion of these two surgeons unsettled the man's confidence and placed him in a quandary. He then came on here with his wife and was referred to me. She is a tall, slender, delicate-looking woman, with rather pale mucous membranes. She complains of constant backache, pain across the hypogastrium and over the abdomen in general. The pain is most severe in the right inguinal region and extends down the right thigh, which, she says, feels numb. She suffers from general debility, loss of flesh (having lost fifteen pounds in weight since the birth of her child), loss of appetite, constipation, and sleeplessness. For weeks past she tells me she has been unable to go to sleep without an opiate. The abdomen is very lax. There is marked tenderness over the cæcal region and along the course of the ascending and transverse colon. The appendix is readily palpated, is markedly tender, but no decided thickening is detected. The kidneys are not found prolapsed. The uterus is large, succulent, tender, and in fair position. A thick, tenacious discharge fills the cervical canal. The right ovary is considerably enlarged, prolapsed, and very tender. The left ovary does not seem to be enlarged. Urine withdrawn by catheter showed a moderate amount of albumin, but no casts. I learned she was excreting it in very small quantity. I declined to express an opinion as yet, and advised her entering a private sanatorium to be under observation and treatment. Under suitable regimen the kidneys soon acted normally. On the first day she passed only 700 c.c. urine, on the second 1,100 c.c., on the third day 1,450 c.c., and from this on the amount and quality were normal.

At my second examination the uterus was found in complete retroversion, in which position it was found at every subsequent daily examination during the week prior to the operation. The abdominal pain and tenderness persisted in spite of rest in bed and appropriate treatment. I concluded I had to deal with a case of chronic appendicitis, associated with subinvolution and retroversion of the uterus and cystic degeneration of the right ovary.

On February 4, 1900, I performed median laparotomy, having first dilated and curetted the uterus. The right ovary contained a cyst the size of an almond, which was excised and the wound in the ovary sutured with catgut. A similar-sized cyst was found in the left ovary, which was treated in the same way. The uterus lay in complete retroversion. It was brought forward and held in position by suturing the round ligaments to the fascia of the rectus muscle. A search was now made for the appendix. It was readily found in the usual position, covered with a few membranous adhesions, and the peritoneal covering was highly infected. Appendectomy was done in the customary manner. The appendix on being slit open presented an erosion, the size of a five-cent piece, of the mucosa. The abdominal wound was closed with tier sutures. Recovery from the operation was perfectly normal. The patient is making a rapid and satisfactory convalescence. She is free from pain, has a good appetite, sleeps well, and has gained three and one-half pounds in the first week after getting up from bed.

It may be argued that the appendix would be difficult of access by a median laparotomy, especially when it was extensively and firmly adherent. Such, however, has not been my experience in the class of cases under consideration. As a rule the appendices in these cases are but slightly adherent, and are very easily reached by a median incision. Still, if on examination prior to operation a firm adhesion of the appendix is suspected, then the Battle-Kammerer incision through the sheath of the right rectus muscle, with traction of the muscle toward the median line, may be adopted. This incision gives ready access to most of the situations which a diseased appendix may adopt, while it permits at the same time with moderate ease the examination and surgical treatment of the right adnexa. I have at times been able to investigate through it the condition of the uterus, and even of the left adnexa. When I am morally certain beforehand that disease of the appendix exists, I usually adopt this incision. It seems to me to be preferable to the rather complicated incisions recently recommended[1] to accomplish the purpose of investigating the condition of the right adnexa when operating for appendicitis in female subjects.

Of course cases of appendicitis are sometimes encountered in which neither of the two foregoing incisions will be applicable. I merely make this statement so as not to be understood as advocating certain incisions for all varieties of appendicitis. A few weeks ago I operated upon a woman in whom I could feel an enlarged appendix lying firmly attached to the side of the ileum. I made an oblique incision directly over the mass, and found the appendix firmly adherent to the iliac wall, lying to the outer part and behind the cæcum. It was embedded in a mass in the centre of which was about two ounces of pus. After having located the position of the appendix, and before attempting its removal, I enlarged the incision downward so as to bring within reach the right adnexa. I found the right ovary converted into a cyst the size of a hen's egg, and removed it. Then after walling off the intestines as well as possible, I proceeded with the removal of the appendix. While enucleating it from its bed of exudate some pus (about two ounces) appeared, which was quickly mopped up. The abdomen was closed with tier sutures save a small area where a gauze strip passed down to the abscess cavity. This was removed in three days, and the patient made a perfectly normal recovery, leaving for her home in a neighboring town fifteen days after the operation.

Nowadays the question is frequently asked, When doing a laparotomy for pelvic lesions, do you always search for the appendix and remove it, be it diseased or not? The question no doubt would be differently answered by different gynæcologists. My own practice is based on the principle never to remove a tissue unless its removal is indicated by disease. Whenever it is feasible in the performance of a laparotomy for other conditions than appendicitis, I search for the appendix for the purpose of investigation, but do not excise it unless it shows some pathological change. Personally I do not feel justified in subjecting my patient to the additional risk, be it never so slight, of removing a healthy appendix for the reason that at some future date it may become diseased. Of course, this is a matter of mere personal sentiment. I have said when it is feasible, for no operator, I take it, would be so foolhardy as to waste any time over the search for the appendix unless there were good reasons for so doing, after a very difficult and tedious operation on the pelvic viscera. Moreover, in these cases such a search is as a rule unnecessary, for if the appendix is at all involved it is generally found adherent to the diseased pelvic structures, and comes under the operator's hands without his having to look for it.

---

[1] See papers by Dr. Robert F. Weir (The Medical News, February 17, 1900), Dr. Willy Meyer (The Journal of the American Medical Association, February 17, 1900), and Dr. George R. Fowler (The Medical News, March 3, 1900).

Two Unusual Cases of Annular Syphilides in Negroes.—T. Caspar Gilchrist's first case had ringed and gyrate lesions over the face, axillary region, and inner surfaces of the thighs. Near the chin were three rings one within another. In the second case the face and neck were chiefly affected. The chancre had existed six months previously. In doubtful cases ringworm and erythema multiforme have to be excluded. In the latter the backs of the hands will be coincidently affected and the margin will not be raised, firm, or indurated. Annular syphilis may occur as late as the third or fourth year. In one case mentioned it was as late as the tenth year. This form seems much more prevalent in the negro race. The writer agrees with Crocker that it belongs in the papulosquamous group. An article on the "Anomalies of Syphilis," in the current number of the *American Journal of Dermatology and Genito-Urinary Diseases*, shows illustrations of an almost identical case.—*Maryland Medical Journal*, April, 1900.

The Effect of Strong Heat in Pruritus.—Edmund Andrews recommends applications as hot as can be borne for the relief of obstinate itching, especially pruritus of the anus and adjoining regions—perineum and scrotum or vulva. Hot water has been used in anal pruritus, but with imperfect success, because of the difficulty of applying strong heat thoroughly to the deep sulcus in which the anus lies. The water must be as hot as can be borne without blistering. A large dish of it must be at hand, and two or three compresses placed in it. The patient taking a crouching position picks up one compress and instantly presses it against the anus. In a moment or two it will be partly cooled. He then drops it into the dish and immediately uses another, thus keeping up a constant and very strong heat until the itching ceases. One such treatment, the author says, will often make the patient perfectly comfortable for twelve or twenty-four hours.—*The Clinical Review*, May, 1900.

Nearly Complete Occlusion of the Trachea by a Tumor Originating in the Cicatrix of an Old Tracheotomy.—Bayer's patient was tracheotomized in his fourth year for croup. In his twenty-third year he contracted an initial specific lesion, and in the next few years received irregular treatment. At the age of thirty years he suffered from difficult breathing, which became noisy in both inspiration and expiration. Examination showed the subglottic space obstructed by a sort of membranous diaphragm, perforated a little to the right side of the median line by a small orifice. Closer examination showed that the supposed diaphragm was in reality a mass of granulation tissue. Surgical intervention was refused, but the patient was placed on appropriate treatment, and massage was given both internally and externally over the site corresponding to the tumor. The tracheal occlusion gradually disappeared, and a complete cure resulted. Tracheal occlusions in general arise from a tumor in the trachea proper, from deformities in its walls, from cicatrices or pressure by neighboring organs, or from the presence of horizontal fibrous partitions inserted on the inside of the normal wall of the tube and developing their surface in a plane at right angles to its axis.—*Revue Hebdomadaire de Laryngologie, etc.*, March 10, 1900.

Acute Serous Meningitis and Sero-Purulent Meningitis due to Streptococci.—P. Nobécourt and M. Delestre note two cases which were seen in an epidemic of broncho-pneumonia, and which were both fatal. The first patient, a boy three and one-half years old, was brought to the hospital for diarrhœa and for cough. Nine days after the appearance of meningitic symptoms he died. Liquid from cerebro-spinal puncture gave pure cultures of streptococcus. The lungs showed the ravages of broncho-pneumonia. There was a diffuse œdematous congestion of the meninges of the convexity of the hemispheres. No tuberculosis was present. The cerebro-spinal liquid was clear and limpid. The second case also showed the lesions of broncho-pneumonia. The cranial meninges were distended by a cloudy liquid, rich in leucocytes. Bacteriological examination of the cerebro-spinal liquid showed the streptococcus analogous to that seen in the first case. So the same micro-organism can sometimes cause a serous, sometimes a sero-purulent, inflammation in the meninges.—*Annales de Médecine et de Chirurgie Infantiles*, April 15, 1900.

On the Relationships between Anæsthetics and Insanity.—G. H. Savage states that an anæsthetic may cause insanity. As to the advantage of one anæsthetic over another, the writer has had no experience of special danger from any one. Various forms of insanity have been observed in this connection. An anæsthetic may relieve for a time in a few maniacal cases. It may be given to the insane with impunity, as a rule, when operations or examinations are necessary. But there is danger that it may lead to a fresh attack of insanity if it is given to patients who have had previous attacks of insanity, and to those who are subject to recurrent insanity of any form.—*The Clinical Journal*, April 11, 1900.

A Plea for Examination of the Male Genitalia in Obscure Cases.—Ferd. C. Valentine says that whenever a woman with manifestations of nervous disease comes to the general practitioner or the neurologist, the latter at once proceeds to establish or eliminate the presence of a genital affection as a possible cause of the ailment for which advice is desired. The same rule does not hold in the case of a male patient, but the author thinks it might do so with great benefit in many cases. The symptoms may not at all point to the genito-urinary apparatus, and yet the cause of them may well reside in that part. There are many pains and symptoms simulating disturbances of the gastric, motor, sensory, and circulatory systems which are evolved and maintained solely by a genito-urinary disease. As regards exploration for urethral stricture, which is only one of the many affections of the genito-urinary system that may find expression in symptoms in distant parts, Valentine cautions against the giving of an opinion after the simple passage of a metal sound or even of a metal bougie-à-boule. He advises the use of a soft-rubber bougie-à-boule, even two numbers smaller than the rigid instrument employed, and says that only when this is whipped out of the urethra and encounters none of the characteristic impingement, can the urethra be pronounced clear. Besides instrumental and visual exploration of the urethra, and tactile interrogation of its adnexa, an examination of the urine will oftentimes give important clews not only to the character but also to the site of a urethral disease.—*The Cleveland Medical Gazette*, May, 1900.

Functional Relation between the Thyroid and the Parathyroid Glands.—Gustav Lusena thus sums up the results of his experimentation: While in some cases the theory that the removal of the thyroid and parathyroid apparatus accelerates the process of nutritive exchange, and increases the gravity and rapid course of the cachexia is quite true, the theory cannot be upheld which would attribute all the symptoms which occur after parathyroidectomy and thyro-parathyroidectomy to an increased or diminished rapidity in the metabolic processes.—*La Riforma Medica*, March 28 and 29, 1900.

The Bacteriology of Influenza.—Arnaldo Cantani believes it to be highly improbable that the bacillus of influenza should be met with in the mouths of healthy individuals. Even in those suffering from chronic catarrh it is found only after a superadded acute and typical attack of influenza. Once introduced, its persistence is remarkable, and is shown in frequent relapses. The specific nature of the bacillus is indisputable. As a result of experimentation, it would appear that the intoxication produced by this disease is due to a poison contained in the bodies of the micro-organism. There are clinical affections which exactly simulate influenza, but are due to other bacteria. These and the typical bacteria are best found in the sputum and in the nasal secretions.—*La Riforma Medica*, April 6, 7, 9, 1900.

Malarial Neuritis.—E. Sacquépée and Charles Dopter give a description of twenty-two cases culled from medical literature and three from their own practice, of polyneuritides absolutely referable to malarial infection and to no other cause. In one case the sensory nerves of the legs and arms were affected, the pain being of an excruciating nature. The patient died, and the cubital and external popliteal nerves were subjected to a minute examination. Not a single fibre was found in a normal condition; the chief lesion was a breaking up of the myelin into small droplets, with a varicose and moniliform condition. The fibres were, in fact, almost totally destroyed. In a second case, lancinating pains of the thigh, and finally of the whole leg and the arms, returned at intervals, but were benefited and finally cured by quinine, electricity, massage, and tepid douches. In the third case paralytic, painful, and trophic phenomena occurred from time to time; quinine, antipyrin, faradization, and occasionally morphine, were given in treatment, and the patient's condition was greatly improved. Some muscular atrophy remained.—*Revue de Médecine*, April 10, 1900.

Epilepsy: Artificial Trepanning.—G. Jacquin reports the following case of a man thirty-seven years old: The patient never had convulsions in childhood. There was no history of alcoholism or syphilis; no venereal excess. The patient had an attack of typhoid fever when eighteen years of age; it was severe and attended by delirium, and lasted four months. Three months later the first convulsions appeared. In October, 1897, he fell into the fire and received a severe burn on the head which amounted to a veritable trepanning. A sequestrum was formed and thrown off. For a time after the accident the epileptic attacks were less frequent, but gradually the frequency increased till they occurred as often as before the accident. This case goes to prove with other examples that trepanning sometimes secures a temporary amelioration, but never a perfect cure of the affection.—*Archives de Neurologie*, April, 1900.

Cutaneous Grafts: Strips Taken from an Amputated Leg and Grafted with Success Nine Hours after Amputation.—Alfred L. Dupraz cites the case of a man suffering from an extensive wound of the hand. On this wound, which had been protected with adhesive plaster since the day before, the writer grafted, according to Thiersch's method, strips of skin taken from a leg amputated nine hours previously. The strips of skin had been preserved in sterilized serum. The grafts took with great success.—*Archives Provinciales de Chirurgie*, April 1, 1900.

Note on the Etiology of Subscapular Friction; Role of Pleurisy.—M. Péré declares that physiological subscapular friction does not exist. Subscapular friction is the result of the approach of the two osseous surfaces—subscapular and costal. This condition can take place in the event of an exostosis, in callus following a fracture, in an exaggerated protrusion in front of the spinal border and of the inferior angle of the scapula, in the denudation of the osseous parts following atrophy of the scapular muscles, or in an abnormal projection following pleurisy, scoliosis, etc. In these conditions, when the movements of the scapula on the thorax are too extensive or too frequent, a serous bursa may be interposed between the two bones and by its inflammation reproduce the friction by substituting its rugous walls for the two bony surfaces.—*Archives Provinciales de Chirurgie*, April 1, 1900.

The Diazo Reaction in Consumptives Applying for Sanatorium Treatment.—Hermann Lorentz proposes the use of the diazo reaction in order to determine whether a given individual with pulmonary tuberculosis will probably be benefited by sanatorium treatment. During the past year he has applied this test several times in the case of each of the patients in one division of the Halila Sanatorium, and presents a table of the results obtained in the fifty-four examinations. The only deaths that occurred were among those who presented the diazo reaction. All those who did not present this reaction on admission, with the exception of three, were improved during their stay in the sanatorium. Of the three exceptions, in two the diazo reaction subsequently appeared, and the third patient left the institution. The appearance of this reaction in marked degree was always followed by a rapid destruction of the lungs, but it was independent of the number of bacilli and of the presence of fever. The writer regards the diazo reaction as a valuable aid to prognosis, its presence being of bad omen; but its absence does not indicate an absolutely favorable course, as the condition may grow worse after a time, and then the diazo reaction will probably appear.—*Finska Läkaresällskapets Handlingar*, March, 1900.

The Treatment of the Stump of the Umbilical Cord.—F. Ahlfeld protests against the statement of Martin, that the successful treatment of the stump of the umbilical cord is as yet "a consummation devoutly to be wished," and refers to the method (fully described in the second edition of his "Text-Book") that has been employed with most favorable result in far over a thousand cases treated at the "Marburger Anstalt." He gives a brief description of the method, and states that they have not had a single case of umbilical disease since a number of years. He does not approve of the methods suggested by Martin.—*Centralblatt für Gynäkologie*, March 31, 1900.

A Case of Congenital Hemeralopia.—W. Koster reports a case of congenital perinuclear cataract in which the opacity was so even and so nearly transparent that the patient had almost normal acuity of vision in a strong light, but at dusk, or when the illumination was dim, was nearly completely blind.—*Weekblad van het Nederlandsch Tijdschrift voor Geneeskunde*, March 31, 1900.

Pregnancy and Birth after Hysterocolpocleisis.—Menge cites an instance in which pregnancy occurred after hysterocolpocleisis had been performed on a woman, aged thirty-five years, who had borne seven children. Examination upon her admission to the "Universitäts-Frauenklinik," Leipsic, revealed the presence of a large vesico-cervico-vaginal fistula. She stood the operations well, but less than three years later again became pregnant. Menge gives a very complete report of the case, which is certainly quite interesting.—*Centralblatt fur Gynäkologie*, March 31, 1900.

Contribution to the Knowledge of the Neutralization of Poisons.—Ernst v. Czyhlarz and Julius Donath, in their researches regarding the power of some organs to neutralize poison, found, among others, that by tightly bandaging the hind-legs of guinea-pigs as far above the knee as possible, they could with impunity inject into the leg thus ligated quantities of strychnine sufficiently large to have caused certain death within two to five minutes in other animals of the same weight. They conclude from this that the poison was neutralized by the subcutaneous cellular tissue, the musculature, and the blood and lymphatic fluid contained in the same.—*Centralblatt für innere Medicin*, March 31, 1900.

Treatment of Ozæna with Normal Horse Serum.—Pedro Borrás y Torres reports the results of hypodermic injections of normal horse serum in eight cases of ozæna. The results were of three kinds: (1) General symptoms, fever, joint pains, etc., such as commonly follow injections of the various therapeutic sera and organic extracts; (2) local symptoms at the site of injection, pain, swelling, and sometimes a morbilliform eruption; (3) symptoms on the part of the nasal mucous membrane, greater circulatory activity marked by turgescence and an increased secretion. After four or five injections the crusts were expelled and the odor was no longer perceptible, either objectively or subjectively. This amelioration, however, continued only so long as the injections were repeated at regular intervals, and the dose was not reduced. No change at all was produced in the atrophied mucous membrane by this increased secretion. The initial dose of the serum was 5 c.c., gradually increased to 15 c.c. The injections were repeated every other day, or twice a week, according to the individual tolerance.—*Gaceta Médica Catalana*, March 31, 1900.

Variety in the Diet of Typhoid Fever.—Andrew H. Smith states that considerable experience has shown him that quite a variety of fluid and semi-fluid food may be given in cases of typhoid, even in the earliest stage, not only without danger, but with decided benefit. The aim should be to give the minimum of food that will sustain the patient, not the maximum amount that he can take. "Starvation fever" is often abolished by administration of a more nutritious semi-solid food. A good diet list is: Milk, broths, soft-boiled eggs, junket, custard, the soft part of raw oysters, milk toast, scraped chicken, scraped beef, chicken and rice boiled to a jelly, sago, tapioca, cornstarch, animal jellies. The effect should be carefully watched.—*International Medical Magazine*, April, 1900.

Hysterogenous Tympanum.—M. Ricard reports a case of pain and partial deafness in the left ear of a young girl aged seventeen. The instillation of a few drops of cocaine caused an hysterical attack, taking the form of suffocation, vertigo, and loss of consciousness. Water used in the place of cocaine produced the same effect. Repeated applications of warm water finally brought about a cure.—*Revue Hebdomadaire de Laryngologie*, April 15, 1900.

Intestinal Antisepsis in Typhoid Fever.—James M. Anders believes that the principal indication for the use of intestinal antiseptics is the meteorism which owes its origin to decomposable material in the prima via. They have a mitigating sphere of usefulness. They exercise a mitigating influence upon the diarrhœa when present. The bowel antiseptic employed by the writer is salol. The powdered form is best. Turpentine is to be preferred when marked distention of the bowel is present. When intestinal irrigation is used, the writer employs salicylic acid or mercuric chloride.—*International Medical Magazine*, April, 1900.

On Carcinoma in Cattle.—Leo Loeb sums up the results of observations on this subject as follows: (1) In 1899 one case of carcinoma in fifty thousand was found in cattle. (2) The most frequent place for its occurrence is at the inner canthus of the eye. (3) The female sex predominated. All cows with carcinoma were, however, from six to fifteen years old, while the majority of steers are usually killed when young. This fact must be taken into consideration in this connection. (4) All animals with carcinoma were much emaciated. (5) There was constant absence of metastases in the deeper lymph glands or other organs, although the metastases in the retromaxillary lymph gland very often attain a great size.—*Medicine*, April, 1900.

The Plantar or Toe Reflex.—Horatio C. Wood, in the examination of a number of adult sufferers from various diseases involving the pyramidal motor tract, has not been able to verify Collier's statements in regard to the plantar reflex, *i.e.*, that there are two distinct forms, one in the normal adult, the other in children, and that in certain diseases in the adult there is a reversion of the form, so that it is possible to make a diagnosis as to the seat, or even within certain limits the nature, of the disease by studying the toe reflex. In children the author has several times found the adult reflex. In short, the result of his study has been to indicate that the condition of the toe reflexes cannot be relied upon as a basis of diagnosis.—*University Medical Magazine*, April, 1900.

Meteorismus in Abdominal Typhus and its Treatment.—W. E. Tschernow bases a report upon one hundred and twenty-eight cases. When meteorism is pronounced, the bowel must be emptied. Injections with water, or water and glycerin, or glycerin alone, may be employed, or a mixture of asafetida water and turpentine oil. When the diaphragm is elevated by meteorism and the lungs are pressed upon and the heart is displaced, we may be forced to puncture the abdomen in patients who present lung complications. This procedure is not difficult when the stomach or large intestine is to be punctured, but in meteorismus of the small intestine puncture succeeds only when the distended loop of gut is prominent behind the abdominal walls. Meteorismus is produced by an increased gas production in the intestine, or caused by atony and paresis of the intestinal walls from local auto-intoxication of the neuro-motor apparatus of the intestine by products of abnormal fermentation.—*Klinisch-therapeutische Wochenschrift*, April 15 and 22, 1900.

Traumatism in the Pathogenesis of Syringomyelia.—Vincenzo Cito quotes a number of cases of this disease following injuries received by falls, blows, etc. He believes that the traumatism is the chief etiological factor, and that it produces hemorrhagic foci which Minor divides into two varieties, local and localized, the former situated at the seat of the lesion and distinctly circumscribed, the latter characterized by an accumulation of pure blood in the form of a central hæmatomyelia or simply by central softening with or without blood. In the majority of cases these foci are the starting-point for the formation of the cavities, surrounded by a ring of newly formed nerve tissue.—*Gl' Incurabili*, March, 1900.

The Treatment of Infantile Spastic Paralysis.—A. Codevilla reports a number of cases in which transplantation and plastic operations on tendons have succeeded in overcoming spastic contractions of hands or feet. In the majority of cases of infantile spinal paralysis, the vicious position and the deformity are chiefly due to the lack of equilibrium between the forces which move the articulation. Some muscles are paralyzed and others relatively normal, so that with each voluntary or reflex movement some muscles contract while their antagonists are inert. This gives rise to the vicious position or the deformity, and it is only rational to suppose that a cure may be obtained by a better distribution of force. This can be done by musculo-tendinous transplantation, with stretching or shortening of certain tendons in order to obtain a passive equilibrium in the normal position. No rules can be given as to the operation, for the conditions vary in each case.—*Rivista Critica di Clinica Medica*, April 21, 1900.

The Diagnosis of Chlorosis and Chloro-Anæmia.—Alfred Stengel says that the prominence of certain symptoms, as cardiac palpitation, or cough due to vascular disturbance, frequently interferes with the diagnosis of chloro-anæmia. More often still mistakes occur when the clinical manifestations are a little obscure. We must not expect to find the greenish pallor of the books in every case. Our tendency nowadays is to pay too much attention to the blood examination; its importance is great, but there is danger in relying too much upon this one method of investigation. We must take into consideration the history and the clinical course of the case. We should be especially careful in pronouncing cases with unusual and atypical symptoms chlorotic. Chloro-anæmia is simply a form of secondary anæmia presenting an unusual blood picture. It is most frequent in the early stages of phthisis, carcinoma, and secondary syphilis, and may be met with very characteristically in post-hemorrhagic anæmia.—*University Medical Magazine*, April, 1900.

Pyelophlebitis and Hepatic Cirrhosis. — Attilio Colpi thus concludes a study of two cases: (1) We may have a cirrhosis secondary to thrombosis of the portal vein. (2) Its characteristics will show that the thrombosis is primary, and not secondary to cirrhosis of the liver. (3) The thrombus is of gradual, not sudden, formation. (4) The formation of interacinous connective tissue is secondary to thrombosis of the portal vein. As a result of the gradual diminution of the blood supply to the liver, the function of the hepatic cells is abolished, and we have atrophy and destruction of the cells, the compensatory circulation in the internal branches of the portal vein not being sufficiently powerful to nourish them. (5) The pressure of the congested blood further contributes to destruction of the hepatic cells.—*La Riforma Medica*, April 10, 11, 12, and 13, 1900.

The Rudimentary Ophthalmoscopic Stigmata of Acquired Syphilis.—A. Antonelli writes of the frequent presence of vestiges of neuritis of the optic nerve, retinitis, chorio-retinitis, or simple chorio-retinal pigmentary dystrophy in the eyes of syphilitics, in addition to the classical lesions of the fundus of the eye. These stigmata are essentially the same in acquired and in congenital syphilis, but in the former they are usually associated with a true papillitis or lesions of the fundus, which is not the case in hereditary syphilis. An ophthalmoscopic examination may sometimes clear a doubtful diagnosis in general paralysis or tabes or other diseases in which syphilis is the unrecognized cause.—*Gl' Incurabili*, March, 1900.

Appendicular Pleurisy.—M. Dieulafoy describes this affection, which is secondary to appendicitis, the pleura becoming infected by propagation through the adhesions and lymphatics. The infective agents may or may not perforate the diaphragm. The pleurisy occurs a few days after the onset of the appendicitis, at about the time when the symptoms of the latter are beginning to subside, and is almost without exception a pleurisy of the right side. There may be very slight dry pleurisy, or pleurisy with effusion, but as a rule there is extensive effusion, the fluid being fetid and putrid. Prognosis is bad. Surgical intervention should be prompt, and when peritoneum and pleura are both infected may have to consist of the operation for empyema and laparotomy. Prophylaxis is the only rational treatment, and will consist of early appendectomy.—*Bulletin de l'Académie de Médecine*, April 10, 1900.

Yellow Fever is a Preventable Disease.—Antonio Matienzo says that, although the situation and climate of Tampico offer the most favorable conditions for the reproduction and development of the germ of yellow fever, and although there have been visitations there at various times, yet the disease has not become endemic. He reports briefly the nine cases occurring in that city from April 10 to October 13, 1899, and recounts the sanitary measures taken in each case to prevent the spread of the disease. From his study of these cases he concludes that yellow fever, like smallpox, diphtheria, scarlatina, etc., is an avoidable disease. The prophylactic hygiene of the affection consists in isolation and the most thorough and scientific disinfection in addition to general sanitary measures, such as a pure water supply, subsoil drainage, sewerage, the drying up of pools and marshes, and the protection of river lands from overflow.—*Boletin del Consejo Superior de Salubridad* (Mexico), No. 8, 1900.

Prevention and Treatment of Pelvic Inflammatory Diseases in the Female by the General Practitioner.—R. R. Kime believes that fifty per cent. of pelvic inflammations are due to infection after abortion or labor, twenty-five per cent. to gonorrhœal infection, and the remainder to various causes, such as rheumatic diathesis, chilling during menstruation, venereal excesses, and uncleanliness in minor gynæcological manipulations. He makes a plea for greater cleanliness in what are ordinarily considered matters of minor importance, and gives minute directions for the various emergencies of the puerperal period, post-abortion week, etc. He lays the greatest possible stress upon the necessity of uterine and alimentary drainage.—*Annals of Gynecology and Pediatry*, April, 1900.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, June 2, 1900.

THE CARE OF THE CONSUMPTIVE POOR.

THE opinion is rapidly gaining ground in this and in other countries that steps should be taken to provide proper accommodation and treatment for those persons suffering from pulmonary tuberculosis whose means will not allow them to live under the conditions best calculated to cure or arrest the progress of that disease. Attention is also being drawn to the fact that the consumptive individual is a source of more or less danger to those in the immediate neighborhood, and that therefore his isolation will be to the best interests of the community at large and the only effectual method of successfully preventing the spread of the malady. In order to bring this much-to-be-desired state of affairs to pass, sanatoria on a very large scale must be erected within a convenient distance of cities. However, much money will be required for the accomplishment of the scheme, which will certainly not be forthcoming in sufficient quantities from private or public charity. Consequently it is argued that it is incumbent on the State to act *in loco parentis*, and that the people should be taxed for the benefit of their poor brethren.

Dr. Howard S. Anders read a paper on this subject at the joint meeting of the Philadelphia County Medical Society and the Pennsylvania Society for the Prevention of Tuberculosis, held on January 10, 1900, in which he said: "In the evolution of the care of consumptives, State aid is truly an opportune, just, and consummate factor. First the private pay sanatorium; then the hospital for poor consumptives maintained by voluntary contributions; and now the public hospitals and sanatoria for advanced and incipient cases respectively. England has accommodation for about five thousand poor cases supported by charity only, leaving about seventy thousand cases more unprovided for. Germany has about fifty sanatoria, but mostly for pay cases of tuberculosis, although many more for the poor are in process of installation by the government and by private enterprise separately and co-operatively. The Swedish parliament recently voted 850,000 kroner for a sanatorium for South Sweden; and 2,200,000 kroner given by the people to King Oscar has been turned over by him for sanatoria in northern and central Sweden."

The striking success of the sanatorium treatment of consumption has been so decisively demonstrated that it would be needless to dwell upon that part of the question. There can be also no doubt that the indigent require this description of treatment to a much greater extent than the well-to-do, and have the right to expect it. Dr. Edward O. Otis, in a paper read at the meeting referred to above, said: "If it is the duty of the city, as most cities so consider it, to provide for the care and treatment of its injured and sick poor suffering from other diseases, it is equally its duty to provide for the equally worthy poor consumptive. It is his misfortune to have this fearful disease, not his crime or personal election. He sees a neighbor with appendicitis taken to a perfectly appointed hospital and operated upon by the most skilful surgeon, or another with pneumonia receiving like care and skill; but for him the city neither will nor ought to open the doors of its general hospitals, and he must either drag out his life in wretchedness, or as a last resort go to the almshouse. And further, there is the added reason why he should be provided for, because his disease is a communicable one and he is endangering others."

The question of treating the poor consumptive in a manner satisfactory to himself and to others is one beset with difficulties on all sides. It is manifest that the matter is too large to be undertaken by individual effort, and that if anything is to be done the State must take it in hand. It has been pointed out in the MEDICAL RECORD many times that the inroads of consumption might be very greatly checked in cities by municipalities insisting that the poor are housed in sanitary healthy dwellings. By all means build sanatoria for the poor consumptives, but at the same time strike at the root of the evil. The following words, written by Dr. Clifford Allbutt, in *The Practitioner*, January, 1899, are very much to the point: "Are we to hope that consumption, like smallpox, may become a tale of the past? If so, like smallpox it must be banished by preventive means. Is there any prospect of such a consummation? Undoubtedly there is, and while we are perfecting our means of cure, let us not rest until these perfect means are no longer wanted. Tuberculosis has fallen into the class of infectious diseases, and must be resisted by the methods applicable to infectious diseases. These are to seek for an antidote and to abolish the immediate cause."

REPORT OF THE CHIEF SURGEON OF THE DEPARTMENT OF MATANZAS AND SANTA CLARA.

THE fact that Cuba, and particularly its towns, at the time of the American invasion were in the most deplorable sanitary condition is a well-worn story. The first portion of the report referred to above gives a detailed account of the successful efforts made by the medical department in Matanzas to place the military camps in that province in a satisfactory hygienic state. It is stated that yellow fever would appear to be practically abolished among the troops, and the only diseases that occasioned any anxiety were the venereal affections. In a total strength of 1,121 at the time of the publication of the report there were in

Matanzas 150 sick, or a percentage of 13.3; of these 70 were venereal in character, or a percentage of 6.2, leaving a sick report of 7.1 per cent. of other diseases.

The most serious problem affecting the commissary department, according to the chief surgeon, is that relating to the supply of ice for troops serving in the tropics. It is pointed out that civilization and sanitation have demonstrated that ice has long since ceased to be a luxury and become a necessity, consequently in the modern days of ice machines there is no excuse for the absence of this article in all of our garrisons. The present system of purchasing from outside parties, except in transient cases, is expensive, uncertain, and in every way undesirable. Ice plants of sufficient capacity should be located in certain localities which will be distributing-points for the smaller garrisons.

The public charitable institutions, which in this department, as in the other provinces of the island, were found to be in an incredibly filthy condition, were placed under the supervision of the medical department, and were thoroughly cleansed and reorganized, greatly to the benefit of their inmates. The latter portion of the report is chiefly devoted to a consideration of the work of the sanitary department, and demonstrates the good effect of prompt and vigorous measures. The statement is made that the sanitary condition of Matanzas and Santa Clara—when the report was issued—was excellent. The death rate had decreased and starvation and yellow fever were absent. Nevertheless attention is drawn to the fact that the present methods of sanitation are but the forerunners of what remains to be done, and that unless a permanent, scientific, economic, and efficient system be established, the work already done will in great part bear little more than temporary fruit.

Chief Surgeon Ives concludes his report: "I would state that since my association with this command, which dated from December 3, 1898, the health of the troops has been excellent. Prior to embarking for Cuba the sanitary conditions in all camps of the division with which I had the good fortune to serve were everything that could be expected, thereby resulting in as healthy and fine appearing a body of men as then existed in the army. It would not be inappropriate to state that the condition of almost perfect health in this command and its freedom from typhoid is the natural sequence of military sanitation, systematically and thoroughly applied. . . . The health of the command compares favorably with that of any in the division. All medical and line officers seem keenly alive to the importance of the sanitary situation, and are working diligently to prevent infection, and the fact of the absence of all traces of such indicates that up to the present time at least their efforts have been eminently successful."

All evidence points to a hopeful anticipation that, under the vigorous leadership of Governor Wood, aided by the earnest co-operation of the medical and sanitary departments, Cuba, instead of as in times past being a hotbed of disease and looked upon as the white man's grave of this part of the globe, may become an altogether desirable place of residence, possibly a health resort.

News of the Week.

Dr. Harry Warren Lincoln has been appointed gastrologist to the Bushwick and East Brooklyn Dispensary.

Nu Sigma Nu.—The third annual banquet of the XI. Chapter of the Nu Sigma Nu medical fraternity of the University and Bellevue Hospital Medical College was held Thursday evening, May 24, 1900, at the Hotel Belvedere.

American Proctological Society.—The following officers were elected at the meeting of the American Proctological Society at Washington, May 6, 1900: *President*, Dr. James P. Tuttle, of New York; *Vice-President*, Dr. Thomas Charles Martin, of Cleveland, Ohio; *Secretary*, Dr. William M. Beach, of Pittsburg, Pa.; *Executive Council*, Drs. S. T. Earle, Jr., of Baltimore, Md., A. B. Cooke, of Nashville, Tenn., and J. R. Pennington, of Chicago, Ill.

The Fifteenth Annual Conference of State and Provincial Boards of Health of North America was held at the Hotel Dennis, Atlantic City, N. J., on June 1 and 2, 1900. The set discussion was on school hygiene. The officers of the conference for 1900 are: *President*, Dr. U. O. B. Wingate, of Milwaukee, Wis.; *Vice-President*, Dr. Charles O. Probst, of Columbus, Ohio; *Treasurer*, Dr. J. A. Egan, of Springfield, Ill.; *Secretary*, Dr. J. N. Hurty, of Indianapolis, Ind.

National Confederation of State Medical Examining and Licensing Boards.—The tenth annual meeting of this confederation will be held in the Hotel Traymore, Atlantic City, N. J., on Monday, June 4, 1900. Members and ex-members of State medical examining-boards, physicians, and educators who are interested in the cause of higher medical education are invited to attend. Every State or Territorial board whose duty it is to examine or license physicians intending to practise in the jurisdiction of the board, by whatsoever name it may be called, is urged to affiliate with the National Confederation, if it has not already done so. The officers for 1899–1900 are: *President*, Dr. J. N. McCormack, of Bowling Green, Ky.; *Vice-Presidents*, Drs. N. R. Coleman, of Columbus, Ohio, and B. F. Crummer, of Omaha, Neb.; *Secretary-Treasurer*, Dr. A. Walter Suiter, of Herkimer, N. Y.

The Roentgen Society of the United States.—There has been organized a Roentgen Society of the United States, with the *American X-Ray Journal*, St. Louis, Mo., as the official organ. This society is the only one of its kind in America. It is national in character, and is represented by physicians, surgeons, dentists, and radiographers in the several States. The constitution is similar to those of the Roentgen societies in Europe. The annual dues are $5. The first regular meeting will be held in December, 1900, in New York. Many papers have been promised by eminent men abroad and here, and a very successful scientific meeting is looked for. There will be an exhibition of *x*-ray and electro-therapeutic apparatus, radiographs, etc., during the meeting of the society. The chairman of the committee of arrangements is Dr. Monnel, of New York. The society will be represented at the International Congress of Medical Electrology and Radiology, in Paris, France, by Dr. Price, of Cleveland, Ohio. The secretary of the society is J. Rudiš-Jičínský, of Cedar Rapids, Iowa. The president is Dr. Heber Robarts, of St. Louis.

The Delaware County (Pa.) Medical Society celebrated its fiftieth anniversary at Media on May 27th, and the event was made the occasion of a gift to Dr. William B. Ulrich of a silver loving-cup in recognition of his fifty years spent in the practice of medicine.

Asociated Health Authorities of Pennsylvania.—At the meeting held at Mechanicsburg on May 23d and 24th, Prof. A. J. Beitzel, of Mechanicsburg, read a paper on "School Hygiene." Miss Dora Keen, of Philadelphia, presented a communication on "The Medical Inspection of Schools." Dr. Benjamin Lee, of Philadelphia, read a paper entitled "Recent State Legislation for the Protection of the Health and Lives of School Children." Mr. C. Herbert Obreiter, of Lancaster Township, presented a communication entitled "The Rural Director as a Health-Officer." Dr. A. C. Abbott, of Philadelphia, read a paper on "General Hygiene." Mr. Moritz G. Lippert, of Phœnixville, advocated State inspection of commercial dairies and herds. Dr. H. B. Bashore read a paper on "Rural Hygiene." Dr. R. S. Maison, of Chester, spoke upon "Township Supervision." Mr. W. H. Allen, of Philadelphia, discussed measures calculated to render State health protection effective.

Pathological Society of Philadelphia.—At a stated meeting held May 24th, Dr. A. A. Eshner presented the heart and the brain from a case of rupture of an aortic leaflet and cerebral hemorrhage, with right hemiplegia and aphasia, and he pointed out the difficulty of diagnosis especially from cerebral embolism. Dr. L. Pearson and M. P. Ravenel reported a case of pneumonomycosis due to the aspergillus fumigatus. The specimens were obtained from a calf thought possibly to be tuberculous, but not reacting to tuberculin, and the lungs presented an appearance of mixed emphysema and condensation, with peculiar hemorrhage-like lesions of varying size. Cover-slip preparations disclosed a fungous growth, which culture proved to be the aspergillus fumigatus. Dr. Joseph McFarland exhibited cultures and tissue preparations showing plague bacilli. Dr. A. O. J. Kelly presented a communication on "Papillomatous Epithelioma of the Pelvis of the Kidney," adding the report of one case to the few already on record. Dr. Simon Flexner made some remarks on "The Nature of the New Tissue in Cirrhosis of the Liver and its Distribution," detailing the employment of various stains, showing that all of the connective tissues take part in the hyperplasia. Drs. E. P. Davis and H. F. Harris reported a case of chorio-epithelioma without uterine lesion, the patient having been a multiparous woman in the third month of pregnancy, in whom it became necessary to empty the uterus for the relief of pernicious vomiting. The woman failed, however, to recover, and post-mortem examination disclosed neoplasms in the brain, liver, kidney, lungs, and elsewhere, which on histological examination were found to be chorio-epitheliomata. The uterus was free from disease.

A Long Hospital Service.—Dr. John Cameron, who lately resigned, on account of advanced age, his position of physician to the Royal Southern Hospital, Liverpool, had been actively connected with the institution for fifty-two years.

The University of Edinburgh.—Dr. John Wyllie has been appointed to the chair of practice of physic in the University of Edinburgh, rendered vacant by the death of Sir Thomas Grainger Stewart. Dr. Wyllie is fifty-six years of age, and has been a member of the medical profession for thirty-five years.

Smallpox in Hudson River Towns.—Several cases of smallpox have recently been discovered in North Tarrytown and other places in that vicinity. The houses where the disease exists have been quarantined, and all the children in the school at North Tarrytown have been revaccinated.

Havana Temporarily Free from Yellow Fever.—A report to the surgeon-general of the army from Major W. C. Gorgas, chief sanitary officer of Havana, states that there were no deaths from yellow fever in that city during April. This was the first month without a death from the disease since May, 1899, and the only one during the last ten years, with two exceptions, February and May, 1899. The total number of deaths during the month was four hundred and eighty-two.

Philadelphia County Medical Society.—At a stated meeting held May 23d, Dr. L. J. Hammond exhibited a new growth of undetermined nature removed from the abdominal wall of a woman. Dr. H. W. Cattell made a demonstration of lantern slides prepared from fresh specimens, with an exhibition of some pathological specimens preserved by Kayserling's method. Dr. J. P. Crozer Griffith read a paper entitled "Percentage and Laboratory Feeding of Infants in Health and Disease," in which he pointed out by means of illustrative cases the great advantage of methods of scientific precision in the artificial nourishment of infants. Dr. Lewis S. Somers presented a communication entitled "The Use of Adrenal Extract in Hay Fever," reporting the results obtained in some twenty cases. Although the drug exhibited marked local effects, little benefit was observed from its administration by the stomach.

The International Congress of the Medical Press will meet in Paris on July 26th, 27th, and 28th. The two chief subjects proposed for discussion are: (1) The advisability of founding an international association of the medical press and the conditions on which such an association should exist; and (2) the application of the principle of the protection of literary property to medical literature. Other questions which have been suggested for discussion are: the unification of medical technical terms; the extension to members of the medical press of certain privileges accorded to members of the political press; a better understanding as to what constitutes a legitimate quotation; the principle which should govern exchanges of papers; the representation of medical papers in foreign countries; and the part of the medical press in the organization and preparation of medical congresses. The committee on organization consists of: President, Professor Cornil; vice-presidents, Drs. Lucas-Championnière and Laborde; treasurer, Dr. Cézilly; and general secretary, Dr. R. Blondel, 8 Rue Castellane. All publishers, proprietors, editors, and members of the staffs of medical journals are eligible for membership in the congress upon the payment of a fee of 25 francs ($5). The families of members and medical men and medical students may also attend as spectators on payment of an entrance fee of 10 francs ($2). They may participate in the fêtes and receptions, but cannot take part in the discussions of the congress, nor can they vote on any question before the meeting.

Dr. John B. Walker has been appointed visiting surgeon to Bellevue Hospital, second division, vice Dr. F. H. Markoe resigned.

New York State Hospital for the Care of Crippled and Deformed Children.—In an editorial note on "Medical Legislation in New York State" in the issue of May 26th, it was inadvertently stated that the bill calling for the establishment of the above-named institution failed to pass. The bill not only passed but was signed by the governor, as was noted in these columns at the time.

Yellow Fever among American Troops.—Five cases of yellow fever have broken out at Santa Clara among men of the Second Cavalry who are married to Cuban women and who live out of the barracks. There are only two cases in the province of Havana, and there is not one in the city.

How to Free a Town from Mosquitos.—At a meeting of the Società Medico-Fisica Universitaria of Sassari, on March 23d, Dr. C. Fermi gave an account of certain experiments made in Sassari, in conjunction with Dr. Lumbau and Dr. Cossu-Rocca, with the object of freeing the town from mosquitos. He was able to discover all their breeding-places in different parts of the city, in drains, cisterns, puddles, etc. The method adopted was the destruction of the larvæ by means of petroleum placed in the breeding-grounds twice a month. The mosquitos were destroyed in shops by means of chlorine, and in houses by means of other culicides, such as a mixture of pyrethrum, chrysanthemum flowers, valerian, and calamus aromaticus, or the "zanjoline" of Celli and Casagrandi. The results obtained were so satisfactory that Dr. Fermi concludes from them that it is always possible to free a town from mosquitos unless the conditions are exceptionally unfavorable—as, if it be situated in the midst of a swamp. He estimates the expense of freeing a town of fifty thousand inhabitants at 1,000 to 1,500 lire ($200 to $300) a year. This includes the wages of the staff required to carry out the measures prescribed.—*British Medical Journal*, May 12, 1900.

A Martial Medical Man.—A troop of Westchester County cavalry has been organized in Mount Vernon, N. Y., and Dr. Edward F. Brush of that city has been elected captain. Dr. Brush, who is a graduate of Bellevue in 1875, was formerly mayor of Mount Vernon.

The Plague is reported again in Brazil, several cases having been discovered during the past week in Rio de Janeiro. A case has occurred at Durban in the person of an East Indian employed in the army transport service.—The first death of a white man at Manila from bubonic plague occurred on May 21st. The victim was a government teamster. Seven natives have died since the outbreak of the plague at Quiapo Market.—In San Francisco the house-to-house inspection of Chinatown was continued by the inspectors of the board of health during the first part of the week, but no case of bubonic plague was discovered. The United States circuit court has issued an order restraining the health officials from inoculating the Chinese. The Colorado State board of health has established a quarantine against California.—In Sydney, N. S. W., there have been two hundred and forty-seven cases of plague since the beginning of the epidemic, eighty-nine of which have resulted fatally.—The disease has appeared again in Osaka, Japan.

Navy Department, Bureau of Medicine of Surgery, Washington, D. C., May 12, 1900.—Changes in the medical corps of the United States navy for the week ending May 26, 1900. May 21st.—Medical Director T. C. Walton detached from duty at the naval laboratory, Brooklyn, N. Y., and from other duty May 20th, and ordered home to wait orders and retirement May 31st, at sixty-two years of age. Passed Assistant Surgeon W. C. Braisted, orders to the *Mayflower* revoked; when the *Detroit* is placed out of commission detached and ordered home and directed to hold himself in readiness for orders to sea. Passed Assistant Surgeon G. T. Smith detached from the naval laboratory and department of instruction, Brooklyn, N. Y., June 14th, and ordered to the *Mayflower*, June 15th. May 22d.—Passed Assistant Surgeon G. D. Costigan detached from the Boston navy yard May 29th, and ordered to temporary duty on the *Pensacola*, and then to the Asiatic station via the *Gaelic*. Assistant Surgeon E. Davis detached from the naval hospital, Brooklyn, N. Y., May 29th, and ordered to temporary duty on the *Pensacola*, and then to the Asiatic station via the *Gaelic*. Assistant Surgeon J. T. Kennedy detached from the *Independence* June 4th, and ordered to the Asiatic station via the *Gaelic*. May 24th.—Assistant Surgeon T. M. Lippett detached from the *Oregon* and ordered to the *Newark*. May 21st.—Pharmacist S. W. Douglas detached from the *Wabash* and ordered to the Key West naval station for such duty as may be assigned as relief of Pharmacist I. N. Hurd. Pharmacist I. N. Hurd, upon reporting of relief, detached from the Key West naval station and ordered to the *Wabash*.

Obituary Notes.—Dr. J. S. R. Hazzard, of Springfield, Ohio, died suddenly on May 26th, at the age of seventy-four years. He was one of the foremost men in the State for years, and a raiser of fine stock. Delaware was his native State. He was a graduate of the medical department of the Western Reserve University.

Dr. John MacDonald, a surgeon in the employ of the American Line, died at Philadelphia on May 21st from pneumonia. He was born in India of Scotch parents in 1835, and studied medicine in London. For the past eighteen years he had been a steamship surgeon, and for four years was on the *Waesland*, on which vessel he died.

Dr. John L. Leprohon, of Montreal, died in that city on May 23d. He was a veteran of the Civil War and a founder of Hancock Post, G.A.R. He was a graduate in medicine of McGill University in 1843.

Dr. Horace B. Scott, United States navy, retired, died at Wallingford, Conn., May 29th, aged forty-three years. He was graduated at Trinity College in 1878, and later from the Jefferson Medical School. For several years he was a surgeon in the United States navy until his health failed, when he was retired.

Obituary.

FESSENDEN NOTT OTIS, M.D., NEW YORK.

Dr. Fessenden N. Otis died on Thursday, May 24th, in New Orleans, at the age of seventy-five years. He was born in Ballston Spa, N. Y., on March 6, 1825, and was graduated in arts from Union College. His medical degree was conferred by the New York Medical College in 1852, and in 1876 he received the honorary M.D. from the College of Physicians and Surgeons in this city. After serving a year at Blackwell's Island Hospital he passed some years as surgeon on vessels of the United States and Pacific Mail steamship companies, and was later superintending surgeon on shore of the Pacific Mail Company. In 1862 he was appointed a police surgeon, and was president of the medical board of the police department for several years. In 1862 he was appointed lecturer on diseases of the genito-urinary organs at the College of Physicians and Surgeons, and clinical professor in the same branch in 1871. He was also connected at various times with many dispensaries and hospitals in New York City.

Early in his medical career Dr. Otis turned his attention to diseases of the genito-urinary system, and his labors and teachings contributed much to the advancement of this specialty. His views regarding the normal calibre of the male urethra were thought extravagant at the time they were first propounded, and he was obliged to defend them stoutly in many rather heated discussions before medical societies and in the medical press. He was the inventor of many urethral instruments, especially dilating instruments, and was the author of many papers and works on genito-urinary diseases and syphilis. He also wrote several works on the tropics and the Panama Railroad, and before graduating in medicine published a book of instruction in drawing.

Ten years ago Dr. Otis resigned his medical positions and retired from practice, travelling for a long time in Japan and the Far East. He never lost his interest in medicine, however, and used frequently, while in New Orleans, to attend the clinical lectures at the Charity Hospital in that city.

Progress of Medical Science.

New York Medical Journal, May 26, 1900.

Report of a Case of Hæmaturia due to Renal Carcinoma; with Endovesical Photographs.—F. Beirhoff reports the case of a woman, aged fifty years, who had passed blood in the urine at intervals for over a year. Cystoscopy showed no changes in the vesical mucosa. The right ureteral orifice was occluded by a blood clot which protruded for about 1 cm. into the bladder. The left ureter was normal, and was seen to discharge clear urine actively. The lower left portion of the bladder was seen to be occupied by a large blood clot, which prevented proper manipulation for ureter catheterism before another irrigation to discharge the clot could be made. In view of the fact that the patient had a second time become comatose, and that catheterization of the ureters was not an absolute necessity here, this procedure was omitted, and a diagnosis of right unilateral hæmaturia of renal origin, probably due to renal tumor, was made. The patient was, in view of her extremely critical condition, at once replaced in bed, and a course of active stimulation continued. Later, nephrectomy was performed by Professor Gebhard, the right kidney and as much of the ureter as could be reached being removed. The kidney was found to be carcinomatous. The subsequent history of the case was uneventful, the urine being for two days slightly tinged with blood, due to the discharge of the vesical and ureteral clots, after which it remained free.

On the Dietetics of the Convalescent Stage of Fevers.—A. Rupp believes that density of food is one of the chief conditions that determine its digestibility. Therefore weak stomachs and lazy intestines should not be burdened with foods that are impervious to the juices of the digestive canal. To quote Hutchinson: "The intestines demand a certain amount of insoluble residue"—and they get it—"to act as ballast and serve as a stimulus to peristalsis." All this does not militate against allowing convalescents puddings and gelatins and creams. The absorption and digestibility of these luxuries can be favored by sipping water, plain or carbonated, as they are eaten. Sometimes, from nervous causes or from the lack of having something to do, the stomach will give rise to insomnia, or to distress and uneasiness and even nausea. Such cases must be studied individually and treated accordingly. A cup of milk, diluted or undiluted, with or without lime-water, or a crust of bread, and even cold water sipped, may give relief.

A Study of the Application of the Galvano-Cautery in the Nose.—B. Douglass believes that the cautery is a destructive element even more powerful than the knife; that it destroys physiological tissue as completely as if it were removed from the body; that its effects extend, unlike those of the knife, to a region beyond its limit of application; that it is subject to all the dangers of surgical accident which come from using the knife, with the single exception of hemorrhage; and that, besides the ordinary surgical dangers, it has special dangers of its own—that is, it may furnish a nutrient pabulum for bacterial growths. Used in the hands of a novice it is capable of producing a subsequent atrophic condition worse than the original disease. Its present method of use by linear cauterization is, to say the least, theoretically incorrect, but in special and selected cases, used by a proper method and in the hands of a careful operator, it will give better results than cutting methods.

The General Characteristics of Ray Fungi and their Relation to Certain Bacteria.—L. Hektoen reviews the literature on this question, stating that Olsen regards most bacteria as adaptation forms and not as true independent species. They are in reality imperfect and imperfectly known fungi. The ray fungi are genuine mycelial fungi which pass by various stages into bacilli, and the tuberculomyces (the name, according to the new view, of the bacillus tuberculosis) is a ray fungus or streptothrix because it has branches. Allusion is also made to the branching of diphtheria, glanders, and other bacilli. An extensive bibliography is appended.

Treatment of Anal Chancroids.—The plan commended by M. A. H. Thelberg consists of the following steps: general anæsthesia, dilatation of the sphincter, cauterization of the chancroid with the Paquelin cautery, rubbing orthoform into the wound, and the insertion into the bowel of a good-sized rubber drainage tube wound about with iodoform gauze and dusted with orthoform. The usual dressing with T-bandage is then applied. The bowels are controlled for three days, then moved with magnesia, an enema of olive oil and castor oil in equal parts being given at the same time. A cleansing enema follows the catharsis, and a ten-per-cent. iodoform suppository is introduced. Results have been excellent in eleven cases.

Physical Training in School and Home.—By H. S. Pettit.

The Instruction of the Hospital Corps of the United States Army.—By W. H. Wilson.

A Summer Plaster-of-Paris Jacket for Pott's Disease.—By R. T. Taylor and S. H. McKim.

Septicæmia among Young Chickens.—By L. F. Rettger.

Journal of American Medical Association, May 26, 1900.

Medicine as a Business Proposition.—G. Frank Lydston discusses the business side of medical practice and shows some of the reasons why the average medical man is not as prosperous financially as he ought to be. Among other drawbacks, he devotes much space to the "inconsistencies and absurdities of ethics," concerning which he says: "There was once a time when it appeared a goodly thing for the chosen few to get together, like the 'three tailors of Tooley Street,' and, after establishing to their own satisfaction the fact that they were indeed 'the people,' formulate rules for the guidance of the many. These rules were called 'ethics.' And the profession has been wrestling with its ethics ever since, trying to determine what it was all about, anyhow. The ethical garment of half a century ago no longer fits—it is frayed and fringed and baggy at the knees; full many a patch has been sewed on it, in individual attempts to make it fit from year to year, until it is now, like the Irishman's hat, respectable by age and sentimental association only. And the public, the ever practical and heartless public, has also wondered what 'twas all about, and exhibits little sympathy for a profession which, while drivelling of ethics, has 'strained at gnats and swallowed camels.'" He says that the present system of ethics is not only hypocritical, but somewhat confusing. "The young man on the threshold of medicine doesn't know 'where he is at.' He is confronted by the unwritten law that only celebrated men and quacks may advertise. Small fry, who haven't the ear of the newspapers nor a chance for a college position, are tacitly ordered to keep their hands off. And the young fellow watches the career of the big man, who hides every other man's light under his own bushel, and marvels much." Other obstacles in the way of success of any but the favored few are the hospital and dispensary evils and the superabundance of medical colleges.

Experiments and Observations in Scarlet Fever. W. K. Jaques discusses the investigations which have been made in Chicago regarding the supposed germ of scarlet fever, and concludes that the "crescent" of Wynkoop and the "diplococcus" of Class are merely different forms of the same germ. He thinks the symptoms in the disease are caused by the multiplication of the germs themselves and their irritating presence, and not, as in diphtheria, by any toxins they may produce. He says in this respect the scarlet-fever germ resembles the typhoid bacillus. He purposes making experiments in the production of artificial immunity after the following method whenever an opportunity presents itself: "Raise a small bleb by means of a fly-blister; with a hypodermic needle inoculate the serum without breaking the blister, if possible. If the patient is susceptible, the germs ought to multiply in this serum, and before passing into the blood they would have to get through the barrier of inflamed capillaries filled with leucocytes. In this manner their entrance would be slow and the blood could gradually take up the products of germ multiplication in the serum, while the cells would be stimulated to the production of a defensive antigermin."

Carcinoma in Early Life.—Walter L. Bierring reports eight cases of cancer occurring in patients aged respectively twenty-three, twenty-six, twenty-seven, twenty-eight, thirty, thirty-two, thirty-four, and thirty-five years. He says the disease in early life is becoming more frequent, though whether it keeps pace with the general increase in carcinoma he thinks it will be difficult to determine. He reviews the several etiological theories of the cause of malignant new growths, but brings forward nothing of importance which might contribute to a solution of the problem.

Philadelphia Medical Journal, May 26, 1900.

Syphilis.—S. H. Friend treats of the special pathology and advocates reclining rest-treatment in the constitutional stage. He concludes: (1) That without regard to the system, organ, or tissues affected, and irrespective of the period of syphilitic infection, all syphilitic lesions begin in the arteries. The truth of this special pathology is demonstrated by a study of the symptomatology of syphilis. There are few symptoms of the disease which cannot be explained by (*a*) an acute change in the arterial wall caused by the infection, (*b*) by a chronic change in the arterial wall or a destruction of the artery, a sequel of the syphilitic infection, (*c*) by a relapse of the syphilitic infection causing changes in the arterial walls and destruction of the artery. A study of the pathological phenomena of the disease shows that almost every phase of those phenomena, including the formation of connective tissue, gumma, and the virulent infectiousness of the blood, is explained by the disease in the walls of the arteries. (2) That (*a*) the special pathology of syphilis is in a disease of the arterial walls; (*b*) that this disease of the arterial walls bears the same relation to syphilis as does the disease of Peyer's glands of the intestine to typhoid fever; the disease of the skin to smallpox; the formation of a false membrane to diphtheria, etc. The foregoing special pathology demands that reclining rest be made a routine treatment during the constitutional stage.

Clinical Notes on a Case of Paranoia.—A. W. Ferris relates an interesting history of a medical man who, having strong neurotic heredity and history of eccentric childhood, after a life of early dissipation became extravagant, acquired exalted and egotistic religious delusions, and claimed to be "the second coming of Christ," carrying out his ideas by producing voluminous "Scriptures," seeking followers, etc. He finally had systematized delusions of persecution, with occasional outcrops of hypochondriasis, and a possible capacity for homicide.

Rickets.—J. L. Morse gives, with pictures, an account of the skeletal changes: rosary thorax, enlargement of the epiphyses, and deformities of the long bones, bow-legs, knock-knees; weakness of the spine, pot-belly, feebleness of leg-muscles, increased nervous irritability; changes in the skin, glandular system, respiratory tract, circulatory system, enlargement of the spleen, etc. He finds the causes to be dietetic and hygienic. The prognosis is good as to life, and treatment must be along the lines of dietetics and hygiene.

Friedrich's Disease, with the Report of a Fatal Case.—F. S. Pearce and J. M. Swan relate the history of a girl, aged nineteen years, first seen in 1895, when knee jerk was still present. Six months later, in 1896, it had entirely disappeared, and nystagmus, at first absent, appeared the following year. At no time were there pains in the joints or muscles, and the athetoid movements first noted in the hands subsequently appeared in the neck. There was no post-mortem obtainable.

The Hospitals for the Insane and Study of Mental Diseases.—By Stewart Paton.

Mütter Lectures of the College of Physicians of Philadelphia.—By J. B. Roberts.

Intestinal Indigestion and its Consequences.—By W. H. Porter.

Boston Medical and Surgical Journal, May 24, 1900.

On Ischæmic Paralysis and Contracture of Muscles.—Augustus Charles Bernays says that the only operation or therapeutic measure that suggests itself to his mind as promising any real benefit in this condition is the excision of a transverse section of the radius and ulna. The piece to be resected should be from 2 to 4 cm. in length, and both long bones would be shortened just that much. The contracted muscles and their tendons could then possibly exert a greater play upon the wrist and fingers. It is clear that the muscular tissue in the forearm would not be increased by this operation, as, indeed, it cannot be by any possible surgical proceeding. The effect of the operation would be to give such remnants of contractile substance as may be in existence a chance to exercise their power to a greater advantage. The functions of the fingers would thus be more or less improved, and the usefulness of the crippled hand increased.

The Ideal Rations for an Army in the Tropics.—By Edward L. Munson.

Some Thoughts on Medical Education.—By Frederick C. Shattuck.

Medical News, May 26, 1900.

Cystitis Papillomatosa.—Frederic Bierhoff reports three cases of this affection, which occurs in women as a form of chronic cystitis, its symptoms being frequency of urination, accompanied by more or less pain and tenesmus, the urine passed being clear or turbid. Its seat is at the trigone, which it usually covers, and it may extend over into the urethra, from which at times it appears to start. Its villi or papillæ spring from an inflamed base, and are discrete. To diagnose the condition, the ureteral cystoscope is armed with a ureter-catheter and inserted into the bladder, so that the window lies directly over and close to the inflamed area; the catheter is then gently laid diagonally upon this surface, or is passed over the surface at an angle. It will at once sink into the mass of papillæ, or pass between them, and the individual papillæ will stand out distinctly as discrete, rosy-red tongues against the deeper color of the catheter.

Organotherapy in Tabes and Other Nervous Diseases.—Martin A. H. Thelberg reports two cases in which the administration of spermin had undoubted beneficial effect where other medication had failed. In the first case, after six injections, incontinence, bladder and rectal pains disappeared, and general tone, well-being, and cheer improved considerably. After twelve injections had been given, ptosis and oculo-motor symptoms were cured. In the second case, one of paralysis agitans, the frequent insomnia, which in this patient seemed to be caused by autointoxication from gastro-intestinal disturbances, is usually relieved by a single injection of 1 c.c. spermin given hypodermically. The stumbling gait is also gratefully affected.

Inaugural Address.—By Edward D. Fisher.

British Medical Journal, May 12 and 19, 1900.

Remarks on Plague in the Lower Animals.—Frank G. Clemow considers the acquisition of the plague by monkeys under natural and artificial conditions; then, after eliminating mammals and bats, which have never been known to suffer, he takes up the important question of plague in rodents, especially rats, and their sources of infection—from grain, flesh of other animals, rags, insects—the mode of their infection, and the way they transfer it to man. Then the study of rats on shipboard and their infection under artificial conditions is taken up. Infection in mice, squirrels, guinea-pigs, porcupines, marmots, and rabbits is then studied. In conclusion, it may be asserted, the author says, that the following animals are liable to contract plague under natural conditions: monkeys, rats, mice, bandicoots, squirrels, and marmots. Of these, rats suffer far the most frequently, and are, of all animals, the most important agents in the spread of the disease. Mice are less susceptible, but appear, in some instances, to have suffered considerably, and may have been agents in spreading the infection. Monkeys, bandicoots, and squirrels have on rare occasions suffered from plague, but there is nothing to show that they have ever aided to any extent in transmitting the disease to man. Marmots undoubtedly spread a disease allied to plague in Transbaikalia, and possibly in Mongolia. The evidence in regard to cats, dogs, and jackals is far from conclusive, but there is no reason to believe that these animals play any great part in spreading plague. The same is true of pigs, sheep, and goats. Horses and cows do not appear to have ever contracted plague under natural conditions, and may be disregarded as active agents in spreading it. Birds are equally immune to the disease, and there is no evidence to show that either birds or reptiles or fishes have ever aided in multiplying and diffusing the infection. Insects, on the other hand, are probably agents of considerable importance in the spread of plague.

Small-Bore Rifle Bullet Wounds and the "Humanity" of the Present War.—C. T. Dent finds that the great majority of wounds in the present war are inflicted by rifle bullets. Septic wounds, shell and shrapnel wounds, wounds from small-bore arms, skin wounds, injuries of long bones, wounds of joints and of the spinal column are considered. In conclusion he says: "I dread lest the good surgical results be not ascribed fully enough to their proper cause. We know the fearful mortality brought about by overcrowding and by bad hygienic surroundings in the Crimean War, and, for that matter, in the Franco-German, Russo-Turkish, and other later wars. This campaign has already shown that these preventable disasters have been traced to their true source. Air, air, pure sunlight and air, have done more, much more, for our wounded in this war than seems generally to be acknowledged. I dread lest the Army Medical Department, commended and patted on the back as it has been and is, may relax its efforts to improve further. If so, a terrible awakening is in store for us when we next have to face the hideous horrors of war amid unfavorable surroundings. But if we look on our present experience just as an indication that we are working in the right direction, then at least the medical profession may feel that it is doing—not that it has done—its best to contribute to the humanity of war."

Injuries of the Bladder Occurring in the Course of Gynæcological Operations.—J. W. Cousins gives a case in which there was recovery after sloughing of the bladder walls and free discharge of urine through the abdominal wound. In rupture or wound of the bladder, he finds that success of immediate treatment depends (1) upon the complete disinfection of the seat of injury, and (2) upon the accuracy with which the stitches are inserted. It is sometimes an important question to decide whether the abdomen can be safely closed without any provision for drainage. This must be determined by the severity of the injury, the state of the urine, and the condition of the peritoneal cavity. Surely, if other organs can be injured and the abdominal wound closed, there can be no reason why bladder injuries should not admit of the same treatment. In his case, however, it appears highly probable that the introduction of a glass drainage tube was a fortunate precaution, and materially aided in saving the life of the patient by establishing a channel for the direct escape of the urine. On the other hand, if the abdomen had been completely closed at the time of the operation, the rupture would have been followed by the accumulation of septic fluid within the pelvis, which would have very probably terminated in fatal septicæmia.

Herpes Progenitalis from a Diagnostic Point of View.—Arthur Cooper says it must be remembered that herpes is one of the most sensitive of lesions, and that nothing resents ill treatment more promptly or more actively. One of the commonest causes for irregularity is the course of herpes in balanoposthitis. A polycyclic outline of the edge of the ulcer can often be made out with the aid of a lens. A case is cited in which herpes was present at the time of infection with syphilis; a condition in which the latter may readily be overlooked. The following points may be found useful to keep in mind in any doubtful case in which sores are present on or near the genital organs: (1) The chances of irregular herpes should always be considered; (2) the lesion or lesions, and also the inguinal glands, should be closely and repeatedly examined until the diagnosis becomes clear; in the mean time (3) do not apply irritants, and (4) do not give mercury.

An Account of Some Researches into the Nature and Action of Snake Venom.—R. H. Elliot first considers the source of immunity when cobra venom is taken by the mouth, and quotes Professor Fraser's paper, "Filling in Some of the Gaps Suggested." A series of experiments are represented by tables. In a further communication the protective properties of serums and the nature of certain immunities and protections will be taken up.

Case of Suppuration in the Mastoid with Optic Neuritis on the Same Side: Operation: Recovery.—By J. Preston Maxwell.

The Lancet, May 12, 1900.

A Case of Ruptured Liver; Successful Operation on a Pulseless Patient.—T. Carwardine reports the case of a man aged twenty-five years, upon whom a heavy case of glass weighing half a ton had fallen, crushing him against a wall. He was operated on about three hours later. Multiple intravenous injection of saline fluid were made. The abdomen was opened above the umbilicus. It was full of blood. There was no free gas or odor; the spleen was intact, but the liver was felt to be lacerated. The right rectus was therefore cut across—it was pale from anæmia and did not bleed—and a large quantity of clot was turned out of the abdominal cavity. The whole hand could now be passed into a laceration of the liver which extended right across the under surface from about the position of the gall-bladder—which was not to be seen—to the posterior part, dividing the liver almost in twain and leaving the upper part of the capsule floating freely on the blood-clot. The remainder of the right lobe appeared to be badly smashed and could not be defined owing to its crushed condition. The clots and fragments were removed. Then, as suturing was quite out of the question, three long pieces of iodoform gauze were packed in the laceration and a fourth piece below, comprising three and three-quarter yards of gauze several folds thick. In addition a sponge-cloth was packed below and to the left of the liver. The abdominal wound was approximated and nearly two pints of saline fluid were poured into the peritoneal cavity. The duration of the operation was very short and the patient had severe dyspnœa afterward and was restless, thirsty, and sick. He remained pulseless for thirty hours, after which the pulse became perceptible and gradually improved, and the dressings were found to be bile-stained. On the following morning the patient was much better and deliberately sat up and asked for the paper to read the war news. Subsequently the discharge was copious, bile-stained, and smelt strongly ammoniacal, like urine. The gauze was removed at the end of a week and a temporary drain was established in the right loin. The patient went to the convalescent home two months after the injury and returned looking fat and strong with the wound securely healed. The author is able to find recorded only three previous successful cases where a primary operation has been done in cases in which the patient was severely injured and collapse followed quickly.

A Study of the Heart Wall in Diphtheria, Rheumatic Fever, and Chorea.—F. J. Poynton states that the poison of diphtheria appears to destroy the muscle fibres far more than does that of rheumatism. This is a warning not to raise dilatation of the heart—a clinical entity so definite and well recognized—into the position of a primary disease, for if this be done it is natural enough to consider that the greater the dilatation the greater the danger. Yet the truth of this, even for any one disease, is only approximate, for all diseases vary in their virulence and individual effects, and those that attack the cardiac wall may damage the muscle fibre at one time far more than at another. A poison acting upon the myocardium with great virulence will, it is clear, cause such an impairment of the heart's force that death must occur before there is marked dilatation, an occurrence not infrequent in diphtheria. It is probable that in rheumatism also this question of greater or less virulence is an important one. Though the extent of the cardiac dilatation must necessarily be a sign of very great significance, it is in these myocardial affections that the paramount importance of the symptoms becomes apparent; for these symptoms are an index of the muscle failure. In this principle probably lies the explanation of some of those more obscure cases of cardiac rheumatism—cases in which, without evidence of valvular or pericardial disease, there remain unaccountable breathlessness, præcordial pain, and other indications of cardiac inadequacy. Finally, from the theoretical standpoint the changes in the cardiac wall and in acute rheumatism are of interest because their nature and complexity are decided evidence in favor of rheumatic fever being due to a microbic infection.

Mastoid Disease, Acute Otitis Media, and Pyæmia Occurring in an Epileptic as a Result of Injury.—R. A. Wilson's patient was a man aged thirty-seven years, who was beaten about the head with an earthenware chamber utensil in the hands of another patient in a frenzy of acute maniacal delirium. For several years after, the patient complained of pain over the right mastoid process, and eventually a discharge made its appearance from that ear. Symptoms gradually ensued as indicated in the title, and death finally resulted. Several circumstances in the case strike one as being peculiar: (1) The fact that the disease commenced in the mastoid portion and spread to the middle ear, instead of vice versâ; (2) the long period of latency during which the only symptoms were deep-seated pain and slight deafness; (3) the rapid progress to a fatal termination when once the process had spread to the tympanum; and (4) the limitation of the disease to the mastoid and tympanic cavity, and the non-implication of the membranes and lateral sinus, although the ultimate cause of death was pyæmia.

Intestinal Obstruction Due to Gall Stones.—A woman aged eighty years, seen by E. W. Palin, was suddenly seized with symptoms of acute intestinal obstruction which persisted in spite of treatment until the sixth day, when complete relief followed the passage of a gall stone measuring a little over one inch in diameter by three-quarters of an inch in thickness, nearly round, and well saturated with fecal material. Several smaller stones were passed but unfortunately they were lost. There had never at any time in the patient's life been any symptoms pointing definitely to any gall-bladder trouble, but she passed through a very similar attack of obstruction some five or six years ago. Though the obstruction was complete for at least six days, her condition never became serious.

Ptosis of the Liver and the Floating Lobe.—Under the foregoing title, F. Treves describes respectively the sinking down of the liver in the abdominal cavity and the projection downward of a portion of the right lobe in the form of a large tongue-like appendage. The condition was first described by Cantani in 1865. Treves describes the mode of prolapse, symptoms, detailing in full methods of abdominal examination, etc. He finds the floating lobe to be commonly associated with a distended gall-bladder containing gall stones. The operative treatment of ptosis consists in fixing the organ in place by various schemes of suturing. For the floating lobe, we may either excise, suture the lobe to the anterior abdominal wall, or treat the associated distention of the gall bladder by cholecystotomy.

Remarks on the Diagnosis and Prognosis in One Hundred Cases of Double Optic Neuritis with Headache.—By R. T. Williamson and F. Roberts.

Summer Diarrhœa with Special Reference to Causation and Prevention.—The first Milroy lecture. By F. J. Waldo.

Note on Simultaneous Excision of Both Mammæ with Axillary Glands for Cancer.—By H. Snow.

A Mishap with Carbolic Acid.—By H. L. Johnston.

Berliner klinische Wochenschrift, May 7, 1900.

The Pathology of Chronic Fibrinous Bronchitis.—H. Strauss narrates the history of a man aged fifty-eight years, whose sputa presented numerous tube-like bodies which under the microscope were found to be made up largely of the so-called Charcot-Leyden crystals. The sputa were brought up with a cough unlike that of bronchial asthma, inasmuch as it lacked the characteristic inspiratory whistling sound, though in the intervals between the coughing spells the man suffered from dyspnœa. The masses containing the crystals were found to be of a fibrinous nature.

The Treatment of Infected Wounds with Hydrogen Peroxide.—Von Bruns believes that the effect of this agent is partly chemical and partly physical. The nascent oxygen has a stimulating effect on the tissues, and the foamy condition produced tends to loosen up all particles of necrotic material. The actual germicidal effect of the remedy is a very weak one.

Resection of the Rectum.—A case of this nature is described by W. Levy, who discusses the general surgical technique under the headings of skin incision and splitting of the sacrum, isolation of the tumor for the removal of which the operation is planned, resection of the bowel, and subsequent suturing and after-treatment.

Observations on the Demonstration by Means of the Roentgen Rays of the Architectural Structure of Bone.—By J. Wolff.

Examination of the Acid Secretion of the Stomach.—By S. Talma.

Il Policlinico, May 1, 1900.

A Case of Diabetes Insipidus in an Infant of Two Months.—Olimpio Cozzolino reports a case in which the amount of urine passed daily was over a litre. There was nothing in the family history to account for the condition. Treatment consisted of an equal mixture of tincture of valerian and ethereal tincture of the chloride of iron, gtt. v.-x. being given three times a day, and a spoonful of coffee in Scott's Emulsion in the morning. The child recovered. Cases of this disease are extremely rare in young children. Heredity is usually a chief etiological factor, and nervous taints, such as hysteria and peripheric neuritis, traumatism, falls, shocks, acute and chronic infective diseases, and gastro-intestinal catarrh, have all been considered to exercise an influence in the production of diabetes insipidus in children. The author agrees with Heidenheim, that in certain cases there is merely exaggerated but still normal activity of the emunctories of water, very little solid matters being excreted.

New Method of Treatment by the Intravenous Injection of Metallic Iodine.—L. M. Spolverini, giving the results of his experimentation upon animals, says that injections of the strong solution of iodine proved entirely innocuous, even 12 c.c. producing no symptoms of poisoning, either immediate or remote, and no symptoms of irritation in the circulating blood. Animals subjected to this treatment all increased in weight. No thrombus was found in the blood-vessels, and blood taken from human veins and directly from an animal's heart showed no tendency to coagulate when mixed with the solutions used in the injections.

Auscultation of the First Heart Sound in Relation to the Tracings of Ventricular Pressure.—By Balderino Bocci and Adamo Moscucci.

Extra-Pulmonary Absorption of Gas.—By C. Bernabei and Dr. Liotta.

Malaria in Grosseto in 1899.—By B. Gosio.

Hydrocele.—Under infiltration-anæsthesia the upper portion of the sac is cut into and the testicle turned out, the tunica vaginalis stripped off and turned inside out. Stitches are passed to prevent the testicle from re-entering the sac. It is replaced within the scrotum, and the wound sutured.—WINKELMANN.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

MR. TREVES' ADDRESS ON HIS EXPERIENCE IN SOUTH AFRICA —VICTOR HORSLEY ON THE EFFECT OF ALCOHOL ON THE BRAIN—CONFERENCE AT MANCHESTER—LONDON UNIVERSITY —SIR BATTY TUKE, M.P.—PROFESSOR WYLLIE—DEATH OF DAVIES-COLLEY.

LONDON, May 11, 1900.

If you had visited the Medico-Chi. on Tuesday evening you would certainly have thought at first that you had strayed into the wrong meeting. The usually staid and dignified Royal Medical and Chirurgical Society—to give it the full official title—exhibited as many signs of animation as any of its more lively sisters. Instead of a sparsely scattered audience listening to an abstruse paper, there was a crowded room, every seat occupied and standing-room only to be had in a crush. There must have been some three hundred fellows present, and they all seemed cheerful and happy as if they were really enjoying themselves. They had turned out to greet the civil surgeons just home from the war, for it had been announced that these gentlemen would attend and speak. Naturally a full meeting was anticipated, but it was hardly supposed possible for such a number to put in an appearance, and the returned surgeons could not but be gratified at the friendly reception of their colleagues. Mr. Treves would no doubt be specially pleased that his own profession quite understood his recent utterance about the "plague of women" in South Africa. He really only put in forcible, if rather rough phrase, what Sir A. Milner had stated more diplomatically and what had been said in all directions by those who knew the facts. Of course some cried out as if they were hurt, and for a few days the female party was against Mr. Treves. But the tide seems to have turned, and I have heard ladies express delight that he had denounced the society seekers of excitement.

To return to the meeting. Mr. Treves brought no statistics. It is too soon for them. We shall get figures in plenty later on and also lessons in military surgery. Meantime it is interesting to listen to the impressions of one who was present and well qualified to form opinions. Many were curious to hear what Mr. Treves would say about abdominal wounds. He did not advocate interference; he pointed out the difficulties of carrying out abdominal sections under the circumstances of warfare. It is impossible for the surgeon to spend adequate time over one operation when many wounded men are waiting for his attention. Neither can the ordinary precautions and skilled nursing be at his disposal on the field or in the hospital after a battle. Then the modern rifle gives the wounded a better chance. The small bullet does not carry the clothing into the wound; hence this is mostly aseptic and soon heals, a fact frequently observed in this war as to wounds in all parts, while there have been most remarkable recoveries from those of the abdomen, some of which were related by Mr. Treves. The most dangerous of these are those which traverse the abdomen from side to side, but Mr. Treves has himself recorded some marvellous cases of the kind in which recovery took place though nothing was done. He mentioned the circumstances which should, in his opinion, deter from interference—such as the time after the wound, a long transport, retained bullet, wounds involving liver and right kidney, as they usually resulted in recovery, as did also those below the umbilicus. As to the mortality of abdominal wounds by the Mauser bullet he hazarded the guess that sixty per cent. of the wounded have recovered. This, as I just now intimated, is only a rough estimate or an impression. If it should eventually prove to be nearly correct it would show a great fall from the mortality met with in previous wars, and confirm the view of military surgeons generally that wounds from modern rifles are less dangerous than from older weapons. A great many other points were touched by Mr. Treves, who was accorded a vote of thanks for his interesting address.

At the next meeting Mr. Dent will give an account of his experience in the war, and Sir W. MacCormac also will probably speak.

Professor Horsley delivered the second Lees and Raper lecture at St. James' Hall on the 27th ult. This lectureship has been established as a memorial of the late Dr. F. R. Lees and Mr. J. H. Raper. The former of these was perhaps the most learned advocate of the temperance cause, a retiring scholar whose writings were everywhere respected; the latter was an eloquent and enthusiastic platform worker in the same cause. Mr. Horsley opened his lecture with a warning that the emotions excited by tragedies and poverty brought about by alcohol must not warp the judgment in considering the scientific aspects of the subject. He then proceeded to expound what is known as to the effects of alcohol on the brain. He explained and illustrated with lantern slides the structure and functions of the cerebrum and cerebellum, directing the attention of his audience particularly to the arrangement of the sensory and motor areas. The relation of the cerebrum to the cerebellum was then considered. The effect of small quantities of alcohol on the centres for voluntary movements and for co-ordination led to the necessity of explaining that the perceptive and associated centres work as a whole. A demonstration of the way in which the "reaction time" is measured was then given, and Kraepelin's researches were quoted as showing that after a small dose of alcohol it was slightly shortened at first, then it was very speedily lengthened, and continued so as long as the alcohol remained in the system. So far as to the simple reaction period, but when we come to the complex reaction (in which there is an association of ideas), there is no preliminary quickening but the slowing begins at once. Kraepelin had himself been deceived at first as to the complex reaction, for he thought he could add and subtract figures more quickly, but when he proceeded to measure on the recording drum the exact time he was astonished to find the reverse was the case; all his mental operations were really impeded from the first by even small or dietetic doses. Much the same deceptive feeling is produced by other drugs. Mr. Horsley proceeded to explain the effect on voluntary movements, and then stated the structural changes produced on nerve cells. These and other points were considered in the light of the most recent researches, and the lecturer concluded that the common notion that moderate doses, such as people take with meals, have no deleterious effect, cannot be maintained, and from a scientific standpoint the plain teaching is total abstinence.

The three direct representatives in the medical council attended the medical conference at Manchester and expounded their views. There were fifty delegates of medical associations at the meeting, and they represented about four thousand members. The conference extended over three days, and some pious resolutions were carried. I am afraid all three direct representatives have lost influence over the midwives bill, which was one of the subjects discussed. The outcry for an increase in the number of direct representatives in the council is useless. One or two more could do nothing, and no one expects a larger increase—scarcely any one hopes for that.

The London University, having safely effected its flitting to South Kensington, held its first presentation of degrees in its new home on Wednesday. The Prince of Wales was present on the occasion.

Sir J. Batty Tuke took his seat in the House of Commons on Tuesday as the new representative of the universities of St. Andrews and Edinburgh.

Dr. John Wyllie has been appointed successor to Sir Grainger Stewart in the chair of medicine of Edinburgh University.

Mr. Davies-Colley resigned his appointments at Guy's Hospital, where he had steadily worked for above thirty years, about Christmas last. He was in feeble health—in fact he knew himself that he was the subject of mortal disease, but he finished his work up to the Christmas vacation, and then went home, to return to the hospital no more. He died on the 6th inst. in his fifty-seventh year. He was a Cambridge graduate in arts and medicine, F.R.C.S., and had filled examinerships and other offices at his college and his university. But his life-work was at Guy's. He edited several volumes of the Reports, to which he contributed some papers as he did also to the medical journals and society transactions. When it became known that his illness would be fatal he received an address from a great number of Guy's men who had been his pupils, expressing their gratitude for his teaching and example and their regret that his health compelled him to retire. Few men at Guy's would be so much missed.

OUR PARIS LETTER.

(From our Special Correspondent.)

THE INTERNATIONAL MEDICAL CONGRESS IN PARIS.

PARIS, May 18, 1900.

The Thirteenth International Medical Congress is to be held in Paris from the 2d to the 9th of August, 1900. The fact of its taking place during the exhibition will certainly tend to draw a large number of American medical men than would have been otherwise the case. It may be of interest to the reader to have a synopsis of what will happen during this congress, as well as sundry details as to the method of being inscribed, the advantages accruing therefrom, and the subjects chosen for discussion. A few remarks will be added on the hospitals to be visited and the arrangements made by the French government for furnishing information and for lodging visitors. The prices to be paid will also be hinted at.

The president of the congress is Dr. Lannelongue, well known for his works on infantile surgery, the use of craniectomy, and the treatment of chronic abscesses in Pott's disease. On calling at the headquarters of the congress, I saw Dr. Lannelongue as well as Dr. Chauffard, the general secretary of the congress, who gave me in great part the information which follows.

The first steps in the organization of the congress were taken long ago, and consisted in sending out circulars and invitations to a great number of physicians and surgeons, and also to different governments and scientific bodies. Five different classes were established under the following titles: biology, medical science, surgery, obstetrics and gynæcology; lastly, public medicine. Each class is divided into sections, of which there are in all twenty-four. It was, of course, a hard task to find the place to locate them in special halls in the space of a week. The general assemblies will be held in the grand amphitheatre of the Sorbonne; as to the sections, they will be held at the Faculty of Medicine, the Law Faculty, the School of Pharmacy, the College of France, the Sorbonne, the Pasteur Institute, the Assistance Publique amphitheatre, and the Val de Grâce, a military hospital. All these buildings are near each other, so that it will be easy for a member of the congress to go from one to the other. The ophthalmological section will attend the Hôtel Dieu; that of dermatology will, of course, hold its meetings at the St. Louis Hospital.

I shall now describe the method used for each member of the congress, how he is classified, and what paper he receives on writing for admission. This can be done either directly by writing to the general secretary, Dr. Chauffard, 21 Rue de l'École de Médecine, and enclosing a postal order for 25 francs, or else through a foreign committee, the president of which is Dr. Osler, of Baltimore, for America. Suppose an American physician to have written for admission. In a month he will receive a receipt for his 25 francs on stamped paper, a membership card, and a railway ticket to be used on arriving in France. On crossing the frontier this ticket is to be stamped by the railway officials, and the price of one single ticket paid. On leaving, this ticket, which must have been countersigned in Paris at the École de Médecine, serves as a free pass, but the same route must be followed without any stop-over. All this is indicated in a special circular printed in five languages. The applicant, moreover, receives the definite programme, the insignia to be worn, and invitations to the first and second general meetings. There is also sent a prospectus indicating a certain number of agencies, who will see to furnishing apartments or lodgings to the members of the congress. I notice on this prospectus that the "Agence Desroches" will receive the visitors at the station, conduct them to a hotel, and give them all the requisite information. The first day will be 20 francs, including room, lights, attendance, and first breakfast; the other days 10 francs; the last day 15 francs, including the ride to the station. One should notify the Agence, Rue du Faubourg Montmartre 21, of the day of one's arrival and send the first day's price, *i.e.*, 20 francs. The Agence des Voyages Pratiques, 9 Rue de Rome, undertakes the same thing for 6 fr. 50 c. up. There is also the Agence des Voyages Modernes, Rue de l'Échelle 1; the Agence Lubin, Boulevard Haussmann 36; the Société Française des Voyages Duchemin, 20 Rue de Grammont. One of these agencies should be written to at least a month in advance. For medical men travelling by themselves I must mention the fact that about eight hundred beds in the dormitories of the public schools will be put at their disposal. The price will be 5 fr. 50 c. for bed, attendance, and first breakfast. One should write to the office of the Medical Congress, 21 Rue de l'École de Médecine.

On arriving in Paris, the member should go as soon as possible to the École de Médecine, 21 Rue de l'École de Médecine, and show his card to the porter. The latter will direct him to a secretary speaking English, who will stamp his railway ticket, give him his personal card, write down his address, and give him the special invitations. There will be a night festival in the gardens of the Luxembourg, and official receptions by the President of the Republic and by the President of the Council. As souvenirs of the congress there will be the insignia, which are to be made by Vernon, a well-known engraver, and the volumes distributed gratis to the members of the congress.

On leaving Paris the visiting physician will be able to use his railway ticket without any extra charge. Of course luggage over-weight will undoubtedly be charged for.

During his sojourn in Paris the medical man will have a variety of hospitals to choose from, each one being in some way specialized. St. Louis will interest dermatologists on account of its wonderful museum; Necker and Beranjon have two genito-urinary services under the direction of Guyon and Bazy. At the Hôtel Dieu Dieulafoy is professor of clinical medicine. Potain is at the Charité. Ferrier, professor of surgery, has a service at La Pitié. Finally the physician should not fail to visit the newly constructed Boucicaut Hospital, where he will be able to see the latest type of hospital erected in France, and visit what is considered the best specimen of a maternity in this country.

LETTER FROM THE FALKLAND ISLANDS.

(From our Special Correspondent.)

The health of the colony of the Falkland Islands is most satisfactory. The death rate from preventable diseases has not exceeded that of former years, there being an entire immunity from contagious diseases, grippe, variola, diphtheria, typhus fever, etc. A few cases of scarlet fever simplex of an exceedingly mild form occurred recently, which has been stamped out. The climate is hostile to all diseases of a contagious or infectious nature. Tropical diseases could not exist for a single hour, the climate being too cold and bracing, and the strong westerly and southerly winds, with the amount of iodine in the air, would prove a sovereign prophylactic against their incursion.

The presence of tuberculosis, whether attacking the mesenteric glands, joints, or in the insidious form of phthisis, is met with, which is not to be wondered at considering the numbers of waifs and strays that elect to take up their abode in these islands. Notwithstanding this drawback, the climate and highly nitrogenized food successfully combat them, there being an entire absence of want or destitution of any sort. The humblest laborer receives at least 6 *s.* per day, and some of the above-mentioned diseases no doubt have been superinduced by living too highly, and over-indulgence in intoxicants. The large number of cases of drowning is not surprising considering the low temperature of the water, the ice zone being not far distant, and the sinuosity of the kelp, which entwines itself around the legs and arms of the swimmer, and with waving motion brings him beneath the surface.

The absence of specific disease is remarkable considering the number of blue-jackets and marines who for five months each year visit our shores. This fact speaks well for the medical officers in charge, or for the highly moral and respectable class of men in the navy. A few cases of tertiary or secondary syphilis have been under my treatment, but only one case of primary.

The usual diseases of childhood occur, such as urticaria, varicella, fevers, and convulsions, the latter the result of dentition or intestinal worms.

The Falkland Islands colony, when any other statistical test is applied, is phenomenally comfortable and thriving. But for the natural decay that comes with age, and a few deaths by accident, the Falklands might almost lay claim to being the islands of the immortals. The deaths number twenty-four in a population of some two thousand, but when fatal accidents to new-comers from drowning and shooting and other exceptional causes are taken into account, the rate is whittled down half-way to zero. The rate of infant mortality is little more than a fourth of the English average. It is impossible to find conditions more favorable to vigor of body and length of days. It would surprise many physicians at home to see how that dread malady phthisis is warded off, and I believe in many instances completely buffeted by the health-giving qualities of these islands. Let it not be thought that disease and pain are unknown. A chronic intractable rheumatism is apt to twinge the back in the form of lumbago, or the knee or elbow joints; but the bane of the islands is chronic indigestion. Pyrosis (or water-brash) is continually reminding the inhabitants that they are mortal, and yet the fault is their own; the source of mischief lies in the enormous quantities of coffee and tea consumed in the strongest forms, the indigestible character of the bread they eat, and the ignorance of most of the women of the rudimentary laws of cooking. Tested by exports and in comparison with the number of inhabitants, the prosperity of the Falkland Islands is unexcelled by any of Her Majesty's possessions, and represents the sum of £65 per capita in produce unaided by manufactures. The well-being of the inhabitant is further evidenced by the fact that the sum per head of the population deposited in the Government Savings Bank averaged £22. In the balance of loss and gain, the islanders with a small portion of sunshine and warmth, but without phthisis or crime, and £22 per head in bank, are certainly happy among colonists.

Ethyl Chloride is sprayed upon the inside of a thick Esmarch inhaler and administered. As soon as the patient is insensible to a pin's stick ether is substituted. The advantages are rapid anæsthetization, less disagreeable after-effects, and simplicity.—J. P. Tuttle.

Clinical Department.

PLACENTA PRÆVIA AND TWINS.

By ANTHONY BASSLER, M.D.,

NEW YORK.

THE following case occurred in the practice of Dr. Albert T. Swan, and by virtue of its rarity and successful issue is worthy of recording:

Mrs. C——, aged thirty-five years, mother of eight children, *i.e.*, four normal births; a placenta prævia partialis five years ago, delivered by Dr. H. J. Garrigues; a breech, uncomplicated, two years ago, and the present instance.

The mother could not give a definite account of the beginning of the last pregnancy because at the third month she had a flow lasting several days which she supposed to be menstruation. The history to the present period is uninteresting. Two weeks before delivery, while doing housework she had a slight hemorrhage from the vulva lasting about five hours; confident that she would have no return of the hemorrhage, the household duties were resumed. On February 25th she was awakened in the morning by profuse hemorrhage. Within a short time the diagnosis of placenta prævia was made, and inasmuch as the uterus reached to within three inches of the ensiform cartilage full term was supposed to have been reached, and the vagina was tamponed to control the hemorrhage and excite labor pains. On the following day the tamponade was removed and a fresh packing done. No more bleeding had taken place. This was done for two days longer; as no pains were set up, and infection of the placental site was feared, and as no safety to the mother could exist so long as pregnancy continued, forcible delivery was advised.

On examination under chloroform the uterus was found to be quite globular in shape. High on the left side a hard body was felt which was supposed to be a breech; being fearful of placental separation the head was not sought for in the pelvis. On vaginal examination the cervix was high and was lengthened. The external os was flaccid; the upper end of the cervix would barely admit two fingers, and was very firm. The entire lower uterine segment had a soft boggy feel, and internal ballottement could not be gotten. The cervix was dilated manually by Dr. Swan and myself; as it gave way to the force the placenta bulged down into its cavity and the bleeding increased. This bleeding was effectively controlled by pledgets of cotton wrung out in very hot bichloride solution pressed against the protruding mass. Care was exercised in dilating the cervix so as not to detach the placenta. Only the tips of the fingers were employed in overcoming the contraction above. When the cervix was fully dilated, diagnosis of placental site was made as occupying the right lower segment. A small portion of the placenta was felt on the left side. The flat hand was then passed upward on the left side between the placenta and uterus. About four inches above, the margin of the placenta was passed. Continuing upward between the membranes and uterine wall, about an inch beyond this margin, the amniotic sac was broken into and the hand passed into its cavity. During this time, as a precaution against alarming hemorrhage care was taken to keep the forearm to the right so as not to peel up the placenta. A child's head was seized, brought to the left side of the uterus, and delivered through the rent in the sac. After delivery the flow of blood was profuse. Quickly the hand and forearm were reintroduced and the second child was delivered in the same way. The placenta and its membranes were then removed. Although the uterus had retracted, the subsequent hemorrhage, not yielding to hot douches and acetic acid, compelled packing with gauze.

The mother made a rapid recovery, and excepting a slight rise of temperature on the third day (probably from absorption of stagnant lochia at the placental site) she ceased to be of interest. The children were about fifteen inches long and were attached to a single large flat placenta.

The first case of placenta prævia and twins was reported by Dr. H. R. Storer.[1] The woman was dead when first seen by him, and laparotomy was done in the interest of the children. Two placentæ and separate membranes were found. Dr. C. E. Quinn[2] reported a case in which pains were induced and the first child was expelled in its sac, the hemorrhage being very slight. Dr. Collingwood Fenwick[3] reported a case having two placentæ and two membranes. Dr. H. O. Nicholson[4] reported a fatal case, the mother living six hours after delivery.

Obstetricians differ as to the rarity of this condition. Among Dr. Trask's two hundred and fifty-three cases of placenta prævia, gathered from every source,[5] there was only one such case, and that foreign. Angus puts it as occurring once in 44,500 cases. Barnes states that it is not so common. Winckel states that multiple pregnancy predisposes to placenta prævia, the accident being relatively four times more frequent in plural than in single pregnancy. If Lusk's book be taken as a standard, we might conclude as follows: (1) Placenta prævia with single child occurs once in nine hundred cases; (2) in about every eighty labors one pair of twins are born; (3) by comparing these ratios we should expect to find twins with placenta prævia once in seventy-two thousand cases.

THE LIFE OF A PLASTER-OF-PARIS JACKET.[6]

BY HOMER GIBNEY, M.D.,

NEW YORK.

I PURPOSE giving the history of several cases of the very many of Pott's disease seen at Dr. V. P. Gibney's clinic, orthopædic department Vanderbilt Clinic, at the Hospital for Ruptured and Crippled, dispensary service, and those seen at our office, which, of course, are private cases; many of which in these various places came under my personal hand. The cases reported by Dr. Stokes are ones with which I am more or less familiar, and I know much care is always given to these individual cases as they present, and to this I think is due the fact that our jackets wear so well; and that, when we get an early case, apply a comfortable snug splint, thus absolutely fixing the spine, we are gratified to find on its removal all of the acute symptoms have disappeared, no psoas contraction, and no evidence of active disease.

There are many contributing causes to the longevity of a plaster-of-Paris jacket. I may be pardoned if I mention a few of the most prominent points which, if conscientiously adhered to, carry it to a "ripe old age."

First, the plaster must be carefully bought; that is, dental plaster, smooth and without grit; secondly, the bandages must be well or rather loosely rolled; and thirdly, the meshes of the crinoline must be well filled with the plaster. Each successive turn of the bandage must also be carefully and vigorously rubbed in. I believe one cannot pay too close attention to these apparently minor details to insure a perfectly fitting splint, a lasting support with the maximum comfort.

[6] Read before the Orthopædic Section of the New York Academy of Medicine, November 17, 1899.

I have three cases pertinent to the life of a plaster-of-Paris jacket. Briefly:

Case I.—A boy four years old, first seen in 1891. Symptoms present were abdominal pains and a disinclination to walk. He had been treated expectantly by some homœopathic doctor, a diagnosis not having been made. His family history was good; the hygienic surroundings were excellent, and there was no definite history of treatment. The consultation with their regular family doctor resulted in a diagnosis of caries of the spine—the prominence being at the mid and lower dorsal vertebræ. A Taylor brace was applied and worn with considerable discomfort; a large psoas abscess developed; the boy became much emaciated, and he was said to have developed a pulmonary tuberculosis. His parents were advised to take him at once to the country. Before this was done the abscess was carefully aspirated, but as its contents was thick, cheesy pus the field around was cleaned and an incision made, and the sac evacuated. Prolonged suppuration reduced him to an alarming point of emaciation. It was, however, thought best to apply a solid or permanent jacket. This was accordingly done; the bony prominences were protected, a fenestra being cut to dress the abscess. This jacket was worn for two months, when his general health was so much improved that it became necessary to change it. The deformity had not increased; there were no excoriations; the back and skin were in good condition. A new one was immediately applied. His condition remained good, and this jacket was worn for a year, when a new one was applied. His deformity remained the same, as shown by the tracing, which was taken with a lead tape, familiar to all those who have to do with spinal cases. His back showed no excoriations from the plaster, and the abscess instead of producing constitutional disturbances had, to a very large extent, given him no trouble.

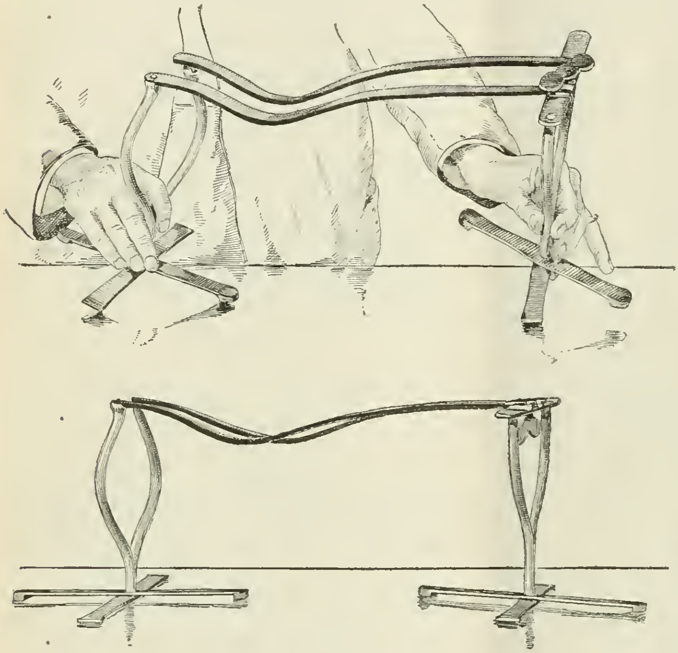

Fig. 1.

Two months ago a new jacket was applied, and he went again to the country and continues to improve.

Case II.—A boy six years old (caries of dorsal spine), was seen first in 1895. He had a fairly good family history. His personal history was fair, and the hygienic conditions and surroundings were excellent. The symptoms present were grunting respiration, attitude over-erect, unsteadiness of gait, and considerable abdominal pains. The kyphosis was most prominent at the tenth dorsal vertebræ. In this case, as in the previous one, a Taylor brace was applied, and this was followed by a Knight spinal. Both of these, however, failed to give him the desired support and consequent relief. His general health began to fail. A solid, permanent jacket was applied, and he was sent to the country. All of his symptoms rapidly cleared up; he gained in flesh, and it was necessary at the expiration of three months to reapply a new jacket, which was worn for eleven months. This was cut down; there were no abrasions and but slight excoriations, and the usual tracing revealed no appreciable increase in the deformity. A new jacket was applied less than two months ago. He runs and romps with other boys, and his general health remains excellent.

Case III.—Woman, twenty-seven years old. No definite history could be given. Following childbirth she had persistently severe pains through the lumbar spine and over the lower abdomen. Her family and personal history was good, and she was surrounded by best hygienic conditions. Her attitude was normal, the gait a little cautious and unsteady. She was exquisitely tender over the third and fourth lumbar spines. A snugly fitting, solid jacket, grasping the pelvis firmly, was applied, and she went to her home in Massachusetts the following day. She did not again appear at the office for a year, when she reported that within a month nearly all of her symptoms had disappeared and that for several months she had been absolutely free from all pain and discomfort. The jacket was cut down; the body was found to have no excoriations, in fact to be in excellent condition. There was no pain on concussion and no evidence of active disease. The spine was fairly flexible except at the point where tenderness and slight prominence were first noticed. A light steel spinal assistant was applied, and she was sent home cured.

These then are but three of the very many spinal cases which I have had the privilege of seeing in Dr. Gibney's practice, and in which we have applied the solid plaster jacket with most beneficial results. Just how long the solid jacket will live is difficult to say. I can but emphasize the cardinal point—careful attention to the minor details.

We have about discarded the swing or upright position in applying the jackets. Especially is this true in the cases of children when the deformity is in the lower dorsal and lumbar regions, we having adopted a slight modification of Goldthwait's frame, which apparatus is shown by the illustrations.

Two uprights on which the shoulders and hips may rest are placed at a short distance from each other on a table or board. Two untempered steel rods one-fourth to one-half inch in breadth are easily shaped to hug closely the deformity or prominence. The child is then held by two assistants, at the arms and thighs, in position on these vaselined rods, which fit into grooves in the uprights; the assistant at either end employing slight traction.

The bandages are thus rapidly applied, and as the plaster is setting or hardening the rods are carefully withdrawn, the spaces and unevennesses are smoothed, and the jacket is trimmed out with a sharp knife under the axillæ and over the hips, the edges being smoothed and bevelled. It is possible thus to make a most effective light support.

For many years we have promoted cleanliness and thus added to the age and efficiency of our solid jackets by putting a long strip six inches wide of linen or gauze next to the skin before the building-up process of the jacket begins. Then we carefully instruct mothers and nurses to move this back and forth under the jacket, first saturating one end with alcohol, thus giving the child practically an alcohol bath every day.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, May 3, 1900.

W. H. Katzenbach, M.D., Vice-President, in the Chair.

Remarks on Hyperchlorhydria. — Dr. Max Einhorn read this paper. He said that at one time it had been considered proper to treat almost all cases of dyspepsia by giving hydrochloric acid, under the supposition that the gastric juice was always deficient, but later observation had shown that sometimes the secretion of hydrochloric acid in these cases was actually greater than normal. Still later it had been discovered that digestion sometimes went on in the stomach when it should not do so, *i.e.*, when the stomach was empty. The present paper dealt only with those cases in which there was excessive acidity. According to his own experience, more than half of the cases of impaired stomach digestion were examples of hyperchlorhydria. Among farmers and others leading a life comparatively free from mental strain, the percentage would probably be much less than among his patients, who had been, for the most part, men in active business in the city.

Symptomatology.—Persons suffering from hyperchlorhydria were usually well nourished, and complained of uncomfortable sensations about one hour after meals. Some of them felt well except after their heaviest meal. Some complained of a burning sensation in the pit of the stomach, or sometimes of water brash. A smaller group complained not only of water brash but of slight regurgitation of food. The burning sensation might be present along the course of the œsophagus rather than in the stomach alone. These were the common symptoms, but they did not include all. Some of these patients complained of dizziness, or of a feeling of apprehension, or of severe headache, coming on perhaps without any distress in the stomach, at about the same time after taking food. In the more exceptional cases the symptoms might be vague, and might even simulate to some extent those of angina pectoris. A characteristic feature of all these different types of cases was that they experienced relief with the ingestion of food, and about ninety per cent. of the cases exhibiting these symptoms would be found to be instances of hyperchlorhydria. The appetite was usually good, and sometimes a hungry feeling was experienced about one hour after meals. Thirst was not increased. About two-thirds of these patients suffered from an obstinate constipation which was dependent upon an abnormal condition of the stomach. Sometimes there was a diarrhœa of similar origin, and the fact that it arose in this way was well shown by the ease with which it was controlled by the administration of an alkali. He was of the opinion that if the symptoms were reasonably distinct no examination of the gastric contents was demanded, but the fact should not be lost sight of that hyperchlorhydria sometimes existed without giving rise to the usual symptoms.

Pathology.—Opportunities for post-mortem study were naturally very rare in this disorder. In one case in which death had resulted from a pneumonia, examination, both macroscopical and microscopical, had failed to show any abnormality of the gastric mucous membrane, not even an ulcer. Most physicians now agreed that hyperchlorhydria was a functional disease.

Etiology.—As had been already stated, the disease was especially common among those subjected to much mental worry or anxiety, such as men in active business, or ladies too much occupied with social functions. Tobacco and alcohol were also prominent factors. As ulcer of the stomach was quite commonly associated with hyperchlorhydria, some had supposed that it was a cause of this affection. This could hardly be the case, because it was well known that gastric ulcers developed in cases not exhibiting hyperchlorhydria. Probably all that could be said on this point was, that hyperchlorhydria made it easy for such ulcers to develop. When these conditions coexisted, it might be impossible correctly to diagnose the presence of the ulcer except by the persistence of the symptoms in spite of appropriate treatment.

Treatment.—As a rule, cases of hyperchlorhydria responded promptly to treatment. Some physicians excluded all starchy foods for the reason that the excessive acidity interfered with the digestive action. He did not indorse this plan, and believed that most physicians had given up exclusive diets in these cases. As it had been found that an exclusive diet of meat stimulated and increased the flow of gastric juice, it had been recommended to exclude meats. His own practice was to try and strike the happy medium between these extremes, believing that exclusive diets were harmful. The diet which he usually arranged for those suffering from hyperchlorhydria comprised tender meats, not too highly seasoned, plenty of milk, water, and sugar. He directed that they should avoid acids, and should restrict the quantity of the starchy foods, particularly potatoes. The great point, after all, was to make them take their food in small quantities and at shorter intervals. These frequent meals in themselves gave relief, as the ingestion of food took up the acid, forming with it an acid albumin. Recent experiments seemed to show that sugar, as such, tended to diminish the acidity. Fats, especially butter, also decreased the acidity. The medicinal treatment consisted in administering alkalies at the time of maximum acidity, *i.e.*, about two hours after meals. One or two teaspoonfuls of bicarbonate of sodium would be found useful for this purpose, or, if the patients were constipated, bicarbonate of sodium and calcined magnesia, or rhubarb, soda, and magnesia, could be administered with advantage. He had also found the greatest benefit from the use of the bromides. Washing out of the stomach was not essential in these cases because there was no impairment of the motor function of this organ. The internal application to the stomach of either the faradic or the galvanic current would be found beneficial, as would also spraying into the stomach a solution of nitrate of silver.

The Occurrence of Mould in the Stomach.—Dr. Einhorn also read a report on this subject. He said that in all of his cases the microscopical picture had been the same. Dr. E. K. Dunham had examined the pellicles in the fresh condition. He had been unable to make them grow on the usual culture media, but had been more successful in growing them on bread. The species of mould had not been definitely determined from the fresh specimens—it might be an aspergillus or a penicillium. He had found these moulds more particularly in two groups of cases, viz., (1) cases of hyperchlorhydria, and (2) cases of gastralgia. It was reasonable to expect some benefit from the use of the gastric douche, or the spray of nitrate-of-silver solution.

Stated Meeting, May 17, 1900.

William H. Thomson, M.D., President.

Poisonous Snakes and Snake Poison, with Demonstrations.—Dr. Gustav Langmann read a paper on this subject. He said that snakes had two raised palatal teeth, both running almost parallel. The pointed hooks upon the back were used for hooking the prey. They had a very dilatable mouth, through which the prey was gradually drawn down into the œsophagus. The innocent teeth extended backward. In the row of teeth of the upper jaw, the poison was concentrated into one powerful tooth, the poison fang; sometimes there were two or three teeth at this point. The fangs stood immovable on erection, and folded like a pocket-knife when at rest. The arrangement of the teeth would aid in discovering if the snake-bite was harmless or not; but snakes did not always leave the imprints of their teeth. The poison gland was situated behind the eye, and was under the influence of the masseter muscle. The secretion was thrown into a groove in the mucous membrane at the base of the fang. The king-cobra was the largest of all poisonous snakes, measuring often fourteen feet, and enjoyed attacking and pursuing men.

Poison Apparatus.—The poison glands were triangular in shape, and this was supposed to be characteristic of all poisonous snakes. The glands were the homologues of the parotid glands. These animals could retain their secretion at will, sometimes keeping it for months. The poison was not odorless, and there was a specific smell for every species; the odor might be called "mousy." Fresh poison under the microscope showed epithelial cells and adenoid masses. It had been supposed until quite recently that the action of the poison was due to very virulent bacteria contained in the secretion. The cultures in different media gave entirely negative results.

Active Constituent of the Poison.—The first chemical examination was made with the viperidæ, and the active principle extracted was called viperine. Dr. Weir Mitchell, in 1883, published the results of his investigations: he found two albuminoids—one dialyzable and coagulable by heat, the other not; these he considered the active principles of the poison. There had really been no definite analysis of the poison made as yet, but there was quite reasonable assurance that the active principles were albuminoses. These albuminoses were peptones of rather recent date; they were the same as what was called propeptone, the intermediary stage in the changing of albumin to peptone. They were products by hydrolysis; they decomposed, took up certain constituents of the water, and so became more soluble and approached the peptones. It was important to know the different ways in which the albuminoses were changed, artificially by superheated steam, or by the gastric juice, or by pancreatic digestion, or by the living cells; these latter might be cells from the living organism or from the plant or bacteria. He asked what was the origin of the albuminoses. They were from the same albumin which had been worked out by superheated steam, by bacilli, or by gastric digestion, but they were entirely different; the toxins created in this way were different and could not be compared at all with each other. Different poisons had a different percentage of peptone and globulin. Gastric action had no influence on the snake poison, but the action of the bile had. A dried poison mixed in glycerin was as active as the fresh poison, even after the lapse of twenty years. Putrefaction would destroy it after a time. Alcohol rendered it inert for a time only.

Physical Effects.—Peptone caused some local œdema, with convulsions, and ended by paralyzing the respiratory centres. Globulin, on the contrary, excited local reaction with hemorrhages around the points of injection. Experience showed that the intensity of the hemorrhages and the paralysis corresponded with the hydrolysis of the albuminoses. Instant death was due to thrombosis.

Symptomatology.—The effect of the cobra bite was first shown by a scratch on the skin, which gave a burning pain with œdema; then appeared vertigo, followed by weakness of the limbs, paraplegia, ptosis, paralysis of the tongue and epiglottis, and inability to speak. The saliva dribbled from the open mouth. The paralysis was general, and the patient lay motionless. The pulse was weak, and continued after respiration had ceased. The respirations were slow and labored. The pupils were contracted. Slight convulsions sometimes occurred before the end. Absorption was exceedingly rapid, as experiments had shown, which were made by injecting the poison into the tail of a rat and amputating the tail after one minute, death following in a short time. If patients did not die from paralysis they recovered quickly. The bite of a rattlesnake caused more pronounced local disturbances. There were hemorrhagic disturbances and bloody exudations of all mucous membranes. Within thirteen minutes constitutional disturbances developed. There was a marked fall in the blood pressure. After a temporary increase of reflexes, tetanus and paresis supervened, and paraplegia of the lower extremities ending in complete paralysis followed. Patients died within twelve hours. If they recovered from the paralysis, septic fever might develop. An authentic case was instanced of a draughtsman in the National Museum at Washington, who was bitten by a snake on the index finger. After several weeks he recovered. He was bitten about the 2d of June. Swelling and inflammation of that finger occurred every year about the 2d of June, resulting invariably in the loss of the nail. It was only after ten years that this curious phenomenon ceased; he was then supposed to have been cured by the South American plant micania guaco. In autopsies the serous membranes were shown to have ecchymoses throughout, especially the peritoneum. The blood was liquid and did not clot even after a long time. The cobra bite gave symptoms analogous to those of acute bulbar paralysis in its most acute type.

The Pathological Effects.—No description of the pathological effects upon the central nervous system had ever been published which could be considered valuable. There were certainly pronounced effects upon the central nervous system and the medulla. Fresh poison added to the blood in a test tube caused the blood corpuscles to swell and lose their hæmoglobin. There was no change produced in the hæmoglobin. In the tissues diapedesis soon set in, and in a few hours after the injection one-half the normal blood corpuscles could be counted. The coagulability of the blood was influenced. Another important effect was the loss of the germicidal property of the blood plasma. Briefly summarized, it might be stated that if the patient died within a few minutes, he died from general thrombosis; if within twenty-four hours, from paralysis of the respiratory centres, and, later, from general paralysis; if after days or weeks, he might die from sepsis.

Prognosis.—The prognosis was not bad. Weir Mitchell once gave the mortality from the bite of the cobra as twenty-five per cent.; at another time he gave it as not more than twelve per cent. In Australia the mortality was said to be about seven per cent.

Treatment.—The object in the treatment of snakebites was (1) to prevent the absorption of the poison; (2) to destroy or neutralize its effects; (3) to accelerate its elimination; (4) the treatment of the symptoms. If the limb could not be immediately amputated, the ligature should be employed. This should be tied as tightly as possible and in several places: for instance, if the finger was bitten, the ligature should be applied to the finger, the wrist, and the elbow. Sucking the wound with the lips or with glass cups was a doubtful measure; if employed, it should be preceded by free scarification of the tissues. Many drugs were considered by the speaker, including permanganate of potassium, hypochlorite of lime, ammonia, alcohol, etc. Often alcohol was given to such an extent for snakebites that patients died from acute alcoholism; in many cases it was difficult to tell whether the snake-poison or the alcohol caused the patient's death. There were few chances of neutralizing the poison *in loco*. Since the kidneys were attacked it was doubtful if such measures should be employed as would increase their activity. Diaphoretics gave dubious results. It had been experimentally shown that, when morphine was administered hypodermically, much of it was eliminated by the stomach—in fact, by repeated washings more than one-half the quantity injected might be recovered. The same was the case with snake venom. Experiments showed that when animals' stomachs were washed out, after they had received a lethal dose of the poison, they lived; the control animals died. The fluid washed out of the stomach produced death when injected into other animals. In the snake-dance, in India, after the performance the performer received large doses of an emetic; then the whole crowd stood around watching the performer empty his stomach. The speaker considered remedies that were supposed to be specifics in snake poisoning, such as strychnine. This drug was repeated until tetanic symptoms appeared; enormous doses of it were given, especially in Australia. It could not be relied upon as a specific. It was noted that an artificial tetanus brought on by strychnine was stopped by the snake poison.

Antivenene Serum.—It had been found that certain animals were immune to snake poison. In the tropics this was regarded as caused by their activity. Poisonous snakes were immune against their own poison; this was ascribed to their own internal secretions. Antivenene he considered to be the only reliable antidote to combat the effects of snake poison. Full protection was afforded if from 5 to 20 c.c. was injected within one and half hours after the receipt of the bite. This antivenene had been used with success in the West Indies, the East Indies, and Africa. It was an open question whether the action of antivenene was chemical or physiological. Dr. Langmann thought it was chemical. He discussed the relation of toxin and antitoxin in detail.

The treatment was thus summed up. The ligature should be used, and followed by deep scarification. Antivenene and solution of calcium hypochlorite (1:60) should be injected. Stimulation with ammonia or alcohol was necessary. Hypodermoclysis of normal saline solution and artificial respiration may be called for. The victim should be encouraged to counteract the depression.

Demonstration of the Snakes.—Every human being had an aversion to snakes which could be overcome by will-power. There were about seven varieties of rattlesnakes. They were quite abundant in the Eastern States. Only a few years ago a man was bitten by one on the Palisades. These snakes, as a rule, were of a timid and retiring disposition, and were not aggressive, as they were reputed to be. If attacked they would stand and defend themselves. Dr. Langmann then showed how to handle these snakes. He removed them from the cage by means of a hooked stick. The snakes clung to it, being afraid to fall. Then, dropping them on a level surface, the stick was placed just back of the head, holding them down firmly, and the neck was grasped with the finger and thumb. The rattles were not an indication of the age of the snake; they got a new rattle with each shedding. The doctor showed, and handled, the diamond-backed rattler, the tiger, the moccasin, the copperhead, and others. The moccasin snake, when excited, would strike the floor with the tail, and the sound produced was very similar to that produced by the rattlesnake. Sometimes this snake was more dreaded than all others. Negroes were particularly afraid of them. The Palisades were still full of the prettiest of all snakes, the copperhead. Three years ago, sixty-nine copperheads were caught there.

Mode of Collecting the Snake Poison.—Dr. Langmann took a glass funnel, over the open end of which was stretched a piece of chamois skin; this was thrust into a cylinder. The snake being held as demonstrated, its head was brought close to the chamois and its fangs were deeply buried in it, the venom entering the cylinder by drops. To facilitate its passage the doctor pressed the poison glands with his fingers.

Demonstration of Rabbits Killed by Snake Venom.—One rabbit was shown which was killed by the intravenous injection of venom and which died in three minutes. On examination the peritoneum had a perfectly normal look and was not at all hyperæmic. The right auricle was filled with blood-clot. There were no hemorrhages. A second rabbit was then poisoned by the hypodermic injection. Here there were numerous hemorrhages. A third rabbit was shown in which there were numerous hemorrhages all over the peritoneum.

Anatomy of the Poison Apparatus.—DR. S. PULLITZER said that all vipers were distinguished by having a short superior maxillary bone which articulated with the lacrymal bone. Vipers brought forth their young alive. These two characteristics all species of vipers had in common. They were all poisonous, and were widely distributed, especially in the temperate and tropical zones, except in Europe, Australia, and New Zealand. Some vipers had a peculiar pit known as the "laureal pit." In 1866-67 a scientific study of this pit was undertaken. It was a depression on the side of the face on a line between the lower jaw and the margin of the orbit. This was called by some "the sixth sense." The function of it has been lett to conjecture, but it was thought to be connected with the elaboration of the poison; also, that it enabled the poison gland to get oxygen. At the bottom of the pit was found a delicate membrane which was invariably ruptured in attempts to dissect it off; it closed off an entire cavity which was lined with epidermis, which made it evident that it communicated with the outside skin and had an outlet. Serial sections were made, and the outlet was found near the margin of the eye. The speaker thought it was purely some kind of sense organ. He thought it might be an accessory organ of hearing, for a rudimentary cochlea and semicircular canals were found. There was no external opening or tympanum or external ear in any snake.

Findings in Nerve Cells after Poisoning.—Dr. P. Bailey presented a paper on this subject, based on experiments with rabbits.

Rabbit No. 1. Snake poison; rapid action. Cells showing changes were confined to the anterior horn of the spinal cord. Most of these cells were normal. A small number of cells presented in their chromatic elements modifications which probably evidenced the early stages of a beginning acute degeneration; *i.e.*, an increase in the granularity of the chromophilic bodies, and a fraying out at their edges, with some distinct loss in chromatic substance. The cyto-reticulum was normal. The nucleus might be normal or there might be an intensification of the surrounding membrane and a thickening of the strands of the nucleo-reticulum. A few cells were found in which there was much greater loss of chromatin, the cell bodies appearing extremely pale and no distinct chromophilic bodies being present.

Rabbit No. 2. Snake poison; long action. The character of the changes was the same as in the preceding, but more advanced and involving a much greater number of cells. Changes were found in the cells of the cortex, cerebellum, olfactory lobe (mitral cells), basal ganglia, medullary nuclei, anterior horn, and spinal ganglia. The cells showing the most marked changes were the anterior-horn cells, the Purkinje cells, and the mitral cells of the olfactory lobe. The changes were those of later stages of degeneration.

Rabbit No. 3. Heloderma poison; rapid action. The changes were almost identical with those found in rabbit No. 1.

Technique: The material was placed in a four-per-cent. alcoholic solution of formalin for twenty-four hours, then passed through graded alcohols. Sections were cut in celloidin and stained by Held's modification of the Nissl method, *i.e.*, erythrosin-methylene blue.

Dr. J. Ewing also presented a paper on this topic. The changes in the ganglion cells of a rabbit, in which moccasin-snake poison was injected, were found by Nissl's stain to be of a somewhat specific type and of the most extreme grade. The general appearance of the cells was that of total disintegration of chromatin bodies without marked loss of the amount of the chromatin substance. The outlines of the Nissl bodies were completely obscured, the substance having been redeposited in finely granular form all over the cell body and even in the pericellular lymph space. In the majority of the large stichocromes neither formed bodies nor reticulum could be distinguished. It was evident that the lesions extended much deeper than the chromatic substance, affecting the underlying cyto-reticulum, which was granular, disintegrated, and in some places completely destroyed. The nuclei were very opaque and the nucleoli often diminished in size and subdivided. The dendrites were very irregular, shrunken, or detached. These changes constituted a true acute degeneration of the cell in contradistinction to the simple disturbance of chromatic substance, which might be entirely physiological. He thought that the changes he had found in the rabbit were the most violent of all the conditions included in his experience with ganglion-cell degeneration.

SECTION ON GYNÆCOLOGY.

Stated Meeting, April 26, 1900.

J. Riddle Goffe, M.D., Chairman.

The Prevention of Dystocia due to Fœtal and Pelvic Disproportion.—Dr. Edward A. Ayers read a paper on this topic. He said that in multiparæ one had as an aid to prognosis the previous history of labors. Inquiry should be made as to the size of the children previously born, the size of the caput or other evidence of head moulding, the character of the pains, and whether or not assistance had been required. Up to the age of thirty-five years it was safe to assume that with each successive labor the child would be a little larger, and that after that age there would be a steady decrease in size. Some notion of the probable character of the pelvis might be surmised from a consideration of the size of the mother's bones generally. A stout woman was apt to have a less roomy pelvis than one not so fleshy. Large external pelvic measurements accompanied a heavy bony framework. When a woman had a satisfactory delivery history, careful internal measurements were not demanded. Measurements of the pelvic outlet were not generally taken, and this omission occasionally led the physician into trouble. The width of the pubic arch should always be considered. In cases of contraction of the true conjugate the child's head usually lay quite high. The variations of the head diameters were not so great as in the pelvis, but the determination of them should not be neglected. The speaker said that with sufficient experience very accurate opinions could be formed of the probability of obstruction occurring during labor, by examining during pregnancy with a view of determining the amount of resistance to the engagement of the fœtal head. This tentative engagement of the fœtal head would show in cases of marked contraction of the inlet a sudden and decided resistance as the head was forced down. If, on the other hand, the pelvis was roomy, the head could be forced down some distance, and its descent would then be checked gradually instead of suddenly.

Induction of Labor.—The chief and almost the only objection to the induction of premature labor was the danger of death of the infant from prematurity. This transferred the danger, to some extent, from the mother to the child. The question was really whether the prognosis for the child was better or worse if delivery was effected two or three weeks before full term by an easy labor, or at full term after a difficult labor. The best means of inducing labor were: (1) The use of the sterile, solid, flexible bougie, which should be tapering and not blunt; (2) the small Barnes' bag used only to excite contractions; (3) the tampon. All of these measures should be preceded by a full dose of castor oil.

Indications for Premature Delivery with Special Reference to Eclampsia; the True Toxæmia of Pregnancy.—Dr. S. Marx read this paper. He said that clinical experience showed that eclampsia was closely allied to renal inadequacy, and that the surest way to health was by the restoration of this function. The treatment must be early and timely. It was not sufficient to determine the presence of albumin and casts in the urine of the pregnant woman; the quantity of urea excreted daily must be estimated, for upon this must largely depend the question of the advisability of active interference. Five per cent. of all pregnant women had albuminuria, yet he had never known uræmic symptoms to arise when sufficient urea was excreted. For a woman otherwise healthy, the daily quantity of urea excreted should be about five hundred grains. The majority of albuminurias were simply danger signals; on the other hand, the absence of albuminuria, in the face of certain symptoms, meant nothing as regards safety. In some of the most desperate cases of eclampsia neither albumin nor casts were present in the urine. Progressive diminution of urea excretion, with or without albuminuria, was a special indication for interference.

Induction of Labor.—He was utterly sceptical as to the frequent occurrence of a truly contracted pelvis in this country. Most obstructed labors were the result of a disproportion between the fœtal and maternal parts. No matter how narrow the pelvis, as determined by the pelvimeter, a child could be delivered with assistance, provided it was small enough. The indication for the induction of premature labor was not to be found in the old-fashioned tables found in the text-books on obstetrics. All pregnant women should be subjected to a thorough pelvimetric examination because this instrument gave a clew to pelvic distortions and contractions. With one or two fingers in the vagina the other hand pressed the fœtal head down into the pelvis. The ease with which the head engaged at the brim determined whether or not premature labor should be induced. Small and even fair-sized fœtuses had been delivered through pelves whose diameters were far from normal, and in persons in whom there was reason for suspecting that major operations would be demanded. When once it was found that the head could not be made to engage, the time for interference was at hand. The pelvimeter should be used for purposes of comparison only.

The Treatment of Tumors Complicating Pregnancy.—Dr. Brooks H. Wells read this paper. Speaking of cancer, he stated that about forty per cent. of the children were born dead, and almost all of the others were feeble. Under these circumstances the child deserved only secondary consideration. In cancer of the cervix in a pregnant woman, operation was urgently demanded, and when circumstances were favorable vaginal hysterectomy should be performed while the uterus was still small. During the sixth month, or later, the viability of the child must be considered. If the case was first seen at term, and the disease was in the very early stage, the cervix might dilate satisfactorily, but there would probably be cervical lacerations. When the cancer involved the vulva, vagina, or rectum, the mass should be removed, if small; if more advanced, operation by the abdominal route gave the best results. The chance of becoming pregnant was less than when fibroids were present, yet when pregnancy did occur it was well known that the fibroids were prone to take on a much more rapid growth. Interstitial tumors grew the most rapidly, particularly where the uterine wall was much thickened. Subperitoneal tumors did not grow so rapidly, and if near the fundus were not of so much importance. In general, the higher the situation of the tumor and the more it approached the subperitoneal type, the less the danger. The most serious cases were those in which the fibroid occupied the pelvic cavity. It should be borne in mind, however, that the fibroids predisposed to abortion. Inflammation and sloughing of the tumor from injuries received during labor were very common, and constituted a grave danger. The mortality in labors complicated by fibroids had been, in the past, almost fifty per cent., and nearly as much for the child. During the early months of pregnancy myomectomy was indicated, and could often be done without interrupting pregnancy. For interstitial tumors of the fundus of the uterus, supravaginal hysterectomy should be done. Inversion occasionally followed delivery with tumors of the fundus. If the fibroid tumor obstructed labor and was in the anterior wall, it could sometimes be pushed out of the way while the patient was in the knee-chest position. Tumors of the cervix must be enucleated when possible, as even when they were very small enucleation was less dangerous than forcible delivery. A fibroid polyp, detected first after labor, should still be removed, as it was apt to slough and give rise to sepsis. To be successful these operations must be done early as a matter of election. Cysts or solid tumors of the ovary might also complicate labor. Large cysts were not likely to block the pelvis, but they caused much discomfort, and were particularly liable to rotation and twisting off of their pedicles. The dangers incident to delivery by version, forceps, puncture, twisting of the pedicle, intestinal occlusion, septic infection, and peritonitis were so great that the records showed a mortality here also of nearly fifty per cent. When seen early in pregnancy, an abdominal section, preferably by an intermuscular incision, with removal of the cysts, gave the best results. After the fifth month, if the tumor was not large or impacted, it was allowable to wait until the child was viable. At term, if the cyst was small, the child might be driven past it, or the tumor might be drawn above the brim. If the cyst was not impacted, and labor was progressing well, operation should be deferred until after the birth of the child. With an impacted cyst, puncture and delivery by version or forceps would seem proper, but the mortality was so great that it was rarely justifiable. Supravaginal hysterectomy was a better method. Labor might also be obstructed by enchondromata, cysts of the pelvis, hydatid cysts, displaced kidneys, and the muscle mass which sometimes resulted from ventral fixation of the uterus. His experience had been that during pregnancy abdominal operations in general were well borne. All unnecessary hemorrhage should be avoided, and particular care should be taken to secure perfect asepsis.

When was it Proper to Interfere in Apparently Difficult or Delayed Delivery, Especially in Primiparæ?—Dr. Malcolm McLean read a paper with this title. He emphasized the fact that the great difference between first labors and subsequent ones was to be found in the different condition of the soft parts. If surgical interference was attempted before the soft tissues had properly relaxed and dilated, great and unnecessary damage would be done to the mother. This was a very common error, and a notable example of meddlesome midwifery. If the presenting part was high up and movable, and the pelvic measurements were within normal limits, interference should be withheld. If the soft parts of the mother, once thoroughly relaxed and moistened with mucus, became hot and dry, the indications for interference were plain.

Dr. E. A. Tucker emphasized the necessity for being cautious in considering deductions from the first labor regarding the character of subsequent labors. In a case presenting suspicious symptoms of uræmia, the daily quantity of urea should be estimated at short intervals during pregnancy. He had recently urged primiparæ to do considerable walking during the last month or six weeks of pregnancy, in order to facilitate the engagement of the head. Such exercise did no harm, and he felt convinced that it accomplished much good in the way of facilitating engagement of the head. A substitute for the walking was the use of systematic exercise in bed—raising and lowering the body so as to exert abdominal pressure. Occasionally one would meet with primiparæ in whom the parts did not relax or become moist, even after many hours; here, of course, interference was demanded, and should be given, if possible, even before the vagina became hot and dry.

Dr. Egbert H. Grandin said that he was a believer in pelvimetry, and thought it would be better for womankind if all practitioners were taught and drilled in its use. Pelvimetry was valuable because it taught that, on the part of the woman, there might not be sufficient room, and hence impressed upon the attending physician the necessity for determining positively at the proper time whether or not one should interfere. He believed there was such a thing as an average normal pelvis, and yet through such a pelvis one woman would not be able to bring a child into the world, while another woman could do so, simply because one child was smaller than the other. If the presenting part would engage under suprapubic pressure, the chances were all in favor of the mother being able to deliver herself, but when the fœtal parts would not enter the pelvic inlet interference was at once demanded. Such interference should be as rapid as possible without injuring the maternal parts. He was sorry that Dr. Ayers advocated the use of the sterile bougie as a means of inducing labor, as it was a most uncertain and tedious method, and there was always risk of rupturing the membranes. If this accident should occur, one method of elective version was placed beyond our reach. Personally, he thought the best method was to use the tamponade of sterile gauze to excite dilatation, and then to complete this process manually.

Urinary Examinations in Pregnancy.—The time-honored teaching that the practitioner should make a perfunctory examination of the urine for albumin in the latter months of pregnancy should be relegated to oblivion. Some of the worst and most sudden cases of toxæmia that he had seen had been those in which there had been absolutely no albumin in the urine, and in which, the physician not having had his attention concentrated upon the quantity of urea and on renal insufficiency, the woman had suddenly passed into the condition of eclampsia.

Treatment of the Toxæmia.—He had recently looked over his records for the past twenty years, and had been struck with the large number of cases of toxæmia he had seen, and the high mortality that had attended the use of all of the approved methods of treatment. Of late years, in cases under his immediate supervision, just as soon as there had been evidence of urinary insufficiency, both as regards the total quantity of urine and of urea, he had not waited for cephalalgia and disturbance of vision, but had promptly emptied the uterus, because he felt that this meant the greatest good to the greatest number. He could not emphasize too forcibly the importance of making the treatment of this toxæmia of pregnancy a prophylactic one.

Dr. G. H. Balleray said that he had seen a good many women go through labor safely and well in spite of the large quantity of albumin in the urine; on the other hand, he had seen them succumb to eclampsia when there had been little or no albumin. He agreed with Dr. Marx that absolute pelvic contraction was rare. The indications of the pelvimeter should be looked upon as entirely relative. Pelvimetry was very much like measuring the outside of a man's house; it did not show positively whether or not the man could pass through a doorway in that house into one of the rooms.

Dr. F. H. Stuart said that the papers just presented had distinguished clearly two sets of conditions—those under the physician's control and those beyond his control. Examination of the pelvis by means of instruments, in his opinion. was fallacious; the digital examination by the experienced physician often afforded more reliable information. He would indorse most heartily the recommendation made by Dr. Tucker, that the patientshould be directed to walk and to exercise the abdominal muscles systematically and freely toward the close of pregnancy. Delay in labor was often owing to a faulty position, and this could have been avoided by preliminary efforts at securing proper head moulding.

Dr. Ayers said that the suggestions about walking in the later months were excellent, but required some modification, for the discussion had included both engagement of the head and the avoidance or relief of toxæmia, and if such exercises were not restricted one might walk from one danger into another.

Restricted Diet.—Dr. Marx said that he had made use of the restricted diet treatment for women in whom it was feared that labor would be difficult because of the large size of the child. It was certainly possible to accomplish a good deal in this direction by restricting the starches and sweets, and limiting the ingestion of water. At one time he had endeavored to improve upon this by administering the thyroid extract, but the women had returned to him complaining that they did not "feel life" so strongly as before. This diminution in the fœtal movements had been so marked as to compel him to abandon this mode of treatment. In closing, he would say once more that it was not albumin but urea that killed.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Seventeenth Annual Meeting, Held at Washington, D. C., May 1, 2, and 3, 1900.

(Concluded from page 877.)

Third Day—Thursday, May 3d.

The Value of the Tuberculin Test in the Diagnosis of Pulmonary Tuberculosis.—Dr. J. M. Anders, of Philadelphia, read a paper on this subject, in which he said that among those who have made use of tuberculin there was a remarkable unanimity of opinion as to its value for purposes of diagnosis. The question of dosage was vitally important, and he said he favored a medium-sized initial dose, which would obviate the disadvantages arising from the necessity of repeated injections, as was generally the case when small commencing doses were used. Recent and extensive clinical testing of Koch's method in widely separated parts of the world, by competent observers, had resulted in a practically unanimous verdict, which emphasized its superior value as an aid to diagnosis of incipient cases on the one hand, and in no smaller degree its apparent harmlessness on the other.

Dr. J. W. Brannan, of New York, said he was somewhat uncertain as to what was considered a reaction after the use of tuberculin. In a number of joint cases of doubtful origin in which the tuberculin was used for diagnostic purposes, the injections were followed by a rise of temperature and an increased pulse rate, but no tenderness or other local signs about the joint. The speaker asked whether in such a case it could be claimed that the patient had reacted to the tuberculin test.

Dr. Charles E. Quimby, of New York, said that in cases of pulmonary tuberculosis the injection of a very small dose of tuberculin would sometimes produce an obvious increase in the râles heard over the suspected area, even when it did not produce an evident rise of temperature. The speaker said he usually started with a dose of half a milligram.

Dr. Charles Denison, of Denver, in discussing the question as to what constituted a tuberculin reaction, said he thought that sufficient weight was not attached to the local reaction in the affected lung. After such an injection, there was usually an elevation of the pitch, and a peculiar, harsh bronchovesicular sound which was diagnostic, and which could not be detected previously.

Dr. H. L. Taylor, of St. Paul, said he wished to protest against the statement made by Dr. Anders that tuberculin should not be used as a therapeutic agent. The speaker said he was thoroughly convinced that much good could be done by the judicious use of tuberculin in a therapeutic way.

Dr. Arnold C. Klebs, of Chicago, said he had frequently seen local changes in the lung produced by the use of tuberculin. Still, in looking for a reaction, the temperature must be our main guide. In his own practice he had adopted the following rule: The temperature of the patient was taken at frequent intervals for a week previous to injection: this was averaged, and if, after the injection, there was a rise of 2° F. above this average, it was regarded as constituting a reaction. Of course there were variations to this rule. Furthermore, different preparations of tuberculin gave different reactions, and there was no absolute standard to go by. The speaker said he usually began with a dose of one-tenth milligram, repeated, if necessary, after two or three days, and increased up to one or two milligrams if the previous ones are negative.

Dr. E. O. Otis, of Boston, said that in the course of his experiments with tuberculin in cases of cervical adenitis, the results of which were published last year, he found that the reaction occurred in a certain number of cases of syphilis. As to what constituted a tuberculin reaction, Dr. Otis said that in addition to the increased temperature he would expect to get malaise and general depression. In the syphilitic cases which reacted, he had no reason to suspect any latent tuberculous focus.

Dr. Edward R. Baldwin, of Saranac Lake, said he thought that tuberculin was rarely needed in the diagnosis of tuberculosis of either the lungs or joints. It should be used only as a last resort, when the older methods of diagnosis had failed.

The Hydriatic Treatment of Tuberculosis.—Dr. J. H. Kellogg, of Battle Creek, Mich., read a paper on this subject, in which he said he considered it remarkable that such an old and valuable remedy in the treatment of tuberculosis as water should have been so much neglected. Upon the application of cold water to the body there was an awakening of all the vital functions, which exerted a marked influence on the circulation of the blood. Instead of the rather too vigorous application of cold water by means of ablution or the use of a sprinkling-pot, as was done in some institutions in Europe, Dr. Kellogg preferred dry friction of the skin followed by the application of cold water by means of the hand, accompanied by vigorous rubbing of the skin. The temperature of the water should be 60° F., gradually lowered as the patient became accustomed to the applications. Dr. Kellogg also demonstrated a rapid and simple method of applying a cold pack to the chest.

Dr. Charles L. Minor, of Asheville, referred to the importance of simplifying hydrotherapeutic methods of treatment, so that they could be easily and quickly taken advantage of by the physician in his general practice.

Dr. R. H. Babcock, of Chicago, said that while he regarded hydropathy as a valuable adjunct to the general treatment of tuberculosis, he objected to the statement made by the author which implied that a certain number of his patients were cured in consequence of this method of treatment.

Petroleum in the Treatment of Phthisis.—Dr. William Duffield Robinson, of Philadelphia, read a short paper in which he recommended a refined preparation of the oleum petrolatum of the United States Pharmacopœia as a valuable remedy in the treatment of pulmonary tuberculosis.

Stamina: with Special Reference to the Consumption of Fat Food for its Maintenance as a Preventive of Tuberculosis.—Dr. A. N. Bell, of Brooklyn, read a paper with this title. He said that after a somewhat extended observation and careful study of the relations of tuberculosis to food, he had come to the conclusion that, other conditions being equal, tuberculous diseases were prevalent in the inverse ratio to the use of fat of some kind as an article of diet.

In persons on the verge of pulmonary consumption, inability to digest fat food was one of the most prominent symptoms. They were afflicted with dyspepsia, of the kind in which an acid stomach was predominant—that kind of dyspepsia which was the common effect of the excessive and too exclusive use of farinaceous food; insomuch as, in some cases, to have created a loathing of fat food in every form. Nevertheless, in medical practice generally, this condition was an indication for the use of fat food. Cod-liver oil, emulsified or otherwise, was almost universally the first remedy resorted to, and the most persistently urged. Butter or bacon was the most digestible of all fat foods. Fat was the needful thing to energize both digestion and nutrition, and that form of it which was the most acceptable was the best.

Dr. Judson Daland, of Philadelphia, said that tuberculosis had appeared in Iceland in recent years. It was supposed that it had been introduced from Denmark.

The Blood Changes in High Altitudes.—Dr. S. E. Solly, of Colorado Springs, made a few remarks on this subject. He stated that during the past year he had done considerable work in connection with examinations of the blood. Perhaps the most interesting part of this work was that done upon twenty-five college students in Colorado Springs. They were all healthy, as far as could be ascertained. The blood-count was almost always high in young men at universities, and it was higher than the average in those whom he had selected for his experiments. It was noticed that in those students who had always lived in that altitude, the blood-count and hæmoglobin did not average quite so high as in those who were there for a comparatively short time—two years or less. There was also an intermediate class between these two extremes. Dr. Solly said that his findings rather argued in favor of the theory that while the blood-count and hæmoglobin were higher in those altitudes than at the sea level, there was a loss rather than a gain by long-continued residence there.

Dr. Daland, in reply to a question as to whether the peripheral blood was always a good index of the character of the blood throughout the body, said he thought there was no question but that the peripheral circulation was often greatly modified by external conditions, such as friction, for example, and that the blood in that region varied at times from that in the deeper vessels. Still, for experimental purposes we could secure it only from the peripheral vessels, and we must abide by the results.

A Case of Endocarditis.—Dr. Harold Williams, of Boston, briefly reported a case of mural endocarditis with the findings at the autopsy by Dr. T. Leary. This case was chiefly remarkable because of the unusual group of pathological lesions, and because of the absence of murmur in spite of the fact of extensive mitral disease. The absence of pain was another unusual feature.

Dr. R. C. Newton narrated the history of a case of malignant endocarditis which had recently come under his observation, in which the physical signs were very obscure. There was an entire absence of pain. The patient lived about six months after the onset of his symptoms, and died of exhaustion.

Dr. N. S. Davis, Jr., of Chicago, reported a case of what he regarded as malignant endocarditis, with recovery.

Dr. J. W. Brannan said it was well known that the presence or absence of a murmur, or the character of the murmur, could not always be relied upon to indicate the anatomical conditions we had to deal with in cases of heart disease.

The president, Dr. Jacobi, said there were cases of endocarditis in which the murmur disappeared, or in which there was no murmur. In malignant endocarditis there might be extensive changes and deposits without a murmur. When, however, the deposits were along the edge of the valves, we had a murmur. The speaker reported a case of malignant endocarditis, of gonorrhœal origin, with recovery.

Dr. Babcock said that although a cardial murmur might be regarded as a very valuable guide-post, pointing out the direction in which we were to search, it was comparatively unimportant in the actual diagnosis of valvular disease. We must chiefly rely upon the secondary physical signs in determining the nature of the lesion. Theoretically, it seemed that the presence or absence of a valvular murmur depended largely upon the size of the orifice through which the blood passed. The entire subject, however, was still involved in obscurity.

Exercises Suitable for Children Suffering from Heart Disease.—Dr. J. Madison Taylor, of Philadelphia, read a paper on this subject. He began by alluding to the fact that a fair number of cases of heart disease were met with among people who had lived a long and arduous life, in whom the cardiac disability was recognized in very early years and pronounced by competent clinicians to be most dangerous. Dr. Taylor said that in carefully selected instances, the use of regulated activities afforded much relief to many of the distressing symptoms which accompanied and followed disordered conditions of the heart. The term "exercise," as he employed it, should be clearly kept in mind as being a normal use of the bodily parts—not merely of the muscular system, as it was usually understood, but particularly the inter-relation of the viscera and their mutual co-operation. The first and most important item was that the individual should learn to sit, stand, and move in proper attitudes, for only thus could this symmetrical activity of the various parts be maintained. The next was to secure and practise full flexibility of the movable joints and skeletal tissues. An invaluable form of exercise was the act of breathing correctly, which should be taught, enforced, and practised. After outlining certain forms of exercise more fully, Dr. Taylor related his experience in adapting these measures to children, showing what remarkable results were sometimes brought about by movements which would seem to be of the simplest sort. Among these he mentioned readjustment of the muscles of the trunk and limbs, also stretching, both active and passive, and the cautious use of massage and baths. Most of the movements should be begun in the recumbent posture, and all should be followed by long periods of rest, lying down. Each individual case must be carefully studied, and the rules governing it should be formulated from watchful experience.

Dr. Jacobi said that in the treatment of acute cardiac disease he knew of nothing better than absolute rest. In addition to this, we should stimulate the peripheral circulation and relieve the heart by massage and passive movements, or applications of cold water or alcohol to the skin. The skin normally contained an immense quantity of blood, and if there was no peripheral circulation the heart would suffer.

A Case of Cardiac Aneurism, with Thrombosis of the Left Coronary Artery.—Dr. Judson Daland, of Philadelphia, reported this case. The patient was a man over fifty years of age, with an old history of syphilis, who died suddenly. The autopsy showed an aneurism of the left ventricle, with extensive fibroid degeneration of the wall of that cavity and the intraventricular septum. There was also a thrombosis of the left coronary artery.

Officers Elected.—The following officers were elected for the ensuing year: *President*, Dr. R. H. Babcock, of Chicago; *Vice-Presidents*, Drs. A. C. Peale, of Washington, D. C., and S. W. Langmaid, of Boston; *Secretary and Treasurer*, Dr. Guy Hinsdale, of Philadelphia; *Member of Council*, Dr. A. Jacobi, of New York.

Therapeutic Hints.

Catarrhal Laryngitis.—

℞ Ammon. et potass. tartrat.	gr. $\frac{1}{20}$
Liq. ammon. cit. (Br.)	♏ x.
Elix. aromat	♏ v.
Aquæ	q.s. ad ʒ i.

M. S. Every four hours for a child of two or three years.

—Ashby and Wright.

Croup.—

℞ Chloral	gr. lxxv.
Potass. brom	gr. xlv.
Ammon. brom	gr. xxx.
Aq. cinnamomi	℥ ij.

M. S. Teaspoonful for child of seven years. Repeat in twenty minutes if not relieved. Decrease for younger children.

—Joseph Holt.

Creolin Pills.—

℞ Creolin	6 gm.
Spt. vini rect. dil	1 gm.
Ext. glycyrrhizæ, Pulv. glycyrrhizæ	āā 6 gm.
Gum. tragacanth	1 gm.

M. ft. pil. div. No. c.

For use in intestinal fermentations, infectious diseases, etc.—Spoeth.

Diuretic.—

℞ Salicylate of sodium and theobromine	āā 5 gm.
Syrup of orange-peel	25 gm.
Distilled water	60 gm.

M. S. Dessertspoonful every two or three hours.

—*Journ. de Méd. de Paris*, March 25th.

Acute Colic, when non-surgical:

℞ Chloroformi	7.5
Tinct. opii camph	50.
Ol. cajuputi	2.
Acaciæ pulv., Syrupi	āā q s. ad 100.

M. ft. emuls. S. Dessertspoonful in water every two or three hours.

—William Pepper.

Chloro-anæmia.—

℞ Artemisin	0.001 mgm.
Quassin. crystal	0.001 mgm.
Ferri protoxalat	0.10 cgm.

M. ft. pil. No. i. S. Take four daily.

This is said to bring rapidly back appetite and a good color.

Rebellious Intermittent Fever.—

℞ Quininæ sulphat	4. gm.
Ferri et potassii tartrat	10. gm.
Acidi arsenosi	0.10 cgm.
Aquæ destil	300. gm.

M. S. The day following the fever a teaspoonful every hour; subsequently every three hours.

—Baccelli.

Rheumatism.—Alkalies should always be prescribed along with the salicylates, and the one to be preferred is some potassium salt, the bicarbonate or the citrate. These remedies should be continued for two or three weeks after the joint symptoms have subsided. Iodide of potassium and sodium are often useful in the symmetrical type, in which the same joints on each side are affected. With regard to diet, meats and meat teas are contraindicated. Milk may disagree, and this may be overcome by adding to it a little salt. A temporary vegetable diet is useful. In the commencement the less food the better.—William Ewart.

After-Pains.—A hot meal may be better than medicine. For the instant relief of exhaustingly severe pains a piece of tissue paper is saturated with five or six drops of amyl nitrite and stuffed into a two-drachm vial, and the patient inhales this whenever she feels the pains coming on.—Winterburn.

Dysentery.—Free gentle purgation is kept up with

℞ Sodii sulphat	℥ i.
Aq. fœniculi	℥ iv.

giving as much as is required for the effect of producing bloodless stools.—W. J. Buchanan.

Grippe.—

℞ Sodii benzoat	20 gm.
Tinct. aconiti	gtt. ix.
Syr. polygalæ	100 gm.
Aq. bul.	q.s. ad 300 c.c.

M. S. Dessertspoonful three times a day in hot infusion.

Grippe with Circulatory Asthenia and Arterial Hypotension.—Daily intestinal lavage, after which 5 c.c. of the following can be injected:

℞ Caffeinæ,	
Sodii benzoat	āā 10 gm.
Aquæ bul.	ad 100 c.c.

—Grasset.

Gonorrhœa.—

℞ Methylene blue	gr. i.
Oil of nutmeg	gtt. i.
Oil of sandalwood.	gtt. ij.

In capsules. Give four daily.

—O'Neill.

Phthisis.—

℞ Tannin	6
Spt. vini rect	20
Glycerini	60
Elix. Garus (Fr.)	30
Aq. destil	160

M. S. Teaspoonful three times a day.

—Derscheid.

Grippe in Children.—

℞ Tinct. aconiti	gtt. v–x.
Sodii benzoat	1–3 gm.
Syr. lactucarii	5–10 gm.
Syr. aurant. flor	20 gm.
Mucil. acac	120 gm.

M. S. Dessertspoonful every two hours.

—Périer.

Or,

℞ Antipyrin	1 gm.
Aquæ laurocerasi	2 "
Syr. tolu	40 "
Aq. destillat	60 "

M. S. In three or four doses during the day.

—Comby.

Obstipation.—

℞ Hydrarg. corrosiv	0.1
Strychnin. sulphat.	0.05
Aquæ destil	30.
Ext. cascaræ sagrada fl	120.
Glycerin	ad 250.

M. S. One to three teaspoonfuls daily.

—R. C. Fisher.

Anæmia.—Give iron in hot solution.

Bronchitis.—Potass. iod. 0.3 in a tablespoonful of water half an hour before meals will give relief in three or four days; given after meals in a larger quantity of water it is said to have much less effect.

To Abort a Cold.—Give a nasal douche with a pink solution of permanganate of potassium. Place a plug of cotton in each nostril, soak with the solution, and leave in place for an hour.—Max Nassauer.

In Nursing Women.—Opium, morphine, atropine, hyoscyamus, colchicum, arsenic, cocaine, chloral, and salts of lead should not be given, and digitalis, ergot, and antipyrin should be withheld when they produce untoward effects.—Marifan.

Pertussis.—The following is to be applied to the pharynx:

℞ Acid. phenic. cryst	1.50 gm.
Glycerini puri	10 "
Syr. tolutani	5 "

M. S. External use.

—Guida.

Cervical Metritis.—

℞ Tinct. iod.,	
Glycerin (neutral)	āā p. æ.

Apply every second day, then every third, and finally once a week. At the same time inject daily for ten or fifteen days with:

℞ Iodi bi-sublimat	0.50 cgm.
Potass. iodidi	1.0 gm.
Aq. bull	1,000 "

—Cariere.

Pruritus Scroti.—

℞ Hydrarg. chlor. corros	0.50 cgm.
Spt. vini rectif.,	
Aquæ chamomil	āā 25 gm.
Chloroformi	gtt. v.
Aquæ camphoræ	100 gm.

M. S. Apply.

—Leistikoff.

Gout.—

℞ Lithii benzoatis	ʒ iiss.
Sodii phosphatis	ʒ v.
Tinct. colchici sem	ʒ iiss.
Aquæ cinnamomi	ad ℥ iv.

M. S. Dessertspoonful two or three times daily.

—Butler.

Snake Bite.—

℞ Selaginella apus (snake moss)	ʒ ss.

Macerate in an ounce of sweet milk and give at once. Also apply some of the moss to the wound.

—Rawley White, of Virginia.

Ulcerating Blepharitis.—Epilation, followed by washing for ten minutes morning and night with the following solution, diluted with three times its volume of tepid water:

℞ Hydrarg. oxycyanid	0.30 cgm.
Sodii chloridi	3. gm.
Aq. destil	500. "

Touch daily with a crayon of blue pyoctanin.—Coppez.

Convulsions in Children.—Hot or tepid bath or mustard bath if the child seems to have been chilled. To prevent recurrence give:

℞ Potass. brom.,	
Sodii brom.,	
Ammon. brom	āā 0.20 cgm.
Syr. codein	5. gm.
Syr. auranti flor	30. "
Aquæ	100. "

If the child cannot swallow, give a rectal injection with

℞ Musk	0.20 cgm.
Chloral hydrate	0.30 cgm.
Camphor	1 gm.
Yellow of egg	10 gm.
Water	100 gm.

J. Simon.

Parasitic Blepharitis.—

℞ Bals. peruv	2 parts.
Lanolin	4 "
Ol. amygdal. dulc	2 "

M. S. Apply to the margins of the partly closed lids and leave on for a half-hour or more.

—Roehlmann.

Medical Items.

How Frozen Meat Deteriorates.—Meats frozen and kept in cold storage for long periods do not undergo organic changes in the ordinary sense—that is, they do not putrefy, soften, or smell bad, but they certainly do deteriorate in some intangible way. After a certain time frozen meat loses some life-principle essential to its nourishing quality. Such meat lacks flavor; it is not well digested or assimilated. Its savorless condition cannot be remedied or successfully disguised by the use of sauces and condiments. Those who eat cold-storage food for any length of time develop diarrhœal disorders, lose in weight, and would eventually starve to death unless a change of diet was made. The same reasoning applies to tinned fruits and vegetables. They should not be used after a certain period has elapsed. Especially should people be warned against using stale eggs and old milk and cream. Milk and cream are kept for days, rancid butter is washed and treated chemically, but all food, and especially cold-storage food, is damaged by long keeping, and will not nourish the body properly. There is the greatest abundance of food, but it does not satisfy.—*Sanitary Record.*

The Home of Genius in Great Britain.—According to Mr. Jonathan Hutchinson, the home of genius in Great Britain is in the vicinity of Shakespeare's birthplace. In *The Home University* he has written a short article in support of this point, showing that within a radius of fifteen miles of Coventry were born Shakespeare, George Fox; Butler, the author of Hudibras; George Eliot, and Walter Savage Landor. Mr. Hutchinson suggests that the cause for this may be some surviving strain of Italian descent in the district, and further remarks that others have directed attention to the fact that it was here in the very centre of England that the Romanized Britons were less disturbed than elsewhere. It seems exceedingly probable that what we call genius is seldom or never produced by races of men only recently civilized, but that it occurs in those who in some degree trace their descent to the other stocks. The features of many European men of genius suggest some admixture of Semitic blood, and during the three hundred and sixty years of the Roman occupation it must have been that many Italians settled in England and subsequently left their descendants.

Medical Students in Paris.—The annual report on the attendance at the Faculty of Medicine of Paris has been published. There were inscribed at the Faculty for the year 1898–99, 4,315 students, of whom 4,122 were candidates for the diploma of "docteur en médecine," or of "officier de santé," an inferior qualification now abolished except for a few students who began their studies under the previous law of the students; 3,542 were French and 570 foreigners. There were 3,983 men and 1,229 women. The diplomas of "docteur en médecine" given were 671 in number; of "officier de santé," 13; of midwife, 48; and of surgeon-dentist, 68. The statistics show that 180 students less than in 1897 were inscribed, but it must be remembered that this includes the names of 160 struck from the rolls for not having been present during the past five years. Among the foreigners were 180 Russians, 79 Roumanians, 26 Germans, 25 Greeks, 24 West Indians, 21 Swiss, 12 Spanish-Americans. Most of the women were foreigners—100 out of 129—of whom 91 were Russian, 5 were Roumanian, 2 German, and 1 Swiss. The individual examinations were 9,119, passed before 34 professors and 36 professeurs agrégés. The number of candidates refused was 1,591, or 17.4 per cent., a rather high percentage of the 671 diplomas given; 79 were bestowed on foreigners and did not admit to practice in France.—Paris letter to *Therapeutic Gazette.*

The Age of Medical Graduates in Japan.—A Japanese paper, the *Jiji Shimpo*, finds reason for lamentation in the fact that whereas medical students in Europe graduate at twenty-two or twenty-three years of age, in Japan the age is over twenty-six. The paper in question points out that Japanese mature and age earlier than Europe, and that as the period of usefulness in life in Japan is considered to be over at fifty, the period of active practice is short. In Europe a man is usually at his best at fifty, and even at sixty, seventy, and over grave and reverent seniors are not looked upon as uselessly barring the way of ambitious juniors.—*Journal of Tropical Medicine.*

Dental Anomalies.—Among anomalies of the teeth are macrodontism, microdontism, projecting teeth, badly placed or misplaced teeth, double row of teeth, or teeth which are striated transversely or longitudinally. Caries of the teeth and Hutchinson's teeth are due to neglect or disease. The latter, however, may often be considered as a stigma of degeneration. Then there is a retardation of the first and second dentition.—Petersen's "Dental Diseases."

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

CHOLECYSTECTOMY FOR GALL STONES.[1]

BY C. L. GIBSON, M.D.,
NEW YORK,
ATTENDING SURGEON ST. LUKE'S AND CITY HOSPITALS.

THE gall bladder was first removed in man by Langenbuch[2] in 1882; the operation proved a success both from the standpoint of technique and curative effect. This new "radical" method of treating cholelithiasis was for the most part unfavorably received at first. In later years its value was more generally recognized, but not along the line of usefulness planned for it by its originator, as most surgeons preferred to reserve it for secondary operations. It was also long after this advanced method was formulated, that even simple operations for gall stones became fairly common, and for some time it was lost to sight in the study of the advantages of cholecystotomy in one or two stages.

As a primary operation for the relief of gall stones it has never come into vogue, although it has always had individual champions. The script of the operation is essentially German, both by origin and practice.

In English-speaking countries the operation has generally been rejected or ignored. Certain French surgeons have used it with success, but have failed materially to increase its popularity among their colleagues.

According to a recent observation of Wolynzew,[3] the operation has been performed only six times in Russia.

It may fairly be stated that in this country the operation as a primary or optional measure is of great rarity. In the few instances that have been brought to the writer's notice the operation generally consisted in the removal of an atrophic calculi-containing bladder, usually buried in adhesions and subjected to such laceration in its search and the evacuation of its contents as hardly to leave any other choice than removal. The records of the New York Surgical Society contain only two cases out of the abundant material presented at its meetings for the last ten years, and they were of the character just described.

Cholecystectomy the writer believes has a far wider field of usefulness than would be indicated by the above. He finds also that certain operators of very great experience have become converted to its value with increased opportunities for its performance.

The operation has commended itself to the writer in two cases in which he employed it, although in each case the condition to be dealt with was quite different.

The history of the patients is as follows:

CASE I.—Mrs. R. F——, aged twenty-two years, admitted to St. Luke's Hospital June 3, 1899. Three months previously she submitted to double oöphorectomy at another institution. Since this operation she has had occasional uterine hemorrhages. She gives no history of symptoms referable to previous stomach, kidney, or liver trouble, except that she thinks she has been "bilious" for a few days before this attack. The bowels have been constipated.

Present illness: On the morning of June 2, she woke up with severe pain referred to either side of the upper abdomen and in the back. She had a distinct chill lasting twenty minutes. There was continuance of pain throughout the day. She began to vomit in the evening. To-day her pain continues but is confined to the right side.

On admission the temperature was 103° F.; pulse 120, of good quality and force. The face was flushed, but not presenting a picture of severe trouble. Examination showed a moderate amount of general abdominal distention. The muscles on the right side were very rigid. There was general tenderness over the entire right half of the abdomen, very marked and allowing of only superficial palpation, which yielded no information. Percussion was also without result. Vaginal examination was negative. The diagnosis was not made. She was originally admitted as a case of appendicitis, but it was believed that in the presence of the physical signs, together with the short history, the only possible form would be the extremely virulent type without limiting adhesions and general peritonitis; such a condition, in view of the absence of severe constitutional symptoms, was held to be highly improbable. Therefore operation was deferred. The next day there was a general remission of all symptoms. Palpation could be made more thoroughly, but still revealed nothing. The next day (the third in the hospital) she had a temperature of 100° F., and pulse of 100, rather small and jerky, and she looked bad. Fearing to delay any longer, operation was decided on. Under ether, palpation still remained negative. The incision was planned as an exploratory operation, being situated midway between the appendix and gall bladder; it being believed that one of these two structures was the site of mischief. The finger detected nothing in the cæcal region, and at first nothing above, but on enlarging the wound slightly upward there were found to be some soft vascular adhesions from the omentum and abdominal

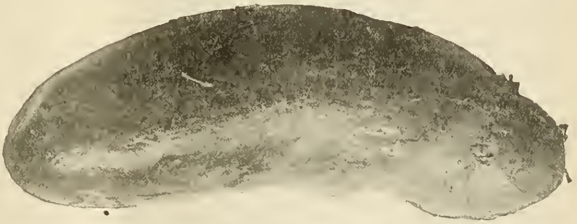

FIG. 1.—Case I. Unopened Distended Gall Bladder. (One-half actual size.)

[3] Centralblatt für Chirurgie, 1900, p. 230.

wall, which having been penetrated revealed a large, elongated gall bladder lying parallel with but not coming below the edge of the liver; it was directed toward the right. It was felt to be full of stones. With a further enlarging of the wound along the edge of the rectus to the free border of the ribs, the entire biliary apparatus was exposed and found to be free except the gall bladder. This was surrounded by acute inflammatory adhesions. Aspiration of the fluid showed purulent contents. Removal of the gall bladder was performed with great ease by gentle blunt dissection after the cellular line between it and the liver had been entered. Holding up the fundus the cystic duct was easily exposed, ligated, and the gall bladder cut away. The stump of the cystic duct was further closed by a suture. Gauze packing of the pocket left by the removal of the gall bladder. Closure of the abdomen except at one angle for drainage.

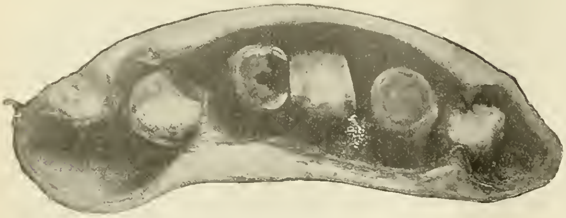

Fig. 2.—Case I. Section of Gall Bladder, showing Stones *in situ*.

The patient experienced no shock after the operation. Reaction was manifested by a temperature of 105° F. twelve hours after operation, after which convalescence was uneventful. The gauze was gradually removed. There was never any leakage, and the patient was discharged in a month with a firm wound and fully restored to health, which condition has since been maintained.

Case II.—Miss M. E. T——, aged forty-nine years; admitted to St. Luke's Hospital June 6, 1899. She has always been well except for the last two or three years. She has been troubled with palpitation of the heart and shortness of breath.

Present illness: Five months ago she began to feel a dull pain in the liver region, more marked when she lay on that side, also several attacks of sharp shooting pains, but lasting only a few minutes. Some two months ago she became jaundiced within twenty-four hours without any accompanying attack of pain. The urine became dark and the stools clay-colored the next day. She thinks there have been times when the jaundice has faded, only to return in a few hours, never entirely disappearing. She has lost sixty pounds of flesh.

Examination showed the patient to be very poorly nourished. The skin, mucous membranes, and conjunctivæ were of a deep yellow color. The skin in several places showed ecchymoses and petechiæ. The tongue was thickly coated. The liver flatness began in the sixth space; the edge of the liver could not be felt.

Operation, June 10, 1899. An incision was made six inches long, parallel to and just below the free border of the ribs. The gall bladder was found to be the size of a crab-apple, well up under the liver. A stone was found in the cystic duct and a larger one in the upper portion of the common duct. This latter was opened and both stones were removed; a dressing forceps was passed to the duodenum without obstruction, and a flexible bougie into the duodenum. The incision in the common duct was sutured with some difficulty and not entirely satisfactorily. There remained the gall bladder to be dealt with. As it could not be satisfactorily drained owing to its inaccessible position, it was removed by the free use of the scissors; some hemorrhage occurred, but not to any alarming extent *per se*, although all the operative field oozed freely throughout the operation. Packing of gall-bladder wound was done, with drainage of the site of the common-duct incision by a glass tube through which a rubber tube passed. The greater part of the incision was closed.

The patient did not rally well from the operation and required free stimulation. There was considerable bloody discharge on the dressing on the next day, June 11th.

June 12th: There was some discharge of bile on the dressings, still bloody; the jaundice was markedly improved, stools were yellow. She was still very weak.

June 14th: There was less bile but still a bloody discharge. Jaundice was decreasing; general weakness was increasing.

June 15th: Her condition was steadily getting worse. Bloody discharge continued. Fearing the weakness to be due to continued bleeding, the entire wound was reopened without an anæsthetic. An enormous hæmatoma was evacuated from the abdominal muscles. There was some oozing from the surface of the liver and other points, but no actual bleeding point was found. The patient collapsed rather suddenly, dying an hour later. No post-mortem was made. Death was due to exhaustion in a feeble subject, especially caused by continued oozing due to the icteric condition.

Briefly summarized, Case I. was that of a young patient with a chronic cholecystitis and the formation of large and numerous stones in the gall bladder, coming under observation during an acute exacerbation of cholecystitis. Cholecystectomy without opening of the gall bladder was early and speedily performed, all steps of the operation being accurately controlled by direct inspection. There was uneventful convalescence with entire restoration of health.

Case II. was that of an elderly woman, with intense and chronic jaundice, a small atrophic gall bladder with stones, and impaction of calculi in the cystic and common ducts. Choledochotomy was performed with evacuation of stones, and demonstration of freedom from further obstruction; cholecystectomy as the most rational means of dealing with the gall bladder situated out of reach under the liver. There was temporary benefit with restoration of biliary physiology. Death occurred by gradual exhaustion, chiefly determined by capillary hemorrhage due to jaundice. The cholecystectomy was not an essential if any feature in the fatal result.

The gall bladder was removed in the first case as a matter of expediency. In so doing the writer was influenced by the following considerations: (1) Avoidance of a long-continued drainage and its attendant annoyances. The cholecystitis was intense and of long standing, and drainage to be effective must necessarily be maintained for a long time. (2) Avoidance

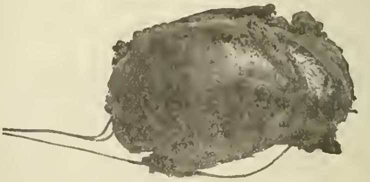

Fig. 3.—Case II. Atrophic Gall Bladder.

of a possible biliary or mucous fistula when the long-continued drainage was stopped, insuring a radical cure, which result can only be obtained with certainty by this method. (3) The avoidance of further disturbances, chiefly attacks of pain due to adhesions from neighboring tissues. Such disturbances were pretty sure to follow the acute inflammatory condition of the adjacent structures. (4) Because the operation presented no technical difficulties and could be easily and safely performed. Hence, given the above advantages it became the operation of choice.

In Case II. the sole indication was the difficulty or inadvisability of any attempt to deal with the gall bladder in any other way.

The foundation of these indications, the writer believes, is to be found in the following reasons. Other things being equal so far as safety and a restoration of the normal anatomy and physiology are concerned, a short convalescence unaccompanied by the discomforts attending the long-continued escape of bile, is to be preferred. The writer believes that in properly selected cases and properly performed the operation is as safe as cholecystotomy. In Case I. there was only the gall bladder to be dealt with, and the freedom of the rest of the extra-hepatic biliary passages was verified with unusual ease and freedom. The gall bladder was shelled out of its inflammatory bed with great ease—much more easily than the ordinary pus tube is removed. The structures at its junction with the cystic duct were all in plain sight, and the ligation and closure of the cystic duct were done with a perfect sense of their surety and effectiveness.

The avoidance of a biliary or mucous fistula was hereby guaranteed. It is a well-known maxim that if the bile ducts are free a sinus after drainage of the gall bladder closes readily. There are exceptions to the rule even if these conditions are fulfilled, and the proportion of fistulæ that require secondary operations, such as suture of the gall bladder or a secondary cholecystectomy, or some such ingenious expedients, is not inconsiderable. And there is a still larger number that close spontaneously but not for many months. Such a condition may not assume much importance to the surgeon, but to a nervous, hypochondriacal, self-observant person in the so-called higher walks of life it is a matter of the greatest importance, and the possibility of anticipating it is well worthy of consideration.

The insuring of a radical cure: Does a cholecystectomy insure a radical cure any more than does a properly conducted cholecystotomy with continuance of drainage till a return to the normal? It is the writer's belief that it does, because it is a radical cure; the focus of disease is at once abolished. It is, however, conceded that a cholecystotomy almost invariably does the same thing, but it is not a certainty. The impossibility of a positive cure in every case will be appreciated if one considers the pathological processes. Gall stones are the products of disease of the biliary passages and not its cause. The principal symptom of gall-stone disease is pain. Pain may be and usually is the result of inflammation of the gall bladder. The pain due to this inflammation is increased by the added complication of stones. Without inflammation of the gall bladder there is practically no pain, provided the stones are in a state of rest. "One in ten persons," says Kehr, "has gall stones; but ninety-five per cent. of persons having gall stones have no decided inconvenience from their presence." In reviewing the histories of a large number of patients after cholecystotomy, one is impressed with the scant evidence of actual re-formation of stones in the gall bladder. Further operations have not infrequently been necessary; but the stones have almost always been found in the ducts, from which they should have been removed at the time of the cholecystotomy. On occasions they have been found again in the gall bladder; but with an evident etiology, as in cases of Kehr and Homans, in which they had formed upon a nucleus of a silk stitch that had worked into the gall bladder. This circumstance would certainly show that the cholecystitis was not cured or the biliary salts would not have been deposited.

There is, however, a condition which is not uncommon after cholecystotomy, if one follows the cases, and it is the symptom that gives rise to the belief that the stones have re-formed, because of the recurrence of the prominent symptom—pain. It is due to the renewal of the cholecystitis, which, again to quote Kehr, "is a recurring condition, in which the succeeding attacks are of a much more pronounced character than appendicitis." To say that once for all this condition can be cured by one course of drainage, when especially there is a continued source of infection from the intestinal canal at hand, is to make an assertion that is contrary to all probabilities and cannot be substantiated by the usual course of analogous processes in the human economy. It is the recognition of this pathological basis of the symptoms that gives us the right to undertake more radical,—that is, curative measures.

The avoidance of disturbances other than those whose manifestations take place within the interior of the biliary passages. By this phrase the writer has in mind the very severe disturbances from adhesions formed by the gall bladder with neighboring organs. They are of very varied character, and not infrequently give rise to masses which so closely simulate a new growth as to make the recognition of their nature difficult, even after the abdomen is opened. They generally give rise to intense pain, and may provoke physiological disturbances of the organs to which they adhere. By some the pain of gall-stone disease is attributed more to these adhesions than to internal disturbances of the biliary tracts. The abdomen has not infrequently been opened without any evidences of stone formation being found at any point; but the breaking down of adhesions, either necessary to the search or intentional in purpose, has frequently given relief to the symptoms. This pain- and symptom-producing element, the writer believes, is a prominent source of the disturbances both before and after evacuation and drainage of the gall bladder; by any operation short of removal of the source of irritation, the condition is likely to exacerbations notwithstanding prolonged periods of latency. It is the writer's belief that this element of the pathological sequelæ of gall stone, though perfectly well known, has not been sufficiently appreciated. It is destined in the future, he believes, to be judged an important factor in the indications for seeking a radical cure.

The ease and safety with which the gall bladder can be removed in a given case are indications for its removal. This point the writer would particularly emphasize, as also the converse, that when for various reasons the operator believes the conditions are particularly difficult, and therefore attended with risk, the operation should be rejected, except under certain conditions when removal of the gall bladder is indicated because no other operation will approach it in effectiveness and safety. Such were the conditions in Case II., the atrophic gall bladder being situated entirely under the liver and therefore entirely unsuited to the normal process of drainage. Every case must be a law unto itself, and the operator must exercise his best judgment according as he finds the situation and according to his self-estimate of his capacity for successfully handling it. The writer therefore repudiates the operation as a routine measure, just as in like manner he would reject the operation of cholecystotomy.

A good many objections have been raised against cholecystectomy, and they are in great part perfectly justifiable if the operation is considered as a routine measure and not from what the writer believes to be its proper sphere. It is claimed that it has no advantages over the simpler and safer operation of cholecystotomy. Perfectly true in some instances; but that it has some very great advantages in general the writer believes he has demonstrated. The testimony of others bear out this statement.

In Duplay and Reclus[1]: "To-day cholecystectomy can and must be considered not only as a physiological operation, but also as a very rational intervention. The merits of cholecystectomy are therefore no longer in doubt." Kehr, in one of his most recent communications, and supported by an experience of nearly one hundred cholecystectomies, says:[2] "Cholecystotomy is not a radical operation, the reservoir so disposed to stone formation being left behind. With a recurrence of the inflammatory process, and when obliteration of the cystic duct results, the disturbances return *de novo*. Such a result has occurred in about six per cent. of the cholecystotomies, and for this reason I have more frequently resorted to extirpation in the last two years, now that I have acquired the necessary perfection of technique for its performance. I have never observed any recurrence of trouble after a cholecystectomy. . . . A cholecystectomy may be a severe operation; but not infrequently it is easier to do than a cholecystotomy. In one case the total time of the operation, reckoned from the first cut in the abdominal wall to the last suture taken in closing it, was only fifteen minutes." Attention is called to the great importance of this statement because it represents the views of the most experienced operator in gall-stone surgery, writing at a time when he had four hundred and thirty-three operations to his credit, of them "nearly one hundred cholecystectomies," and because it marks his conversion to an operation which only three years before he had performed only upon certain restricted indications. In his book[3] published at that time, his experience was based on two hundred and six laparotomies for gall stones, only twenty of these being cholecystectomies. So that while he has doubled his total experience, his operations for the removal of the gall bladder have increased fivefold.

He said then (page 65): ". . . . Total extirpation of the gall bladder is generally only indicated when there is generalized disease of the gall bladder, fistulæ, carcinomatous infiltration, calcareous degeneration or obliteration of the cystic duct." His last report on the mortality of his cases of cholecystectomy was 3+ per cent.

If space allowed, the changes of views of other individual operators due to increased experience might be offered: certainly we have in the radical change of opinion experienced by Kehr sufficient evidence in favor of the operation.

Still another objection sometimes advanced is "that the operation is more dangerous than cholecystotomy." This objection is granted by the writer; but he does not believe that it holds true if the cases are chosen with discretion. The procedure in its early days was damaged by some reports of cases, the unfortunate results of which were loudly proclaimed as definite reasons for the rejection of the method. Investigation of these cases shows that, for the greater part, the blame is not to be placed on the operation, but on the operators who chose to disregard Langenbuch's warning that a *sine qua non* of success depended on the absolute demonstration of the patency of all the ducts.

The operation is also objected to, "because, if stones should recur in the common duct, there would no longer be a guide to the duct." The writer is prepared neither to admit nor to deny that the presence of a gall bladder is necessary to find the common duct when it is the site of an obstruction of a size sufficient to cause it and demanding interference. He believes that only on theoretical grounds can this objection be supported. Langenbuch denies that obstruction can result from stones formed in the biliary ducts outside of the gall bladder. He points out that the two varieties of stone differ markedly in their chemical composition and in other respects. The gall-bladder stones, he believes, are mainly composed of cholesterin deposits and may attain a large size, while the stones formed in the hepatic duct are chiefly composed of bilirubin, and seldom if ever attain a size that makes them a danger.

The operation is also objected to, "because it deprives the body of an organ of more or less physiological importance. This objection can be dismissed pretty summarily by putting the burden of proof on the objectors to demonstrate that the gall bladder fulfils any useful function. As has been well said, it is "a structure of little value but of great importance." Comparative anatomy seems to treat the gall bladder rather as a joke: certain varieties of the animal kingdom have it, others have not; certain subdivisions of a given species are afflicted with it, while other members of the same group get along without it. The elephant has no gall bladder. Dogs, according to the most recent observations,[1] appear to resent the loss of a gall bladder, by setting up a compensatory hypertrophy of the cystic duct which replaces the lost organ. The reservoir function of the gall bladder must be considered as a physiological fairy tale; normally of the capacity of a *demi-tasse*, it cannot very efficiently store up much of the 600–900 c.c. of bile excreted daily.

There remains to be mentioned an additional indication for the performance of cholecystectomy which is destined to increase its future sphere of usefulness. The influence of chronic irritation in the production of malignant disease has long been recognized, but its practical application to prophylaxis is still little appreciated and still less practised. There are abundant statistics on the association of cancer of the gall bladder with gall stones. In all probability the cases of malignant disease of the gall bladder, not preceded by gall-stone formation, are the exception. It is therefore right, the writer believes, to remove the gall bladder which is endangered by its condition of chronic irritation.

It may be noted that throughout these indications for cholecystectomy it has been compared only with cholecystotomy. It may be asked why ideal cholecystotomy should not sometimes compete with cholecystectomy. This operation the writer now absolutely rejects, although he performed it with marked success six years ago, the patient remaining well while under observation (two years). With a greater experience and a clearer appreciation of biliary pathology he would no more venture to repeat the procedure than he would suture the incision made in an acute abscess. A gall bladder containing stones is a diseased organ, and the removal of the products of disease in no way influences the underlying pathological condition.

The scope of this paper forbids the consideration of the indications for cholecystectomy for conditions other than cholecystitis with or without cholelithiasis. Such details may be advantageously studied from the accompanying table taken from Kehr. It has been reproduced here in full that the reader may properly appreciate what an important part the operation of cholecystectomy performs in the treatment of the several varieties of biliary affections.

[1] G. N. de Voogt: Centralblatt für Chirurgie, 1898, page 1097.

Variety of Affection.	Symptoms.	Diagnosis.	Treatment.
I. Stones in the bladder whose walls are little if at all diseased. Cystic duct patent. Contents of gall bladder, clear bile.	Symptoms almost constantly wanting (latent stage). Now and then gastric pains (temporary closure of the cystic duct). No passage of stones, no enlargement of liver.	Palpation negative. Occasionally slight tenderness in the gall bladder region (bimanual examination). Often mistaken for gastric ulcer, intestinal colic, floating kidney, hernia of the linea alba.	Medical.
II. Stones in the previously inflamed gall bladder. Cystic duct temporarily patent. Adhesions between gall bladder, intestines, and omentum.	As under I., frequently severe colic, due to kinking of cystic duct, from distention of gall bladder, causing vomiting and pain on pressure. Intervals may be entirely free from disturbances.	As above, during the colic tumor of the gall bladder is noticeable if the inflammation of the gall bladder continues to increase.	Operation is surely indicated if there are frequent relapses. The best one is cholecystectomy.
III. As in II. There are no stones, but adhesions exist.	Pain is frequently provoked by a change of position (sitting up). Otherwise as in II.	As in II. Patient's condition suffers markedly from its long continuance. Adhesions may cause stenosis of pylorus, obstruction, sense of oppression.	As in II., cholecystectomy is the best operation.
IV. Acute cholecystitis in a relatively healthy bladder. A large stone is usually impacted in its neck. Fluid cloudy or purulent. Walls thickened.	Gall-bladder tumor. Riedel's lobe. Jaundice infrequent. Severe pains (stomach). Prominence of upper abdomen. Marked tenderness on pressure. General condition not markedly affected if degree of infection is slight, but greatly so if severe. (Acute cholecystitis, with cholangitis. Circumscribed peritonitis (peri-cholecystitis). May or not have fever. Swelling of liver only if cholangitis.	Diagnosis is easy. Possible to mistake it for appendicitis. The diagnosis must demonstrate that the tumor felt is the gall bladder. (Form, mobility, tenseness, etc.) Usually constipation. If the cholecystitis ends with the expulsion of stone, obstruction of the common duct follows.	Best treatment is operative. Under medication (catharsis) the inflammation often subsides; the stone still remains. For the cholecystitis, cholecystotomy and drainage is the operation of choice.
V. Acute cholecystitis in an atropbic, frequently inflamed bladder. Cystic duct obliterated. Diffuse adhesions. A little muco-purulent fluid.	No tumor is felt because the gall bladder is high up under the liver. Pain as in IV. More frequent changes in the manifestations. Jaundice rare; if present, due to inflammation. No passage of stones.	Diagnosis difficult owing to negative palpation. Careful attention to the history is of the greatest help. With severe constitutional symptoms, purulent cholecystitis, without appreciable tumor, and without pronounced colic, has been mistaken for malaria, typhoid, and sepsis.	Cholecystectomy is the best treatment. Internal treatment is useless. Cholecystotomy in two stages, and deep drainage, frequently impossible.
VI. Dropsy of the gall bladder. Cystic duct blocked by stone, or obliterated. Contents clear and sterile. Walls thin as paper.	Symptoms may be lacking. Tumor is all that patient notices. Gastric pain frequent. No passage of stones, no jaundice, no enlargement of liver. Occasionally Riedel's tongue-shaped lobule.	Diagnosis easy. Bear in mind the possibility of mistaking it for floating kidney. The tumor (if no adhesions) is especially movable laterally, can be pushed backward, but immediately comes up again. Little tenderness on pressure. Dropsy of an *atrophic* bladder causes no tumor. Diagnosis then as in V. not easy.	Operation. Cholecystotomy with cysticotomy. Cholecystectomy.
VII. Empyema of the gall bladder. Pus in the gall bladder. Stone in the cystic duct. Adhesions. The disease is either (*a*) the result of an acute serous cholecystitis, or (*b*) begins as an acute empyema.	In the beginning symptoms as in IV., later fever may be wanting. Symptoms as in VI. Tumor is usually smaller than VI. Constipation.	An exploratory puncture must not be performed. Otherwise as in VI. With implication of the peritoneum, the picture of peritoneal irritation becomes most prominent. If perforation, symptoms of perforative peritonitis. In the beginning the tumor of the empyemic bladder very painful. Later the pain may subside, or even fully disappear.	As in VI.
VIII. Carcinoma of the gall bladder with stones, without involvement of the portal glands.	At first only disturbances of digestion. No jaundice. If the gall bladder and portal glands become involved, then jaundice. Tumor of marked hardness and unevenness. Later cachexia.	Little pain. At first diagnosis very difficult, usually made only with appearance of jaundice. With involvement of the portal glands (ascites) diagnosis becomes easy.	No use unless early cholecystectomy with resection of liver.
IX. Acute obstruction of common duct by stone.	Marked jaundice, colic, vomiting. Usually fever (chill). Remission of symptoms when stone passes into the duodenum. Passage of stones.	Diagnosis is easy. Colic is of the type known from time immemorial	Internal treatment. Morphine, hot applications. Operation only exceptionally required (drainage of the hepatic duct).
X. Chronic obstruction of common duct by stone. Stone in the supraduodenal portion.	Jaundice may be wanting. Varies. Stools now brown, now gray. Frequently intermittent fever. Pain is generally present, but may be entirely wanting.	Gall bladder usually cannot be felt. Liver more or less enlarged. Tenderness on pressure, more in the middle line. Spleen often enlarged.	Choledochotomy with appropriate treatment of the conditions present in the gall bladder.
XI. Chronic obstruction of common duct by stone. Stone impacted in the duodenal papilla.	As in X., jaundice is usually intense, less apt to vary.	As X.	Possibility of choledocho-duodenostomy. If after three months, medical treatment (Carlsbad) unavailing, operation is necessary.
XII. Chronic obstruction of the common duct by a tumor situated in the pancreas or duodenum, or obliteration of the common duct.	Marked and unvarying jaundice continually increasing. Stools always clay colored Usually absence of fever. Little or no pain.	Gall bladder generally enlarged. Spleen normal. Liver increased in size. Little or no pain on pressure.	Expectant treatment. Cholecystenterostomy.

In conclusion the writer would express his belief that cholecystectomy as a means of treating cholecystitis and cholelithiasis is called for under the following conditions:

In all cases of cholecystitis with or without stones, acute or chronic, provided that the gall bladder and gall ducts can be properly explored, and that the conditions promise an easy removal of the gall bladder. It is to be borne in mind, that the more distended the gall bladder, the more likely is its separation from the liver to be easy. And provided that the common and cystic ducts (sometimes also the hepatic) are demonstrated to be free from stone, and that in addition to stone there is no other obstruction of the lumen of the common duct such as a tumor, benign or malignant, of the pancreas.

The operation is also recommended even when its performance is difficult or possibly entails a slightly greater risk in a limited class of cases—that is, when it is the only satisfactory way to deal with the gall bladder (as illustrated in Case II.), and as a prophylactic measure against malignant disease in the presence of long-standing irritation.

If these various limitations receive a strict interpretation, the number of cholecystectomies that are justified by the above indications will be comparatively restricted, and the operation will be done only under circumstances that permit of its greatest usefulness with a minimum of risk.

48 West Forty-ninth Street.

Precautions Taken to Keep the Plague of Women from the Hospitals of South Africa.—Surgeon-General Jameson, speaking a few days ago at a medical meeting in London, and referring to the "plague of women" of which Mr. Treves had complained as infesting the hospitals of South Africa, said that already Mr. Treves' remarks had borne fruit, for he was informed that the engineers had encircled with barbed wires the hospital containing cases of enteric fever.

ACUTE SUPPURATIVE FOLLICULITIS OF THE SCALP.

BY WILLIAM S. GOTTHEIL, M.D.,
NEW YORK.

THE inflammatory affections of the hair follicles form one of the most unsatisfactory chapters in dermatology. Their nature, varieties, classification, and nomenclature are still matters of dispute. Examining two or three of the more prominent text-books, I find that Hyde, under the caption of "alopecia follicularis," mentions a whole series of interesting and important affections of the hairy parts, which he admits have not as yet been distinctly differentiated from each other, nor the series from all others. Crocker mentions follicular disease of the scalp, but maintains that it is always secondary to eczematous disease of that organ. Lesser barely refers to folliculitis and perifolliculitis of the scalp, or sycosis capillitii, saying that it is of extremely rare occurrence.

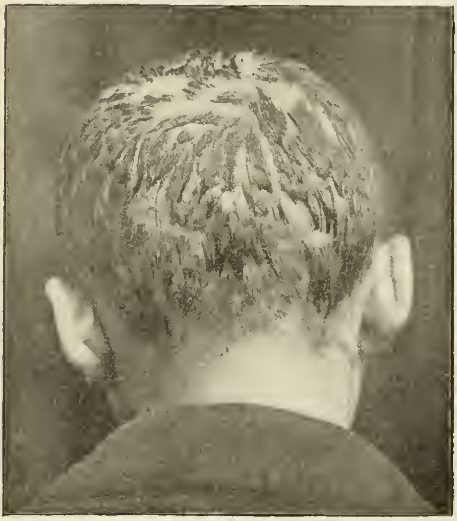

FIG. 1.

Follicular inflammations of the scalp similar to the ordinary folliculitis, or non-parasitic sycosis so common on the bearded face, have been described by several authors under an astounding variety of names. Thus we have the folliculite destructive s. epilatoria of Quinquaud; the folliculite et perifolliculite décalvante of Brocq; the alopécie cicatrisante innominée of Besnier; the acne décalvante of Lailler; the ulerythema sycosiforme of Unna; the dermatitis perifollicularis atrophicans of Sack; the conglomerate pustular perifolliculitis of Leloir; the folliculitis exulcerans of Lukasiewicz; and the bacillogenous sycosis of Tomassoli. And even this by no means exhausts the list.

There can be no doubt at all that several distinct affections, all characterized by a follicular or perifollicular inflammation of the hair sacks, and leading, with or without suppuration, to loss of hair and atrophic changes in the tissues of the scalp, are included in this list. The analysis and classification of these cases is a task that must await a wider experience and more exact records. Certain prominent characteristics, however, are noticeable in all of them. The affections are all chronic, with a duration extending over months and years; they affect localized or isolated areas of the scalp; and they are rarely frankly suppurative, the inflammatory process being subacute and the resultant atrophy being due to interstitial absorption of tissue.

I have had occasion during the last year to observe two cases of follicular inflammation of the scalp which differ in many essential characteristics from those recorded by the authorities mentioned above. In both the process was acute, lasting only a few weeks; the entire scalp was involved, every single hair being affected at about the same time; suppuration was frank, occurring in all the hair follicles; and there was no resultant atrophy of the hair papillæ or other structures of the scalp, and, although I have been unable to find any cases resembling it in its essential features, I have no doubt that the affection occurs occasionally, more especially among the foreign-born and less cleanly of our population, and that other instances will be recognized when attention has been called to the disease.

One only of the two cases above referred to was observed with care during its entire course. It was referred to me through the kindness of Dr. George Lesser of this city, and was under observation from February 18th of this year until the present time (December 15, 1899). Its history is typical, and is detailed below. The other case occurred in a child aged six years, also of Russian parentage; the process was similar, though not so acute, and the patient disappeared from observation after a few visits to the dispensary.

History: L—— G——, aged sixteen years, February 18, 1899. The patient is a well-grown girl, apparently in robust health. She has menstruated for two years, regularly until three months ago; since which time, without any other symptoms, she has been amenorrhœic. Her past history is entirely negative. So far as the surface of her body, other than the scalp, is concerned, the only abnormality is a scar on her left loin, due to a burn received in childhood, and which is occasionally irritated and made sore by the corsets that she wears. Seven months ago a blister

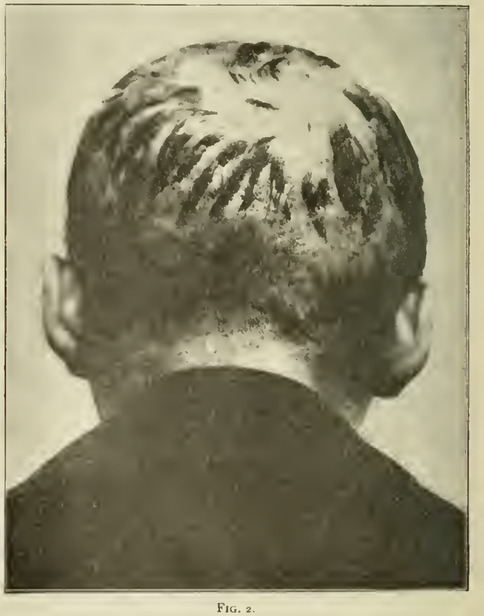

FIG. 2.

appeared on the scar, followed, when it broke, by some suppuration, but which healed promptly under a simple vaseline dressing. She states that this lesion occasionally becomes chafed and opens, as she terms it, and that then there is some discharge from it. Her scalp has always been covered with an abundant growth of fairly coarse black hair, and, until the present affection appeared, she has never had any trouble with it. Some three weeks before, and at a time when the scar on the loin was irritated and discharging, she noticed a painful, pinhead-sized blister among the hair at the front of the scalp. It grew bigger, and filled up with matter, finally rupturing, and when the crust that formed came away it carried the hair shafts with it. After the blister had ruptured, the process was entirely painless; and the patient did not know that the hair had fallen until she accidentally discovered, in the looking-glass, the red bald spot of the exact size of the pre-existent crust. While this process was going on with the first lesion, a few other small blisters appeared on the back of the head, which were hard and very painful, so that she could not rest on her back in bed. The patient cannot report concerning the appearance of these lesions, since she could not see them; but they were undoubtedly similar to the first one, and, like it, left reddened and hairless areas of skin behind them.

Dr. Lesser first saw the case at this time, and reports that there was then a bald, reddened, depressed, tender, bean-size, and apparently cicatricial area on the scalp near the frontal margin of the hair, a few similar lesions were on the vertex and back of the head, together with a number of tender and indurated nodules over which the hair was tightly matted with secretion. Treatment with various ointments and applications did not stop the progress of the affection. New nodules began to appear with frequency, and the older ones commenced to suppurate.

As it was impossible to treat the scalp effectively in the condition in which it was, and as the patient refused to have her hair cut off, she was sent to a well-known specialist for diagnosis and treatment. The diagnosis made was apparently pediculosis, and an application was ordered to be used for twenty-four hours, with the warning not to go near a fire or light while employing it. Inquiry showed that this application was the customary mixture of vaseline, kerosene, and olive oil, with a small amount of balsam of Peru. This she used for one day; and she claims that it burned her so terribly that she lay awake screaming with pain the whole night. Emollient applications were thereupon ordered by the attending physician, with some relief from the pain.

Meantime new nodules appeared continuously, until the whole scalp was involved. From time to time the older crusts would become detached without pain; the entire hair of the affected area coming with them, and bald spots being left behind. The patient felt very bad; she was feverish, and lost her appetite. Her sleep was much disturbed; and during this whole period the only position in which she could rest in bed was prone upon her abdomen, with her face upon the pillow.

On February 21st I examined her carefully. She looked pale, depressed, and anxious; but was otherwise in fair health and well nourished. Her scalp was covered with an abundant growth of thick, bushy, black hair. Near the head this was firmly matted down by dried secretion, ointment, and débris. There was no trace of pediculi or their ova. Scattered all over the scalp were hairless, pea to quarter-dollar sized, reddened, slightly depressed, and moderately tender areas; most of the rest of the scalp was invisible, being covered with the matted and crusted hair. In the few places where the scalp was visible, it was covered with minute red papules, papulo-pustules, and pustules, each one pierced in its centre by a hair. A number of minute pustules were also visible on the redder, tenderer, and more recent bald spots. Removal of the crusts was excessively painful; but, once loosened from their adhesion to the scalp, they were readily taken off, and in each case the entire bundle of hair growing from the affected area was removed with them. The entire scalp was œdematous and excessively painful; the cervical lymphatic glands were moderately swollen. She was ordered to apply cloths thoroughly soaked in two-per-cent. salicylic-acid oil to the scalp, and, after softening, to try to remove the crusts with warm water and soap.

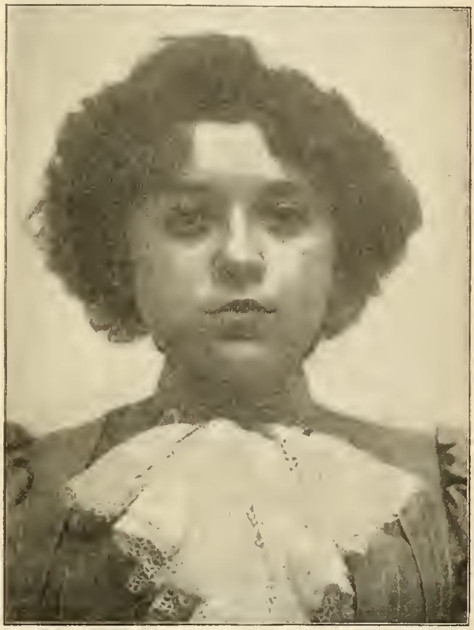

Fig. 3.

On February 26th I noted that the patient had been unable to remove the crusts on account of the pain. More or less extensive suppuration was going on under many of them; and at various places, some of them already denuded, deeper abscesses had formed, which were evacuated. As it was impossible to treat the scalp, or even examine it properly, she was directed to cut the hair off as close to the skin as possible.

March 1st: On this date I took a negative of the patient's head (Fig. 1). All the surface of the scalp not already denuded was covered with closely adherent crusts containing bundles of matted-down hair. Removal of these crusts was still intensely painful; but I succeeded in persuading her to allow me to displace several of them. In every case all the hair came out with the crust, leaving a reddened, slightly moist, and depressed scalp behind. Even where the adherent material had been softened by the applications employed, the hairs came out on removing the débris; the shafts seemed to lie entirely loose in the follicles. But few new pustules had appeared lately; probably because all the hair follicles had been or were involved.

From February 21st to date I made a number of careful microscopical examinations of the hair shafts and crusts. The hairs were always normal, not frayed, and contained no fungus. The crusts and scales consisted of masses of epithelium and fat, with detritus and various bacteria, but with neither mycelium nor spores. As suppuration was in active progress under all the crusts, and as at each examination a number of larger pus collections had to be opened, I proposed the anæsthetization of the patient and a thorough cleansing of the scalp. This, however, the patient refused; and she was, therefore, ordered to wash the scalp as thoroughly as possible every day with warm water and tar soap, and to apply cloths thoroughly soaked in carron oil.

On March 13th I noted that the patient's condition was about the same. A few new pustules had occasionally appeared, and many of the older crusts had been removed, so that the scalp was now about two-thirds denuded of hair. The older bald areas were less red and tender, and the crusts were now more readily removed. There were a few boggy, infiltrated areas of pus collection, which were freely incised. Careful examination revealed the presence of a number of minute, colorless lanugo hairs springing up over the oldest denuded areas. There was no other growing hair upon the scalp; only detached hair matted in the still adherent crusts. She was placed upon a three-per-cent. xeroform-olive-oil suspension in the place of the carron oil.

March 31st: The patient claimed to have got great relief from the last application. She could now, for the first time in many weeks, sleep upon her back, and rest her head upon the pillow. A new crop of minute pustules had, however, appeared upon the denuded and partially lanugo-covered occipito-cervical region of the scalp. They presented in exquisite form the original lesion of the disease, being pin-point to pin-head sized, seated on inflamed bases, and pierced each in its centre by a delicate lanugo hair. It was evidently a recrudescence, or, rather, a renewed infection of hair follicles that had already been involved, and gave me an excellent opportunity to study the disease in its various stages. The pustules increased in size, and finally ruptured, extruding the lanugo hair of the follicle in the pus. But the lesions were isolated and discrete; and, as there were no long hairs to be matted together and retain the pus, they ran a short course and gave the patient little trouble. The accompanying illustration shows the condition of the head at this time.

On April 14th I noted that the patient was now quite comfortable; almost all the crusts were gone; and of her original stiff black hair not a trace remained, save the few loose bundles that were still held in the crusts. The older lesions were now white and covered with thin, fluffy lanugo hair of very light color. No new lesions had appeared. The xeroform oil was continued.

I saw the patient from time to time during the next two months. No fresh lesions appeared; all the crusts came off; the denuded areas whitened; and finally the whole bald scalp began to be covered with an abundant growth of lanugo hair, which in its older portions was already getting longer, stiffer, and darker. All treatment save vigorous cleansing and brushing of the scalp was stopped; a good prognosis as to the restoration of the hair was given, and the patient was discharged.

I sent for her on December 1st of this year, and the accompanying illustration from a photograph (Fig. 3) will give an idea of the condition of her hair. Her scalp was normal, and her hair as abundant as it was before she was attacked by the malady. It was, however, thinner, somewhat lighter in shade, and more curly than was the original pilous covering.

Apparently, then, the case was one of acute general suppurative folliculitis of the hair sacks of the scalp. It is possible that infection occurred from the lesion on the loin; and also that the kerosene applied during its early stages hastened its spread. But its acuteness and generalization, and its superficiality, as shown by the fact that, though apparently all the hair follicles were involved, and every hair shaft detached, the papillæ were not destroyed, and permanent baldness did not result, combine to form a picture that differs essentially from the folliculitides of the scalp described by the authors mentioned in the begining of this paper.

THE EFFECT OF SUMMER HEAT UPON THE PUBLIC HEALTH.[1]

By HENRY DWIGHT CHAPIN, M.D.,

NEW YORK.

THE effect of climatic changes upon the public health is a subject of great interest and importance. When certain conditions are known to be approaching, it is the duty and privilege of preventive medicine to indicate plainly where the dangers lie, and what may be done in an endeavor to obviate them. The depressing effects of continuous heat may be shown most on the nervous and digestive systems, and the extremes of life are especially vulnerable. With reference to the gastro-intestinal tract, not only does great and continous heat depress the digestive power and hence make for disease, but the food supplies also depreciate from the influence of heat, and fermentation has frequently begun before the nutriment is ingested.

A glance at the summer death rate from gastro-intestinal diseases, in comparison with the winter rate, is suggestive in this connection. Four summer months are compared with four winter months during the past five years in the following tables, which will be preceded by a statement of the mean temperature and mean humidity of the summer months:

	MEAN TEMPERATURE (FAHR.).				MEAN HUMIDITY.			
	June.	July.	Aug.	Sept.	June.	July.	Aug.	Sept.
1895	72.80°	72.50°	75.60	70.80°	71	78	64	63
1896	69.80	76.80	76.10	67.20	69	72	69	74

I am indebted to Dr. Tracy for access to the board of health records.

---

[1] Read before the Medical Society of the County of New York, May 28, 1900.

A glance at these tables shows the enormous increase of the summer mortality from gastro-intestinal diseases over the corresponding winter months. It is especially noticeable in the deaths from diarrhœa, in children under five years. One encouraging feature, however, will be seen—that there is a certain diminution in the death rate at this period during the past five years. This is doubtless due to the improved sanitary condition of the city, with a stricter supervision of the food supply, especially milk. There has also been a certain improvement in drainage, sewerage, and the ventilation of dwellings.

It has long been recognized by sanitarians that the death rate among infants, and especially the prevalence of diarrhœal diseases among them, are sensitive tests of the general sanitary condition of the community.

One of the greatest dangers during the heated term consists in sunstroke. The following table shows the deaths from this cause during the past five years, during the four summer months:

Deaths from Sunstroke.

	June.	July.	August.	September.
1895...........	45	4	18	13
1896...........	5	30	725	
1897...........	3	28	2	6
1898...........	..	75	46	253
1899...........	80	10	5	
Totals	133	147	796	272

In looking over the records of the board of health, the most fatal recent years from sunstroke are 1892, 1896, and 1898. The deaths from sunstroke during 1896 reached the enormous number of 765; of this total 671 occurred in one week, and 52 during the weeks immediately before and after, making a total of 723 during the three weeks covering the extreme heated period. If we take the day when the greatest number of deaths occurred as a culminating point of the period of extreme heat in each case, including in each period all days when the temperature rose to 90° F. or more, we find that the culmination in 1892 was on the fifth day, and in 1896 on the eighth day. The greatest number of deaths in any one day was 350 in 1892 and 386 in 1896. The noticeable increase in the number of deaths began on the second day in 1892 and on the fifth day in 1896. Whether this postponement of the fatal effect of extreme heat has been due to a difference in other meteorological conditions than heat alone, or whether it is due to an improved sanitary condition of the city, rendering the population more vigorous and more capable of resisting the morbific effects of heat, cannot be positively determined.

The year 1898 was an exceptional one in that the vast majority of deaths from sunstroke, 253, occurred in September.

A most depressing influence, where there is a continuance of great heat and humidity, is the coexistence of hot days and hot nights. If the nights are so warm that sleep is interfered with, there is little opportunity for recuperation from the exhaustion of the day.

Depression of the nervous system by heat is apparent in lassitude and a general vulnerability to disease. In two nervous affections, the death rate is actually higher in summer than in winter. Thus, during the four summer months of this period, there have been 1,399 deaths from meningitis reported, while during the months of November, December, January, and February of the same period, there were only 1,040 deaths from meningitis. Probably a certain number of cases of meningitis reported were, however, spurious hydrocephalus following infantile diarrhœa. During the five years there were 781 deaths reported from convulsions, while during the winter months the number reached only 737.

In looking up the deaths from alcoholism, there have been fewer reported in summer than in winter, 460 being the number for the summer months, against 525 for the four winter months of these five years. It is well known, however, that alcoholism is a common predisposing cause of death in sunstroke.

The actual increase of sickness in any community due to summer heat is hard to estimate; everything possible, however, that preventive medicine can suggest should be employed to obviate the deleterious effects of heat. A consideration of this subject must include in its scope an oversight of the city, the house and the life and habits of the people. The responsibility of the city is to be doubly watchful in the interests of public health; the streets must be kept scrupulously clean, all garbage and decaying animal and vegetable matter must be promptly removed and destroyed. Perishable food-stuffs, particularly cow's milk, require the greatest watching and regulation As hinted above, the work of the board of health in this connection has already borne fruit.

With reference to milk, while a minimum proportion of cream is now called for by law, there should be a certain standard of freshness as well. The number of bacteria found in each cubic centimetre of milk bears a direct ratio to the age of the milk, as well as the proportion of lactic acid. What is needed is a better regulation of the city's milk supply at its source, viż., the dairy farm. A committee of this society is now at work on this problem and hopes to be able to secure a fresher and cleaner milk for all desiring it.

A very efficient way in which the city can modify the deleterious effects of the heated term is by planting trees and furnishing small parks and breathing-places. In the *Popular Science Monthly* for February, 1899, Dr. Stephen Smith shows how trees are of the greatest utility in modifying and equalizing climatic conditions. He calls attention to the fact that an average temperature of the air of 54° F. is best adapted to public health, as at that temperature the decomposition of animal and vegetable matter is slight and normal temperature is most easily maintained. Every degree of temperature above or below this point requires an action of the heat-regulating power to maintain a proper equilibrium.

In a densely populated city, the summer heat is conserved and reflected by the stone and asphalt of the street as well as by the bricks and mortar of buildings. Even during the night, the stones, by retaining their heat, prevent any appreciable fall of temperature. Here is where the modifying effects of trees can be most beneficial. As trees maintain an average mean temperature of 54° F. in all seasons, it is easy to see what a constant cooling influence they possess in an atmosphere of 90°. Add to this the constant exhalation from the leaves of watery vapor, that has been absorbed from the moisture in the soil and from the surrounding air, and the cooling effect is much enhanced. This takes place most actively during the heated portion of the day when it is most needed.

A general purification of the air is not the least benefit to be derived from vegetation, as carbonic acid is absorbed and oxygen given out, just the reverse of what takes place in the animal economy. The purifying and cooling influence of trees placed uniformly through the city would have a marked influence on the public health in summer. The Tree Planting Association of New York has proven that various species of trees are adapted to our soil, and with a little care can be made to thrive. It seems, however, that in a matter that concerns not only the health but the beauty of the town, the city itself should be responsible for a uniform and continuous effort. If our thoroughfares were lined with shade-trees, the summer heat would not be so intolerable and unhealthful. The construction of the underground road through upper Broadway will injure the life of the beautiful rows of trees now planted in that thoroughfare. It is much to be hoped that not only in the interests of beauty, but of public health as well, efficient steps may be taken to preserve the life of these trees. New York is bare enough without sacrificing any vegetation in a satisfactory state of growth.

With reference to the domicile, the proper efforts must be made in the line of extra cleanliness. Food of all kinds must be removed when the meal is ended and all decaying refuse be not allowed to accumulate. Sometimes by keeping rooms closed during the heat of the day, and thoroughly aired at night, a certain equalization of temperature will result.

With reference to individual hygiene much may be accomplished by a proper observance of the laws of health, especially with reference to eating and drinking. Doctors must especially protest against the indiscriminate use of alcoholic liquors during a prolonged hot spell. Eating to excess of nitrogenous food and rich and "made-up" dishes is also injurious. Overfatigue during the heat of the day should also be discouraged. The temperature of the body may often be satisfactorily lowered by a tepid bath, the effects of which will often remain longer than when a cold bath is used.

With reference to food, extra care must be taken that it is fresh, as a slight spoiling is most disastrous to the consumer. This is particularly true with reference to the universal food, cow's milk. It is estimated that there are 146,600 children under the age of three years in the boroughs of Manhattan and Bronx, or 6.72 per cent. of the whole population. This immense number subsists principally upon milk. Recent studies show that if cow's milk can be properly cooled it will keep a considerable time, and is much better than relying too largely upon superheating. Here is where the subject of ice comes properly under the physician's notice. Any difficulty in the free procuring of ice by the poor during the heated months, whether from a natural scarcity of this article or from a cornering of this staple by commercial greed, is a public calamity.

In 1896, during the heated term the death rate among little children rose to such an alarming state that the board of health requested the city authorities to distribute ice freely among the poor. This was done during the heated term, and doubtless resulted in a great saving of life. The streets were likewise flushed at this time.

SEASICKNESS AND WHAT TO DO WITH IT.

By HERMAN PARTSCH, M.D.,

BROOKLYN, N. Y.

"Repetition is the law of impression," said the Rev. Robert Mackenzie, and that explains why I have not yet succeeded in impressing the susceptible seagoing passenger with an understanding of the theory that explains and the method that succeeds in reducing seasickness to a minimum of about one-tenth of what it may otherwise be. No drugs nor any extraordinary procedures are involved. It is a little matter of simple instruction, which, when repeated to the point of impression, is likely to result in action and do some good. I must therefore repeat the effort, though the words may not be the same. But, first, may I be allowed to account for my position as a self-constituted instructor on this subject?

The first two and one-half years of my professional career were spent as medical officer on various ocean steamships. In April, 1886, the Medical Society of the State of California awarded me a prize for an essay on "Motions in the Etiology of Seasickness." This was published in the *Pacific Medical and Surgical Journal*, November, 1886. In 1890, a Boston firm published for me a book of one hundred and ninety-six pages on seasickness. The undertaking, I suspect, may have proven fatal to the firm's existence, as I have heard neither of the firm nor the book for six or seven years. Also in 1890 I issued a little pamphlet for the instruction of susceptible passengers in regard to seasickness. My efforts on this subject received the hearty and unsolicited approval of Dr. L. C. Lane, president of Cooper Medical College, who was competent to judge by virtue of four years of experience of his own at sea. Approval came also from many other good sources, and, besides, from the four principal steamship companies operating from San Francisco.

By means, then, of the following instructions, understood and based on the brief explanations that are thrown in and also to be understood by the person who is managing his own case, or conducting the case of another, the worst degree of seasickness can easily be replaced by a condition of comparative comfort under the circumstances.

Make no other preparation calculated to avoid seasickness. Continue in your usual ways. A steamer chair will prove a desirable convenience if the voyage is to be long and the weather happens to be good.

Get on board a half-hour before sailing, get your cabin and small luggage arranged to suit you, and have nothing to do but take care of yourself after the ship starts.

Shoes should be warm, comfortable, and easily put off or on. Besides being comfortable, have all clothing as convenient as practicable for dressing and undressing.

Rooms amidship are preferable. Avoid the extreme ends of the ship. Good facilities for ventilation are very necessary.

Strive to have the air inside of the room about as good as outside, even when you are in it; do at least the best you can under the circumstances toward this end. Two sufficiently large openings to the room are necessary. Good, clean, fresh air is of the greatest importance to the susceptible passenger. There is no danger from draughts. Second-hand air is a factor in the causation of seasickness.

Weather and condition of health permitting, stay on deck much of the time, in a steamer chair, in a semi-recumbent position, comfortably covered and eyes closed.

Anywhere on ship, in berth or chair, keep the eyes closed during the daytime, with exceptions of short duration, until immunity from optical vertigo is acquired. Thus you will exclude optical vertigo, by which are meant that dizziness and nausea which are often consequent on the continued observation of unusual relations among our environs, and between them and ourselves.

Whenever the slightest sensation of illness is felt, lie down at once and close the eyes. Use only one pillow, or if quite sick, or it seems likely that you will be, have the head even below the level of the body, with no pillow for a while. I have seen the pillow make all the difference between great misery and almost absolute comfort.

Steamship motion can be analyzed into twenty-six different factors. It is therefore very complicated and, of course, incomprehensible at first. The many variations occur to the passenger unawares. His animal mechanism cannot adjust itself to them, because he cannot at first foreknow them. The case becomes much like that of going up or down stairs in the dark and finding one step more or less than was expected. The variations not being adjusted to, because not foreknown, violence of some kind is the result. The disturbances occur in a continued series, each very slight, but the series results in an accumulated sum of violence which we call seasickness.

What is first disturbed in the animal mechanism is the vaso-nervous system, that which controls the circulation of the blood, and, as a result, the circulation itself must of course be disturbed. The first important result is a relaxation of the blood-vessels in the abdominal cavity; these vessels having much less outside support than those that traverse muscular tissue.

The second effect is the gravitation of blood into the relaxed vessels, thus permitting the occurrence of a deficiency in the brain. One result of this deficiency in the brain is the sensation called nausea. This mechanical deficiency of blood in the brain, with its corresponding sensation (nausea), is to be avoided when observed to be approaching, and corrected when already present, by lying down with the head no higher than the body. If the patient does not promptly lie down, retching will take place. Retching is nature's method of flooding the brain with blood, by squeezing the contents of the abdominal cavity in such a manner as to force upward some of the excess of blood contained in its relaxed vessels. The regurgitation of food or fluids from the stomach is merely incidental, and not essential. The stomach has nothing to do with seasickness except to be incidentally and accidentally implicated.

By the time a patient has been seasick two or three days, and his forces have regardless of his consent been heavily drawn upon by many hours of retching, and having meanwhile, of course, not profited by anything swallowed, he will be suffering from poverty of blood. The sense of hunger will be obscured by the nausea.

Even while lying down, a susceptible passenger will not escape seasickness if his blood becomes impoverished in respect of nutritive material; and, having been seasick, he cannot recover while his blood remains so impoverished. To prevent seasickness one must keep his blood saturated with nutritive material. To recover from seasickness one must saturate his blood with nutritive material. For this purpose one must eat, and if unable to eat enough at a time, he must eat oftener. To eat seven times a day is about right; the three regular meals, ten to fifteen minutes before rising, half-way between meals, and at bedtime.

Always eat and drink at least ten minutes before rising in the morning. It matters little what it is, provided only it is what you want. Porter or stout is good, so are hard sour apples. At sea we may find ourselves liking and longing for things that we hardly ever think of on shore. Whatever you really want, that is the best thing to take; and porter or stout is always good, whether you want it or not.

Whatever is taken before rising must be so conveniently available as not to require the patient to raise his head. In case of porter or stout, the glass must be dispensed with and the liquid taken directly from the bottle.

When one is already seasick, those liquid foods are best which require least digestion, are most rapidly absorbed, and yield the quickest returns—beer, ale, porter, stout, broths, soups, meat extracts. These cannot all be prescribed with success; they should only be suggested—then the patient will choose which he wants, and the stomach will agree on the choice. The sicker the patient the oftener he must eat and the less at a time, and when he feels a repugnance to all other foods, porter or stout taken without raising the head, directly from the bottle, a mouthful at a time, at about five-minute intervals, will prove a great success.

A woman taking care of herself will not generally attend to these details, but will suffer instead. But if she have the help of another who will promptly attend to each detail at the right time without stopping to ask the patient's consent, the scheme works beautifully.

If you are able to be up and about and are regularly going to meals, then always lie down immediately after eating, about fifteen minutes at least. At table do not wait, but begin eating at once on something, or delay going to table until the rush is over, or stipulate with your waiter for immediate attention. When done, do not wait, but go directly to your berth or elsewhere and lie down.

Whenever there appears the slightest sensation of hunger, or nausea, or any indescribable sense of discomfort about the stomach, or in the head, eat and lie down.

The worst case of seasick retching will easily be made comparatively comfortable in thirty minutes or less, by lying down without a pillow, closing the eyes, and taking a pint of porter or stout in six doses at five-minute intervals. Another food for such an emergency, but not so good as stout, is made by mixing well the yolks of two raw fresh eggs with an equal bulk of good brandy. Give a teaspoonful at ten-minute intervals. If you do not feel quite well with a pillow, remove it, and you will feel better. This is very important.

Retching occurs in paroxysms at intervals more or less regular. The best time to take the malt beverage, or any other food, is just after a paroxysm of retching. Should it be taken before and thrown up, then take another dose immediately after the paroxysm. That will stay down, because the next paroxysm will not occur under ten to fifteen minutes, and by that time the patient has had the benefit of the dose, or several doses, and should not retch at all. So after casting up an entire meal it is proper to go and straightway eat another, which is not likely to come up.

All necessary edibles are, I believe, supplied by the steamer steward; but on short voyages it may be more convenient to have one's own variety of such things for extra use in one's cabin. In so providing one should bear in mind the presence of rats on some steamers.

Avoid all needless expenditure of mental or muscular energy. Talking, reading, and listening are done at the expense of power, which the patient may not have to spare, and should be reduced to a minimum by the susceptible at sea.

When the patient is eating too little to keep the bowel well filled, constipation will be only apparent. He must not expect to discharge much cargo when he is taking little in. Respond promptly to the calls of nature. On long voyages when the patient has begun to eat fairly and the bowel is well filled, and real constipation is present, it will be better to resort to instrumental means for relief daily by using an enema of glycerin; twenty drops, more or less, will be sufficient. Do not mix it with water or anything else. The use of purgative or laxative medicines is attended with too much additional and general violence.

Seasickness is sometimes accompanied by severe headache or by much mental uneasiness. If these do not yield to the treatment already prescribed, then bromide of sodium may be given in a dose of half a teaspoonful of the dry powder in a little water; repeat the dose in an hour if necessary. The bromide of sodium may be used with the patient's food as salt (which it much resembles in appearance and taste), but only while the necessity for it continues. Should there be any doubt about its necessity, do not use the bromide at all.

If these directions are promptly, fully, and faithfully executed, the passenger will be able to endure a sea voyage of any length with not more than a tenth of the illness that he might otherwise suffer, and this minimum of discomfort can be without retching. I have promised to get people of known susceptibility across without retching, and have fulfilled my promises.

95 Hicks Street.

Diagnosis of Raynaud's Disease.—Adolf Calmann reports a number of cases which he holds confirm the opinion that the Raynaud symptom complex may occur without demonstrable anatomical disease of the central nervous system, and add to the number of cases in which the Raynaud manifestations are only symptoms of an affection of the central nervous organs, especially of the spinal cord. They afford no grounds for considering a disease of the peripheral nerves as the cause of symmetrical gangrene, equally little for hysteria. The author says, however, that those who assume an immaterial trouble of nervous nature in all of the Raynaud cases far overshoot the mark. Opposed to such a partial opinion are a not inconsiderable number of observations which demonstrate *in vivo* or by obduction an anatomically developed disease process to be the cause of the local asphyxia and its sequelæ.—*The Alienist and Neurologist*, April, 1900.

Sprains.—S. H. Huntington holds that in the treatment of sprains our first object should be to check hemorrhage from the torn vessels and to limit the extent of the injury to what has already occurred. This is best accomplished by firm, even pressure, obtained by strapping the sprained joint with strips of adhesive plaster. If properly applied in sprains of the ankle, the pain is immediately relieved and the patient can walk at once. If the conformation of the sprained joint forbids the use of the plaster straps, apply firm pressure by means of an unyielding muslin (not rubber) bandage, first carefully padding all hollows. A thorough douching of the parts with very hot water may precede the application of the dressings. Passive motion of the sprained joint should begin as early as the second or third day. If motion is made only in the direction and to the extent that the joint is naturally capable of, there is no possibility of stretching or displacing injured parts, and the formation of adhesions will be prevented.—*Yale Medical Journal*, May, 1900.

Pancreatic Digestion from the Standpoint of the Comparative Anatomy of the Bile and Pancreatic Ducts in Mammals.—B. K. Rachford says that certain anatomical conditions have been developed in the carnivora which have the effect of so slowing the rate of passage of food through the duodenum that the time of exposure of foodstuffs in the duodenum of these animals to the action of bile and pancreatic juice is greater than in the herbivora. From these facts one would infer that it is of physiological importance that the fats and proteids should be retarded in their passage through the duodenum in order that they may be longer acted upon by the bile and pancreatic juice while the food yet contains combined acid, and before it reaches the alkaline succus entericus of the jejunum and ileum. This physiological inference finds support in laboratory experiments made by the author.—*Medicine*, May, 1900.

The Pulmonary Complications of Typhoid Fever.—C. E. Edson calls attention to the extra-intestinal growth of the bacillus of typhoid, and to the fact that the care of a patient in this disease includes care of the whole man and not merely of his abdomen. Bronchitis has been found in fifty-four per cent. of Edson's cases. Ulcerations are frequently seen in the upper trachea. Bronchitis may assume a mild or severe form, often masking at first the true nature of the malady. Pneumonia is the most common thoracic complication. It occurs about the second week, rarely before. It may be lobular or assume the true croupous form. Pleurisy, dry or with effusion, may occur at the outset of typhoid, but with the greatest rarity, and it is a very infrequent complication at any stage of the disease. Abscess, gangrene, and infarction are all rare complications and secondary to others, such as pneumonia or infected areas of hypostatic congestion. Small areas of infarction are generally overlooked or confounded with patches of hypostasis. Œdema of the lungs must be considered as a circulatory complication from failing heart rather than a truly pulmonary disorder. A tuberculosis may be implanted upon an unresolved patch of pneumonia, or an old tuberculous infection, latent and never yet active, and may find in the lowered vitality of the convalescent its opportunity to spread. Both these conditions, however, partake more of the character of sequelæ than of true complications. The possibility of the supposed typhoid preceding a rapid general tuberculosis having been not typhoid at all, but tuberculous fever, must be borne in mind.—*Colorado Medical Journal*, April, 1900.

Hepatism and Neuropathy.—R. Massalongo says that chronic diseases of the liver are sometimes, but only exceptionally, accompanied by disturbances of the central or peripheral innervation. Acute or chronic diseases of the liver do not cause such disturbances more than do affections of other organs. The phenomena of auto-intoxication in the human organism are very complex; the symptomatology of the lesions of an organ is never exclusive nor independent; local diseases in the strict sense of the term do not exist. There is too great a tendency to specialize, to create new morbid entities, and to carry laboratory data with too much enthusiasm to the bedside of the patient.—*Rivista Critica di Clinica Medica*, April 28, 1900.

Cystitis Caused by the Bacillus Pyocyaneus.—Thomas R. Brown cites the investigations leading up to the accredited belief that the pyocyaneus may be pathogenic as well as saprophytic. He relates an instance of cystitis in a woman after operation for pelvic adhesions caused by this bacillus as shown by cultures. This is the first case in the author's knowledge in which this cause has been definitely proven. The urine left over night showed a green color, thought to be due to the fact that it contained sufficient albumin to act as a culture medium for the bacterial growth.—*Maryland Medical Journal*, May, 1900.

The Etiology of Tumors.—Antonio Carini says that the origin of tumors is one of the most widely discussed subjects at the present day. The theory of a parasitic origin is the one most generally accepted. From the author's experimental and historical researches he reaches the following conclusions: In tumors extirpated during life under aseptic conditions, he has never succeeded in isolating blastomycetes, even when a histological examination had determined the presence of Russell's bodies (blastomycetes of Sanfelice). By the inoculation of a pure culture of blastomycetes he never obtained true neoplasms. The blastomycetic nature of the Sanfelice bodies (fuchsin corpuscles of Russell) is doubtful. These bodies are not constant in tumors, and are found in other pathological processes in tuberculous organs and in normal organs. The bodies found in tumors, and described as parasites, as a rule do not take the specific coloring of blastomycetes.—*Il Policlinico*, April 15, 1900.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Fifty-first Annual Meeting, Held in Atlantic City, N. J., on June 5, 6, 7, and 8, 1900.

WILLIAM W. KEEN, M.D., OF PHILADELPHIA, PRESIDENT.

GENERAL SESSIONS.

First Day—Tuesday, June 5th.

THE meeting was called to order at 10:45 A.M. in the Marine Hall, Young's Pier, by the president, Dr. William W. Keen, of Philadelphia; and the session was opened with prayer by the Rev. Frederick J. Stanley.

Dr. Keen was then presented with a gavel, sent by the profession of Canton, O., his native city.

Addresses of Welcome.—ACTING-GOVERNOR JOHNSON, of New Jersey, delivered an address of welcome. He referred to the absence of Governor Voorhees on a sea voyage by saying that his excellency was "half seas over," and, hence, unable to be present. The very fact of his being away at this time in search of health was but another proof that there was a power even above that of the chief executive of the State, *i.e.*, the authority of the family physician. As a matter of seniority, the State of New Jersey had a right to entertain this large representative medical body, for history told us that the first medical society was organized in New Jersey in 1766. He had been informed that the minutes of that society were still in the possession of the Medical Society of New Jersey. After adverting to the many advances in medical science during the present century, the speaker bade the association a hearty welcome.

HON. L. P. STORY, mayor of Atlantic City, also welcomed the association in a few well-chosen words.

The President's Address.—W. W. KEEN, M.D., LL.D., of Philadelphia, made an address, of which the following is an abstract: He commenced his remarks by congratulating the association on its great prosperity, as evidenced, among other things, by a membership of about nine thousand physicians. While this number was truly a large one, when one considered that there are over one hundred thousand regular physicians in these United States it seemed strange and anomalous that the association should comprise less than one in ten.

Rush Monument Committee.—With reference to the Rush monument fund, he said that as he had been called upon to fill the vacancy on the committee left by the resignation of Dr. Albert C. Gihon, he had appointed Dr. James C. Wilson, feeling that it was appropriate to select for this place one who was a physician rather than a surgeon, and who was also from Dr. Rush's native city. The committee had actually in hand a little over $11,000—a sum too large to go backward, and not enough to go forward. Probably several thousands of dollars were still in the hands of various State organizations, which had been pledged to this fund.

The Anti-Vivisection Bill.—On the subject of anti-vivisection, the president said that he had been so deeply impressed with the tremendous harm that would be done if the "anti-vivisection bill," or Senate Bill No. 34, were allowed to pass, that he had deemed it his duty to send out letters to the president and secretary of every State medical society in the country, to prominent members in the profession, and to a large number of other influential men, urging them to arouse a public sentiment against the bill. He was proud to be able to bear public testimony to the enthusiasm and unanimity with which the profession in every part of the country had responded. He believed this action had exerted an enduring influence on senators and representatives in establishing and confirming their judgment against the inhumanity of any such bill. A hearing had been granted, before the sub-committee in Washington, to both the friends and opponents of the bill. Among the latter was a noble array of speakers, counting among them such names as Drs. William H. Welch, Henry P. Bowditch, H. A. Hare, William Osler, Mary Putnam Jacobi, Howard A. Kelly, Surgeon-General George M. Sternberg, together with Bishop Lawrence, of Massachusetts, and others. It was encouraging to note that this effort had not been in vain, the present committee having so far changed its views that it was probable the bill would slumber in committee or be reported negatively. One of the most telling and forceful of the communications in opposition to the bill was a letter addressed to the chairman of the committee on the District of Columbia by President Eliot, of Harvard College. It was worthy of note that President Eliot takes the ground that it is the anti-vivisectionists who are inhumane and cruel to the last degree, because they would condemn both man and animals to suffering and death by impeding the progress of medical science.

Members of the Association by Invitation.—Dr. Keen called particular attention to the desirability of limiting the "members by invitation" more strictly than had been done in the past. For instance, it had been the custom, in most of the sections, to invite medical men of distinction, not members of the association, to read papers before the sections. Some of these persons had even been openly hostile to the association, yet year after year had had these courtesies extended to them. It seemed just and right that this loose practice should cease, for membership in the association was open to every American, and any one who did not choose to avail himself of the privileges and advantages of membership by joining the association should be debarred from them.

A Section on Pathology and Bacteriology.—In view of the importance of pathology and bacteriology, he had ventured to ask a number of gentlemen to act as a provisional and unofficial committee to organize such a section, under the chairmanship of Dr. Ludwig Hektoen, of Chicago, feeling sure that the association would give its official sanction at the proper time.

Annual Exhibit.—The annual exhibit was an important financial aid to the local committee. As yet there were no rules or regulations to govern the conduct of this important business. He therefore urged the establishment of a permanent committee, or one member of the previous year's committee to be retained, so as to give greater stability and uniformity of management.

Publication of Papers.—The speaker advised, in connection with the vexed question of publishing the Transactions, that only the more important papers should be printed in full, the example of the *British Medical Journal*, in publishing only abstracts of the less important communications, being worthy of emulation.

Endowment of Medical Schools.—The remainder of the address was taken up with a thoughtful and earnest review of the needs of our medical schools, and the reasons why they should be liberally endowed. Dr. Keen said that the tide of charity in the United States had reached a remarkable height, amounting, in 1899, to the enormous sum of nearly $80,000,000, yet only a small portion of this had been bestowed upon medical schools. In his opinion, the chief cause for this discrimination against the medical schools was to be found in the vicious method by which these schools were formerly conducted—*i.e.*, practically as joint-stock companies. But that day had happily passed. As a consequence of the broadening and lengthening of the medical course of study, the cost of medical education had enormously increased, yet it was not practicable to increase the students' fees, and the latter were entirely inadequate to meet modern demands. President Eliot, of Harvard, very rightly says: "There is no branch of education which more needs endowment. Medical education is very expensive, because it has become, in the main, individual instruction." He was not one of those, however, who believed that the day of the didactic lecture had passed, for, in the language of President Faunce, of Brown University, "never shall we be able to do without the personality of the teacher, flaming with enthusiasm for knowledge, pressing up the heights himself and helping the student on." One or two such men in every school made a good faculty. But the great difference between the modern method of teaching medicine and the older method consisted in laboratory instruction and clinical instruction, both of which must be individual. In the modern, fully equipped medical school no less than thirteen laboratories were needed, viz., (1) the dissection room, or anatomical laboratory; (2) the laboratory of histology; (3) the laboratory of embryology; (4) the physiological laboratory; (5) the laboratory of chemistry; (6) the laboratory of physiological chemistry; (7) the laboratory of pharmacy; (8) the laboratory of pharmacology; (9) the laboratory of practical obstetrics, where obstetric operations may be taught; (10) a laboratory for instruction in surgical operations; (11) a laboratory of morbid anatomy; (12) a laboratory of bacteriology; (13) a laboratory of hygiene. The laboratory in the last few years had done much for humanity; it had discovered the cause of tuberculosis, tetanus, cholera, typhoid fever, and a host of other diseases; it had shown us how to avoid all danger from trichina; it had shown us how to banish erysipelas, pyæmia, and tetanus from our hospitals, and reduce our death rates after operation from fifty or thirty-three per cent. to ten per cent., five per cent., one per cent., or even lower; it had given us a scientific instead of a guess-work hygiene; it had pointed out the rôle of the mosquito in malaria, of the rat in the bubonic plague, and of the fly in typhoid fever; it had limited the spread of diphtheria; it would, in time, enable us to conquer other implacable enemies of the human race—and yet, there were those who would stay this God-given hand of help! Another reason for the increased expense of medical education was the lengthening of the curriculum. When he was a student, the course of study consisted of two sessions, of about nineteen weeks each, or thirty-eight weeks in all; now it was, as a rule, made up of four sessions of thirty-two weeks each, or a total of one hundred and twenty-eight weeks. Comparing the endowments of theological and medical schools it is found that in 1898 five theological schools reported endowments of from $850,000 to $1,369,000 each, yet in 1899 there were only eight thousand students of theology for whom this enormous endowment was provided, as against twenty-four thousand students of medicine—in other words, each theological student had the income of an endowment of $2,250 provided for his aid, while each medical student had only the income from $83.

Grants for Research.—Dr. Keen, in closing his address, said that while the first object of the association should be to place itself on a strong financial basis, he hoped it would before long assume a rank second only to the British Medical Association, and that it would set a fruitful example by giving each year "scientific grants in aid of research." To a profession which gave so freely of its own life-blood surely the public could afford reasonably to endow its schools; it would be returned to the community tenfold, and more devoted, self-sacrificing men and women they never could have.

Report of the Treasurer.—Dr. H. P. Newman, of Chicago, presented the report. He stated that the total disbursements for the past year had been $57,874.75, and that on January 1, 1900, there had been a cash balance of $13,556.38, the total assets amounting to $27,396.86.

Report of the Secretary.—Dr. George H. Simmons gave a detailed report of the work of his office. He said that he had supplied every regular medical college in this country with copies of the Code of Ethics, with the request that a copy be placed in the hands of every graduate in medicine. Among other interesting features of the report was the announcement that the Honolulu Medical Society, having sixteen members, had applied for admission to the American Medical Association.

SECTION ON PRACTICE OF MEDICINE.

First Day—Tuesday, June 5th.

The chairman, Dr. George Dock, of Ann Arbor, Mich., in his opening address discussed the difficulties of modern medicine due to the numerous advances which had taken place in methods of accuracy, and to new discoveries. He said that medicine, as a study, was becoming more difficult. He referred to an absurd superabundance of medical schools in the United States. The laboratory expert should be selected with as much care by the practitioner as was the operating surgeon, and his recompense should be more carefully made. The profession had a weight of guilt in the matter of the great prevalence of mercantile concerns putting forth their cure-all wares, which called for correction.

A System of Personal Biological Examinations of the Condition of Adequate Medical and Scientific Conduct of Life.—Dr. George M. Gould, of Philadelphia, advocated the establishment and systematization of a series of periodical scientific personal examinations, tests, and measurements of the human body throughout life, having in view the discovery of the early symptoms of disease now often passing unnoticed—the symptoms of the symptom—as well as the functional abnormalities that finally led to organic disease. To the methods of the anthropometric, psychophysical, and physiological laboratories should be added those of the specialist and general physician, to determine morbid tendencies and to preserve a general biological picture or epitome of the individual life. He described the possible methods of carrying out the plan, and the function of the physician in the suggested work. He also alluded to the connection with life-insurance problems, with public sanitation and hygiene, with governmental, military, and civil-service examinations, and with the hygienic and educational work of schools, colleges, and universities, and the relation of the same to the specialist and general physician. The speaker made a plea for a living anthropology, with a system of records carried throughout life, starting with the data of inheritance. Something similar to the Bertillon system should be made the basis of the first and of all subsequent examinations. The pathological element had been sadly neglected in all previous anthropological study. The physician's case-books would furnish the most valuable data if they could be utilized for this purpose. With this view histories should be made scientific and preserved for future study.

The Hospital Clinical Laboratory.—This was the title of a paper presented by Dr. C. N. B. Camac, of New York, who spoke of the value of bedside examinations carried out by especially appointed internes for this service. The reader reviewed the work of European laboratories, and discussed the importance of proper record-taking in connection with ward laboratory work. The clinical laboratory contributed only certain elements which, taken in conjunction with clinical data, led to the correct diagnosis. No one instrument of precision by itself alone was sufficient. All contributed to the end in view. The first laboratory was established at Breslau in 1825. The time had come when all the data since then piled up by scientific investigation of this kind should be supplemented by the practical hospital and ward clinical laboratory. Here methods determined upon in anatomical, physiological, chemical, bacteriological, and pathological laboratories could be applied and carried out. Photographs of thoroughly equipped workshops of this kind were shown by the speaker. He had established such laboratories in the Johns Hopkins and Bellevue hospitals in 1896, and similar ones would shortly be established at St. Luke's Hospital. The apparatus was simple and readily brought to the bedside. One of the objections was the expense of microscope and cabinet, in which poisonous reagents were locked away from the patients. The cost was from $30 to $50 per year for maintenance, and the original outlay need not exceed $300.

On Blood Examination and its Value to the General Physician.—This paper was read by Dr. M. H. Fussell, of Philadelphia, who showed simple apparatus to be carried in a bag and used at the bedside.

In discussing both papers Dr. Osler said that apparatus for bedside examinations were as essential to-day as was the knife to the surgeon. Proper diagnosis by the aid of simple equipment would lead to proper treatment. When his time came to fall, the speaker said, he preferred to fall into the hands of the man with his microscope with him in a bag for bedside use.

Dysentery.—Dr. Simon Flexner, of Philadelphia, spoke upon this subject, and described experiments carried out in Manila by a body of young men sent out by the Johns Hopkins Hospital. It was a mistake to suppose that tropical dysentery was of one single kind. There were different groups of organisms to which the disease had been attributed. Many still believed that the bacillus coli communis was the cause. Pyogenic cocci were supposed by others to be causative in their action. There was a protozoon which was now believed to be active in tropical dysentery, the amœba coli. This form of dysentery was not distinct on this point alone, but in its pathological anatomy as well. The studies referred to were made for the most part on American soldiers, in both acute and chronic cases. The acute stage often attracted little attention. Here the amœbæ were commonly found. In other cases the amœbæ did not occur or were few in number. In some very acute forms bacilli were often found, not normally present in the intestines, and showing peculiar reaction. When the acute form became chronic, the ulcers were superficial and were not undermined, and the danger of stricture was not so great as in tropical dysentery. Immunizing experiments in the laboratory showed that small animals could be rendered immune with the products of these micro-organisms. The speaker thought that the bacillus found was the same as that reported as being observed in the dysentery of Japan, and that it was intimately concerned with the acute dysentery of the tropics. Army surgeons in Manila now distinguished an "infectious" in distinction from the tropical form of dysentery.

Notes on Tropical Dysentery.—This was the title of remarks by Dr. J. H. Musser, of Philadelphia, who related the case of a patient who had come from Porto Rico and was treated in the Philadelphia Hospital. There were marked emaciation and extensive pigmentation of the skin, with numerous boils upon the surface of the body. The symptoms were those of colitis and proctitis. The stools were free from fresh blood, and mucus was absent or but sparingly present. Purpura was a striking feature, with signs of scorbutus, which latter might have been the diagnosis made, were it not for the microscopical examinations. In agglutination methods the speaker thought we had a means of obtaining an accurate estimate of the affection.

Dr. Osler said he had formed the impression that the amœba would have to take a back seat since Dr. Flexner had reported his findings in connection with the bacillus he had described. He believed the disease was separate and distinct from that of the tropics, and thought it might be the same form as that which occurred in this country in epidemics seen in jails, hospitals, etc.

Dr. Briggs mentioned a patient who had come from Cuba, whose history was substantially that described by Dr. Musser for his own case, but here the Widal reaction occurred. In a second case it did not.

Dr. Hunter, of Minneapolis, spoke of cases from Manila, in one of which amœbæ were found. In a second case in which they were not found the symptoms were mild while the patient was at rest, but severe under exertion.

Dr. Woodhull, of the regular army, recently stationed at Manila, spoke of the service to medicine at large, as well as to the army, rendered by Dr. Flexner and others who went to Manila to carry out these investigations. He found that many patients had to be sent to a colder climate before they began to show signs of improvement.

Dr. Murphy, of Missouri, said that in Kansas City he had studied three cases of amœbic dysentery. Expectorated pus showed that a liver abscess had perforated the lungs in one instance. He desired to call attention to the occurrence of the disease in northern latitudes.

Dr. Vaughan, of Ann Arbor, spoke of epidemic bloody flux occurring as far north as Michigan. Nothing more than the colon bacillus had been found in these cases, and he was inclined to think the latter the cause of this particular form of the affection. Strychnine hypodermatically acted well in conditions of severe collapse and depression. Dr. Wilson, of Pennsylvania, referred to a case in which the tongue was denuded and appeared sandpapered throughout. The temperature was at times subnormal and never elevated. Emaciation was progressive till death, but there was never any pain. Treatment and dietetics were futile.

Dr. Flexner, in closing, gave credit to Dr. Woodhull for furthering the investigations in Manila by giving full opportunity to prosecute them. Every acute outbreak should be examined bacteriologically, and the blood should likewise be examined. The micro-organism he described was closely allied to the typhoid bacillus, but it could be distinguished. Typhoid blood had no effect upon it. Liver complications in the form he studied were extremely rare.

Serum Therapy in Croupous Pneumonia.—Dr. J. C. Wilson, of Philadelphia, discussed this question together with the bacteriology of the affection. He said that in direct infection by way of the air passages there was an exudate and a toxæmia. The more abundant the exudate the greater was the toxæmia. After brief historical considerations and reference to theoretical points he mentioned intricate problems which had to be solved in the laboratory. Experiments he found to be encouraging for the serum therapy. An analysis of eighteen cases treated with serum placed in the speaker's hands by Dr. McFarlane, of Philadelphia, showed that antipneumococcic serum gave results which were encouraging. In some cases the serum acted in preventing general septicæmia. The clinical histories and records of blood examination were given. Other treatment was not excluded. The pneumococcus was present in fourteen examinations. The dosage of serum varied from 22 c.c. to 460 c.c. It was employed timidly at first, and more boldly later on. Recent serum gave better results than old, and the results showed a general improvement in most cases. There were four deaths. The duration of the disease was from five to fourteen days. The small number of cases did not permit of definite conclusions.

Dr. A. O. J. Kelly, of Philadelphia, in discussing this paper reported a case showing consolidation of the right lower lobe, in which the antipneumococcic serum was given. The patient died, and the autopsy showed conditions which would probably not have been cured by any treatment.

Dr. Rochester, of Buffalo, referred to a trial upon another patient of serum obtained by blistering the skin of a convalescent from pneumonia. There was slight improvement.

Dr. Newton, of New Jersey, inquired as to the mode of preparation of the serum.

Dr. McFarlane, of Philadelphia, answered that it was obtained by administration of living cultures of the pneumococcus to horses, and described the method minutely.

Influence of Sea Air and Sea-Water Baths on Disease.—This paper was read by Dr. W. Blair Stewart, of Atlantic City, N. J. He described the essential differences between sea and land breezes, considering particularly the absence of pollen, dust, miasm, germs, etc., and the presence of ozone, iodine, and moisture. He alluded to the peculiar location of Atlantic City with reference to sea air and tidewater, and its action on neurasthenics. convalescents, tuberculosis, rheumatism, etc. Other subjects discussed were: sea water, its composition, and its temperature at Atlantic City; the surf bath, its time, limitations, physiological action, and its use and abuse, naming particular contraindications and indications in disease. Hot and cold sea-water baths were described, with their use in rheumatism, gout, neurasthenia, etc., and their physiological action. Particular stress was laid on the action of sea water in cases of tuberculosis and neurasthenia, and in convalescence.

SECTION ON SURGERY AND ANATOMY.

First Day—Tuesday, June 5th.

The section was called to order by the president, Dr. H. O. Walker, of Detroit, Mich., at 3 p.m. His address was as follows:

A Retrospect of Surgery of the Stomach.—He spoke of the great advances which had been made since the pioneer work of Billroth, twenty-five years ago. Stomach lesions, he said, might be classed under two heads, the benign and the malignant. In considering the relief of these conditions, he emphasized the fact that beyond peradventure the posterior operation in gastro-enterostomy was the operation of choice, except when the pylorus was bound down by extensive adhesions. In gastroptosis he felt that the shortening of the ligaments was of very questionable value. He spoke of the very great difficulty of early diagnosis, and hoped that much help would come to the surgeon from the gastric specialist. To the medical man, it was of little importance to determine the exact seat of the lesion; to the surgeon it was of the utmost importance, for upon the location depended the character and the prognosis of operation. As to technique he had used Senn's plates, Murphy's buttons, and the various sutures, and had found them all about equal. The cause of death was usually shock or sepsis, or hemorrhage. In regard to the last, it was important to ligate and cut, rather than to use the knife first and then suture afterward. Gastrectomy could hardly, as yet, be considered as established, but he pointed out that physiologically at least it was doubtless feasible, because the stomach being already gravely diseased, its function practically at an end, the patient had now habituated himself to digesting with the unaided gut. He cited many experiments on dogs in which buttons as well as other methods of anastomosis were used, but the animals, habituated to the use of their normal stomachs, were unable to recover from their sudden loss and died within forty-eight hours. In conclusion he said: (1) Non-perforating gastric ulcer must be operated on if medical treatment failed, and posterior gastro-enterostomy was usually the best operation for these cases. (2) Perforating ulcer must always be operated upon early. (3) Benign tumors called for surgical intervention if producing pyloric stenosis. (4) Pylorectomy was indicated in the case of small movable growths; posterior gastro-enterostomy, if the growth was large. (5) In case of hourglass contractions, posterior gastro-enterostomy or gastro-anastomosis should be done. (6) Exploratory cœliotomy was justifiable in all questionable cases.

Non-Perforating Gastric Ulcer with and without Hemorrhage.—Dr. W. L. Rodman, of Philadelphia, read this paper. In Germany, gastric ulcer was said to occur in five per cent. of all cases. While it was possible that this was excessive, there seemed little doubt that the condition was far more common than generally supposed. He said that the best statistics were furnished by Welsh, of Johns Hopkins, from a total of seven hundred and ninety-three cases. These showed the lesser curvature, posterior wall, and pylorus to be the areas involved, three and a half times as often as elsewhere. Also, they showed that one in five was multiple, and that this multiplicity might reach as high as thirty-five. Cicatrices were very common and were frequently seen to be merging into malignancy, while hyperchlorhydria, which was denied by Ewald, was shown by Welsh to be a very constant factor. The etiology was unquestionably in very close relationship with anæmia, it having been overlooked that the occupations commonly supposed to predispose to this disease were invariably accompanied by profound blood changes. Particularly of interest was the statement that ulcer was relatively more common between the ages of forty and sixty years than at any other period. Of the symptoms, pain, severe and boring, influenced by food, localized, was the most characteristic. Vomiting was not so important, but if occurring two hours after eating, and particularly if accompanied by hyperchlorhydria, it was of diagnostic significance. Hæmatemesis was a variable quantity, the color depending entirely on the amount of hemorrhage. It was the cause of death in from three to five per cent. of all cases. The treatment should always at first be medical: three-fourths of all cases thus resulted in cure in from three to five weeks. The remaining one-fourth were conceded by even the most conservative to fall within the realm of surgery. As to the character of the operation, the first question was, "Should the ulcer be excised?" Were it not that there was a mortality of fifteen per cent., this would be the operation of choice. Adhesions frequently contraindicated it. Pylorectomy or gastro-enterostomy might be done, though both might fail to cure. Again, there might be a multiple ulceration. Here gastro-enterostomy should be done, and preferably by Murphy's button.

Dr. Fenton B. Turck, of Chicago, opened the discussion. He dwelt on the indications for operation, and spoke particularly of those cases rendered obscure by pyloric spasm, and absence of tumor. The condition of gastric myasthenia was frequently misinterpreted, and still a third was an hypertrophy of the gastric glands accompanied by degeneration and atrophy of the walls. The diagnosis of perplexing conditions was greatly aided by the passage into the duodenum of a pyloric sound. A beautiful *x*-ray photograph was exhibited showing such a sound in position and outlining with great clearness the greater curvature. The contraindications to operation were not limited to so-called inoperable cases; heart and lungs were factors frequently overlooked. Circulatory disturbances often aggravated the existing auto-intoxication, and so killed, while kidney insufficiency was another very important factor. Important points in the technique mentioned were rapidity; the use of the rubber dam in isolating the operation area, and the avoidance of tugging at the viscera during their manipulation. For this last reason he deprecated posterior gastro-enterostomy. He closed by urging the importance of technique and the ante- and post-operation care of the patient.

A New Method of Elevating the Glottis during Anæsthesia and after Certain Cervical Operations.—Dr. Christian Fenger, of Chicago, spoke on this subject. He said that the method consisted in making a median longitudinal incision over the hyoid. and passing beneath it a strong silk suture. In cases of bony ankylosis of the inferior maxilla this method was of great value to the anæsthetist, while as a post-operative procedure in cases in which the upper hyoid attachments had been cut away, this suture, tied to the dressing, held the epiglottis well open and prevented the inhalation of foreign particles and consequent pneumonia.

Diagnosis and Treatment of Cholelithiasis.—Dr. W. J. Means, of Columbus, Ohio, read this paper. He spoke of the need of early diagnosis and of the very important complications involving intestinal and hepatic changes. Of twenty cases, ten had been operated on, of which all had resulted in recovery; ten had been treated medically, of which number three had been fatal. The average age was fifty years. Fourteen of the patients were females, and six males. The number of calculi ranged from one to two hundred and thirty. Sixteen patients had a history of recurrent attacks, while typhoid had preceded the attack in four. Rigors had been observed in four cases, vomiting in fifteen; jaundice in thirteen, coming within twenty-four to thirty-six hours. Hepatic enlargement was present in eight. Tenderness and rigidity were marked in all. Pain likewise was a constant factor, but of very variable intensity. In fifteen the stools were white. Considering some of these factors in detail, he stated that pain frequently radiated toward the stomach on up to the right shoulder, two hours after eating. Nausea was usually more severe than in appendicitis. Jaundice he considered important, and carefully differentiated the two forms. Cholangitis was a frequent cause of jaundice. Of great importance was the fact that women in the fourth decade of life were the most frequent victims. The treatment was medical and surgical. The first should be employed only in the way of prophylaxis, for the mortality of medical treatment after the deposition of the stones was very high. On the contrary, the surgical intervention was free from danger, and if, as was often the case, the function of the ducts was re-established, the cure was permanent. Early operation here was as necessary as in appendicitis.

Cholecystectomy, with Special Reference to the Removal of the Mucous Membrane of the Bladder in Certain Cases as a Substitute for it.—Dr. W. J. Mayo, of Rochester, Minn., read this paper. He said that trauma, phlegmon, gangrene, and malignancy were the chief indications for total ablation of the bladder. Trauma was very rare. In gangrene, two courses were open—first, excision of the sac; second, drainage. Cases of obstruction of the cystic duct were frequent. Here a permanent fistula discharging mucus often followed cholecystostomy. This condition could easily be cured—he had done it in seven cases—by the entire removal of the mucous membrane. He would also use this method in preference to cholecytostomy in cases of chronic catarrh of the lining membrane, for it was the secretion of these cells which was at the root of the evil. In closing, he outlined the technique of the denudation.

The Importance of Early Operation for Biliary Calculi.—Dr. M. H. Richardson, of Boston, read this paper. Gall stones, he said, must be removed as soon as diagnosed. There was a close analogy between this condition and appendicitis. The earlier the operation, the greater the success. There was slightly more danger in the early operation than in the interval appendectomy, but this was largely due to the greater average age of the patients. In speaking of the chronic cases he dwelt on the influence of cholæmia in lowering the vitality and often causing death. He cited his thirteen fatal cases, all but one of which were chronic, many extending over a period of twelve years. The most frequent complications were acute infection of the gall bladder and appendicitis. The indications for operation consisted in finding faceted stones in the stools, non-faceted stones so found contraindicating operation. Repeated attacks with or without finding stones pointed to operation. Quiescence no more contraindicated operation that it did in appendicitis. Repeated attacks of tenderness and persistent pain over the gall bladder were among the most valuable indications.

Dr. John Wyeth, of New York, on being asked to open the discussion, said that he agreed so perfectly with the spirit of the paper that he would not discuss it.

Dr. Mynter, of Buffalo, said that he believed the hæmatogenous theory of jaundice to be exploded. He thought the colon bacillus was the constant cause, and that all jaundice was due either to inflammatory or other obstruction of the ducts. In regard to Dr. Richardson, whom he congratulated on presenting his fatal cases, he said that all his own early-stage cases had resulted in recovery; not so the late. He urged that continual pain and intermittent tenderness over the gall bladder were almost pathognomonic.

Dr. Nicholas Senn, of Chicago, recommended the use of the *x*-ray. He deprecated the operation of Dr. Mayo because it seemed to him to call for two stages, and spoke of the danger of leaving bits of mucous membrane behind. He recommended a splitting of the peritoneum from the fundus to the point of obstruction, and a removal of the tissues beneath. Again, he protested that gall-stone operations were becoming deplorably frequent, and urged conservatism.

Dr. Grey, of Jersey City, cited a case in which the appendix had become involved by an acute exacerbation of a chronic cholelithiasis.

Dr. H. O. Marcy, of Boston, emphasized the need of ablation of the bladder in many cases, and of the crying need of early operation.

Dr. J. B. Deaver, of Philadelphia, said that perforation-peritonitis was the most fearful condition the surgeon could be called upon to treat, whether it be caused by appendix or gall bladder. He strongly criticised Dr. Senn and supported Dr. Richardson. There must be early operation. Further, the *x*-ray was useless in diagnosing cholelithiasis, though it had a place in the kindred kidney lesion.

Dr. Wyman, of Detroit, urged the simplicity and the value of cholecystostomy, which relieved the cholæmia.

Dr. Merrill Ricketts, of Cincinnati, advocated early intervention. Contracted gall-bladder work was one of the most fearful undertakings in the surgical line.

Dr. Ochsner, of Chicago, said that almost all fatal cases were due to procrastination—the early operations being invariably successful.

Dr. Bevan, of Chicago, said that in 16.5 per cent. of all dissecting-room cases there were gall stones. Of all patients over sixty years of age twenty-five per cent. were found to be in this condition. Thus they must often give no symptoms.

Dr. John Summers, of Nebraska, spoke of the use of Murphy's button in anastomosing the common bile duct and the duodenum; of the need of introducing the finger into the foramen of Winslow, and of a modification which rendered the use of the button easy in these cases.

Dr. Means, in closing, said that he supported the old classification of jaundice. He did not agree with Senn in his conservatism nor in the use of the *x*-ray. Jaundice led the practitioner into grave error because the surgeon had placed too much weight on this factor. He felt that stones almost always produced prodromata.

Dr. Mayo said that Dr. Senn had misunderstood the spirit of his operation. It did not call for a double operation, but was useful, first, for those cases in which a permanent fistula had established itself, and, second, in case of a mucopurulent discharge being a prominent factor at the time of the primary operation. He said that all who had worked on the stomach would realize how easily mucous membranes parted from the other layers, and that this was equally true in the case of the gall bladder.

Dr. Richardson applied to the gall bladder, though to a less marked degree, the rules which governed our treatment of the appendix. He thought Senn's conservatism good, but said that it should not go too far. He admitted that stones might exist without symptoms, but felt that dissecting-room findings were a pernicious argument against the modern operation.

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

First Day—Tuesday, June 5th.

Chairman's Address.—The meeting was called to order by the chairman, Dr. W. E. B. Davis, of Birmingham, Ala., who then read his address. After expressing his pleasure at the honor conferred upon him in selecting him to preside over the deliberations of the Section on Obstetrics and Diseases of Women, he said he believed he could say without fear of contradiction that the members of this section had done most for the advancement of gynæcology. He referred to the illustrious work of Sims and McDowell, and in the words of another said "that the outcome of the labors of these two men in beneficent results had no parallel in medicine." Reference was made to the effort of the late Dr. Parvin to have a combination of the chairs of obstetrics and gynæcology. He believed there was every reason why the gynæcologists should be the teachers of obstetrics; that nothing short of the attainments of the gynæcologist could make the chair complete. He believed we could learn a lesson from Austria and Germany in having large maternities for teaching purposes. He believed the exalted position which gynæcology occupied in this country owed much to the medical journals devoted to this department, and to the national special societies of limited membership whose transactions had gained world-wide reputation. The development of gynæcology had been attended with many errors, but with so many earnest workers only time was required to correct these. For the vaginal section he believed too much had been claimed, although believing it to have a wide field. Peri-tubal and peri-ovarian abscesses of large size, from whatever cause, he believed should be drained by this route, and later abdominal section be done if necessary. Puerperal inflammation occurring in the first month or six weeks after delivery, at term or prematurely, should also be dealt with by vaginal incision. A good percentage of such patients would be cured, and some he stated would bear children. Cases of pelvic inflammation should be operated on without waiting for pus formation. His experience in cases without pus had not been large, but the results had been exceedingly satisfactory. In cancer of the uterus, when the disease had passed beyond the uterus, he advocated palliative operations rather than radical ones. He was gratified to note the increasing popularity of the round-ligament operation for retro-displacements of the uterus. Much honor was due to Pawlik, Kelly, and others for their work in exploring the bladder and kidney; and particularly for the method popularized by Kelly, but he thought it carrying refinement too far when attempts were made to treat pus in the kidney through the ureter. The surgery of the bladder he believed to be little advanced beyond the surgery of Marion Sims' operation in 1878. In the closure of the abdominal wound he employed a method combining the tier sutures with absorbable material and the interrupted through-and-through sutures with unabsorbable material. He used interrupted sutures of silkworm gut uniting aponeurosis, recti muscles, and peritoneum, securing the sutures by means of very small silver tubes corresponding in length to the thickness of the skin and subcutaneous fat through which the ends of each suture are passed and then through a perforated shot. The suture should be superficial or subcuticular.

The Angiotribe in Vaginal Cœliotomy.—This paper was read by Dr. Carstens, of Detroit, Mich. He called attention to the point that Battey had originally removed the ovaries through the posterior cul-de-sac. With the increased knowledge of extensive pelvic lesions, the abdominal route was chosen, while later the removal of the uterus and all the pelvic organs by the vagina was practised, but on account of the tendency to conservatism the abdominal route was generally selected at present. He said that the vaginal route was preferable if thorough work could be done, which was the case in selected cases, but the great trouble in removing a single ovary and small ovarian tumors or diseased tubes by the vagina consisted in the difficulty of applying a ligature and controlling the hemorrhage. In the angiotribe, however, we had an instrument which enabled us to make use of the vaginal route in many cases in which it could not previously have been done. The angiotribe was, therefore, one of the most valuable instruments ever devised in abdominal surgery, as it enabled us to operate with less danger, and with decidedly shorter convalescence.

Angiotripsy.—Dr. Hugh M. Taylor, of Richmond, Va., said his experience sustained the advantages claimed for the angiotribe. In selected cases he thought it was a safe substitute for forceps and ligature. It was very easy to apply, and this should commend it to those who have not served a long apprenticeship in the use of the ligature. He was impressed by the commonly observed fact that post-operative shock was markedly diminished in the cases in which he had used the angiotribe, and he thought this was equally true as to the intensity and duration of post-operative pain. Convalescence seemed to be established at an earlier date and to progress more rapidly. In only one instance did he fail to secure complete hæmostasis by means of the angiotribe. This occurred in resecting a section of badly infected omentum which had wrapped up a necrotic appendix. In all he had used the angiotribe in fifteen cases, all of which were suprapubic sections. He had not used it when operating by the vaginal route. This was largely due to the fact that he had had but a limited experience in working through the vagina. The encouraging reports from so many, he thought, warranted the conclusion that the angiotribe would find a large field of usefulness through the vaginal route. A majority of his cases were very simple in character; about one-half were uncomplicated hysterectomies, while the others were types of cystomas. In only one instance were there post-operative symptoms which suggested the occurrence of hemorrhage. This case was a large unilocular ovarian cystoma with extensive bowel adhesions. He had had no opportunity to use the angiotribe in septic cases, but it seemed especially desirable to avoid the use of the ligature in existing or threatening septic conditions.

Improved Technique in Major and Minor Surgery of the Female Generative Organs.—Dr. Henry P. Newman, of Chicago, read this paper. He said that under the favorable conditions in which operations were now done it must not be forgotten that in handling the organs or tissues of the body we were dealing with living substances of different degrees of resisting-power, and that the success of the manœuvres depended largely upon the amount of delicacy, dexterity, and expedition that was used. A cervical operation, to be successful, must at the same time, in inflammatory conditions, remove all adventitious tissue from the organ, and in deformities of imperfect development remodel the organ to as nearly normal outlines as possible, giving ample lumen to the canal and establishing proper menstrual and intermenstrual function. To accomplish these ends the speaker did tracheloplasty, which consisted in clean removal of a more or less wedge-shaped plug of the diseased tissues from the centre of the cervix by the use of a right-angled knife, especially designed to make the flap, and a pair of curved scissors. In perineal work to restore contour, stability, and function to the pelvic floor, the author recommended the Harris method with a slight modification, of shortening the torn or stretched fibres of the levator ani muscle. In rectal and urethral work for hemorrhoids, fistulæ, etc., the best results could be obtained by clean dissecting out of these lesions and approximating mucous membrane and cut surfaces with catgut or some less yielding suture material. In vaginal section and vaginal hysterectomy the ligature and the angiotribe had replaced the retention forceps. Dr. Newman was the first to introduce the angiotribe into America. He designed his model for use in abdominal and vaginal work, and his experience had upheld his confidence in its advantages.

Dr. J. W. Bovée, of Washington, D. C., was glad to hear such good reports from the use of this instrument, which seemed to him more like a plumber's instrument than a surgeon's. He could not see why cases should have a shorter period of convalescence which were operated on with the angiotribe than those operated on with gauze. He had not had a case of vaginal hysterectomy in which the patient had been in bed longer than two weeks, and he did not believe the use of the angiotribe shortened the length of time. He thought it was only necessary to refer to the French and German literature to learn of a number of deaths in cases in which the angiotribe had been used. He did not think as much of the broad ligament could be removed with the angiotribe as with scissors and ligature. He also believed that hemorrhage was best controlled by ligation of the internal iliacs.

Dr. W. E. Ashton, of Philadelphia, believed that the use of the angiotribe would be more extensively resorted to within the next year by all those who familiarized themselves with its use. He had had little experience with it, because the major portion of his work was by the abdominal route. In reference to the question of lacerations of the cervix he believed it a great mistake to do trachelorrhaphy and curettage, and that rather amputation should be done, when the patient not only recovered but went on to child-bearing.

In the discussion of the papers of Drs. Carstens, Taylor, and Newman, Dr. Wathen, of Louisville, said that much of the objection to operation on the uterus was the result of multiplicity of technique, three to four large retractors—posteriorly, anteriorly, and laterally—generally being used. For the last two years he had performed no operation in the vagina, or done hysterectomy for cancer, in which he had ever used more than one retractor, and generally none at all; with few exceptions he believed them absolutely useless. He had not used the angiotribe himself, but had examined it carefully and recognized that there was a field for its use. He objected to the statement that there was much work done per vaginam by the use of the angiotribe which would otherwise have to be done by the abdominal route. He could not conceive of any instance in which as much could not be accomplished per vaginam by the use of the clamp as with the angiotribe.

Dr. J. Riddle Goffe had had some little experience with the angiotribe, and wished to say a word for it. In order to test the efficiency of it in critical cases he had selected two cases of advanced cancer upon which to try it. He found that even in cancerous tissue the instrument controlled hemorrhage. In a recent case he had used it when he resected the rectum through the vagina, and the result was very satisfactory. In hemorrhoids he had secured perfect hæmostasis. He had reduced the time of application from two minutes to a minute and a half.

Dr. Carstens, in closing the discussion, said he did not care about the size of the instrument if it did the work better than a smaller one. In answer to the man who had spoken of his principles, he said that in the case of an ophthalmologist, he thought, if a patient had an eye dislocated to the extent of three inches the ophthalmologist would take it out, and that it would be good surgery too. He did not claim that the ovary should be taken out unless it caused pain and trouble. He adapted his methods to the conditions, and did not remove every uterus and every ovary, nor use the angiotribe all the time. He thought he had been meek and humble in his declarations; he had said the angiotribe was good for certain cases of vaginal hysterectomy. He did not believe it was good in cancer of the uterus. In that condition he used clamps, getting away as much as possible of the broad ligament.

Dr. Newman, in closing, said that in regard to operation upon the cervix he did not state in his paper that he did trachelorrhaphy, but tracheloplasty. In answer to Dr. McMurtrie he stated that the advantages of the angiotribe were expedition, complete hæmostasis, doing away with the ligature or doing away with foreign bodies, which had been the aim of all surgery; it also did away with the massing of tissue. The lineal stump left was another advantage claimed. Like Dr. Carstens he used the angiotribe when indicated, and had found it very useful when applied in controlling hemorrhage.

Dr. G. B. Massey, of Philadelphia, took exception to the statement of Dr. Carstens that prolapse of the ovary in a young girl was incurable, that nothing but removal of the tube and ovary was proper. He thought that if the ophthalmologist went on that plan the result to the patient would be very bad.

Dr. McMurtrie asked what advantages were claimed for the angiotribe, and to what degree it was superior to the present methods of controlling hemorrhage.

Dr. Porter asked that the gentleman who had recommended the angiotribe would state how long it should be applied, and how many pounds' pressure was required.

Dr. Boldt, of New York, did not believe the angiotribe in the least superior to the ligature, with which he felt more secure than in the use of the angiotribe.

Dr. John C. Da Costa, of Philadelphia, said he was like the Irishman—that the proper way to do a vaginal hysterectomy was by the abdominal route. He did not think ligature on cancerous tissue was good surgery; when all of the diseased tissue could not be removed he thought it better to leave the patient alone. He agreed with Dr. Ashton that trachelorrhaphy was often done in mistake for amputation.

Myomectomy per Vaginam.—Dr. J. Riddle Goffe, of New York, said in this paper that myomectomy was preferable to hysterectomy, and vaginal myomectomy was preferable to abdominal myomectomy in all cases in which it could be employed. He believed the scope of vaginal myomectomy much wider than it was usually thought to be. A report of cases was given illustrating the author's principles.

Myofibroma Uteri.—Dr. H. J. Boldt, of New York, read this paper. He said that the greater number of solid neoplasms of the uterus were fibro-myomata. Tumors consisting only of fibrous connective tissue (fibroids) or only of muscle (myoma) were rare. The original site of such neoplasms, the writer stated, was, strictly speaking, interstitial, and they subsequently grew in the direction of least resistance. The histogenesis of fibromyomata was still a disputed point. His own studies led him to believe with Rösger that they arose from the muscularis of the capillaries. This, too, would explain why in the earliest stages we found many mixed tumors from a histological standpoint. In the matter of treatment the author stated that if by any measure adopted a symptomatic cure could be secured, it should be done in preference to a radical operation. It must not be forgotten, however, that there were instances, although rare, in which nothing but undelayed operations should be advised; they had been mentioned among the degenerations of serious character. The position in life of the patient must be considered, because a woman of the laboring class could not observe the rules laid down for those in better circumstances. No specific had been discovered to check the size of the growth, stop bleeding or the pain. In his observations of the influence of thyroid extract, recommended by Shober and Polk in this country, he had noted three instances of improvement; but with regard to the size of the tumor it must be remembered that this extract had the effect of diminishing the amount of adipose tissue in the abdominal walls. Among the remedies for local use considered palliative, the speaker believed electricity had a limited field.

Arrhythmia Cordis Complicating Fibromata Uteri.—Dr. J. Wesley Bovée, of Washington, D. C., in this paper reported a case successfully operated upon. The arrhythmia was probably of nervous origin, as the pulse was regular during anæsthesia and arrhythmic again during convalescence. He classified the etiological and pathological conditions into (1) nervous and cerebral; (2) neurotic and psychic; (3) reflex; (4) toxic; (5) critical arrhythmia of acute diseases; (6) arrhythmias of cardiopathies. He mentioned several cases demonstrating the wide variance in results from cardiac arrhythmia depending upon the pathological cause. His conclusions were: (1) Arrhythmia cordis was not yet well understood. (2) As a complication of fibromata uteri it was exceedingly rare. (3) It had a serious import, the degree of which depended upon the condition causing it. (4) Its presence as a complication of conditions requiring surgical operations necessitated a careful inquiry into its cause before operation was done. (5) It was a contraindication of more or less influence in all cases for surgical operation. (6) If not due to severe pathological lesions other than those for which operation was to be done, its presence did not necessitate prohibition of operation, but lent additional doubt as to the patient's recovery.

The papers of Drs. Goffe, Boldt, and Bovée were discussed jointly.

Dr. Porter, of New York, said that the field for myomectomy in the larger tumors was much more limited than in the small. He adhered very closely to a limit as regards the age of the patient. He believed the operation should be done with due consideration of possible malignant development, and in patients of the age of forty its use should be limited. The operation in its technique he regarded as very simple; the location of the tumor must help in the selection of an anterior or posterior incision. He preferred the Alexander operation for replacing the uterus to the antero-fixation suggested by Dr. Goffe. When there was difficulty in removing the growth from below on account of its size, abdominal operation was advocated in a large percentage of cases.

Dr. Wiggin spoke in support of incision along the anterior vaginal wall in operations through the vagina, as it facilitated operations in which it was necessary to get at the ovarian vessels. In reference to a remark by Dr. Porter as to the necessity of abdominal hysterectomy when the tumor was of large dimensions, he recalled one case in which the patient would have died had this been resorted to.

Dr. Carstens regarded myomectomy as described by Goffe as excellent and in selected cases applicable: in a great many cases it could not be done; some fibroids were not encapsulated; they were really myomas and went all through the uterine tissues. The younger the woman the more inclined was he to do a myomectomy, and the more advanced the age the more he favored hysterectomy, whether abdominal or vaginal.

Dr. Joseph Price, of Philadelphia, thought nothing was more important than that there should be a consensus of opinion concerning methods of operation. He thought the retrograde changes in fibroids very common. After the age of thirty years he thought the mental state very marked in a woman carrying a fibroid; after operation it was greatly improved. He did not think the lower route could be used by every one, owing to the lack of facilities in some locations.

Dr. Zinke admitted that the operation per vaginam could be done most dexterously by such a man as Dr. Goffe, but in view of that ease he thought how much more easily it might be done through the abdominal wall. He did not believe that the method of Dr. Goffe would ever be practised largely in this country or abroad. He was sorry that Dr. Boldt still found a place for electricity.

Dr. Wathen believed the conditions in each case must be considered in deciding upon the abdominal or vaginal route. The expertness of the operator must also be regarded. He believed it better to begin the operation in either way indicated by the operator's judgment, and be prepared to complete it by any other method demanded.

Dr. C. P. Noble, of Philadelphia, preferred the abdominal route in general, on account of the greater facility in reaching the field of operation, the greater certainty of asepsis, and the greater control of hemorrhage. To the objection to the abdominal route on account of hernia, he said that those who worked from above seldom saw herniæ. In all cases in which it was possible in young women he did myomectomy; in older women, hysterectomy.

Dr. G. Betton Massey, of Philadelphia, expressed the feeling that physicians should guard against professionalism. If they were prejudiced in favor of one method of treatment, patients coming to them did not get what they paid for, and if paying nothing they did not get what the medical profession should give to these patients free. He had noticed this professionalism in regard to the use of electricity. The absence of this professionalism was very marked in the treatment of doctors' own families, for he had treated a large number of the wives and daughters of physicians. He thought the word infection should be used in connection with fibroids rather than the word degeneration.

Dr. Goffe in closing said he did not mean to imply that his method was the only way; but that it was one way. He would do laparotomy in large fibroid tumors. He insisted on the danger of hernia from the abdominal route. He believed that Dr. Noble did not see all the cases of hernia, nor did any operator; the patient usually going to another surgeon. He admitted in reply to one criticism that he might not get out all the tumor; but if the larger part was taken out, as much as possible had been done to prevent development.

Dr. Boldt said in closing that he had given electricity only a limited field as a palliative measure. To say it had no field indicated a want of careful observation. He believed that a certain indefinite number of interstitial myomata would be symptomatically cured by electricity. He stated that the cases of submucous fibromyomata which were lodged in the pelvis, when it was possible to split the cul-de-sac from side to side, were the cases in which vaginal operation was indicated. Interstitial fibromyomata he did not believe indicated vaginal operation.

SECTION ON PEDIATRICS.

First Day—Tuesday, June 5th.

Address of Chairman.—Dr. Edwin Rosenthal, of Philadelphia, called the section to order. He said that pediatrics had become a most important branch of medicine. The most frequent diseases that we had to consider were diphtheria and typhoid fever. In speaking of antitoxins he said that the original antitoxin was a patented preparation. Those preparations now in use, however, were not. He never gave less than 1,500 units for an initial dose, but in cases of laryngeal diphtheria he gave 2,000 units. In speaking of typhoid fever, Dr. Rosenthal mentioned the three methods of treatment, viz., the antiseptic method, the Woodbridge method, and the antipyretic method.

Etiology of Idiocy and Imbecility.—Dr. Martin W. Barr, of Elwyn, Pa., read this paper. He said that, judging from his experience of the last fifteen years, the etiology of idiocy was threefold, viz., heredity, malnutrition, and accidents. In speaking of heredity, Dr. Barr considered mental and physical defects. He said malnutrition was predisposed to by the use of drugs, vicious habits, etc. He then referred to weak-mindedness in certain families among the nobility of Europe. Dr. Barr had a case of insanity which could be traced clearly through seven generations. Out of three thousand and forty cases, nineteen per cent. were imbeciles, five per cent. were insane, and seven per cent. were due to intermarriage. The so-called Mongolian type constituted about ten per cent. of the cases of idiocy. Tuberculosis and epilepsy were mentioned.

Physiological Training of the Feeble-Minded.—Dr. S. J. Fort, of Ellicott City, Md., presented this paper. He said a feeble-minded person was one in whom certain things were lacking that were necessary for association with people in general. He then spoke of the so-called "moral imbecile," and he considered a child that was six years old and unable to talk as feeble-minded. In conclusion, he thought that the institution was not only the best place for such cases, but that it was absolutely essential for their advancement.

A Study of the Circulation in the Feeble-Minded.—Dr. J. Madison Taylor and Dr. F. Savary Pearce, of Philadelphia, presented this paper, which was read by Dr. Taylor. It was based upon observation of nine hundred and fifty-five cases. Cardiac and vascular changes were more common in males. Presystolic murmurs at the apex were the most common organic changes, there being one case that had an aortic murmur. The circulatory changes he thought were very interesting in that all of the cases involved a loss of tone. Dr. Taylor thought that these conditions were due to a toxæmia acting on the neurons.

Infantile Cerebral Palsies.—Dr. A. C. Cotton, of Chicago, read this paper. He considered anything that impaired the function of the brain as palsies. He had collected the histories of twenty-five cases, and found that females were more often affected, and that diplegia was the most common form (seven out of the twenty-five cases), and that dysphasia was the rule. He exhibited some very interesting photographs.

Dr. William M. Leszynsky, of New York, opened the discussion. He did not agree with Dr. Fort in the institutional treatment of feeble-minded children. He thought that "home treatment" would be as beneficial as any. In considering Dr. Cotton's paper, Dr. Leszynsky thought that every case of epilepsy should be examined for infantile cerebral palsy.

Dr. J. P. Crozer Griffith, of Philadelphia, said that he thought tremor, as a post-cerebral symptom, was rare, while choreiform movements were quite common.

Dr. Taylor said that years ago he had thought, as Dr. Leszynsky did, that home treatment for feeble-minded children was the best thing for them, but now he knew that institutional treatment was the only right way to handle these cases.

Dr. Cotton, in closing the discussion, said that he strongly favored institutional treatment, and, in passing, mentioned the case of a child who became self-supporting by such treatment and training.

SECTION ON MATERIA MEDICA AND THERAPEUTICS.

Leon Solomon, M.D., Chairman.

First Day—Tuesday, June 5th.

Chairman's Address.—Dr. L. Solomon, of Louisville, the chairman, expressed the opinion that the greater precision in the knowledge of the use of medicinal agents within recent years was gradually overcoming the therapeutic nihilism so prevalent a decade ago. This branch represented the highest aim of all medicine, and was the culmination of all of the researches of the other departments. After outlining the past history of the section and the plans for the future, he gave a review of the progress in this department for the past year. Particular attention was devoted to the subject of serum therapy. Natural, passive immunity was discussed at length. Ehrlich's side-chain theory offered the best explanation of immunity. The various tissues of the body had different side-chain combinations—as an example, tetanus toxin in an emulsion of fresh brain became much attenuated. The diphtheria antitoxin neutralized all of the side chains. Other antitoxic serums failed because they failed to neutralize all of the side chains. No serum over six months old should be dispensed. The tetanus antitoxic serum fulfilled all the requisites of an antitoxin, and would be of undoubted service if we could diagnose the disease at its inception, as in the case of diphtheria. In discussing the antipneumococcus serum he pointed out that inasmuch as the pneumococci circulated in the blood, the phagocytic power of the leucocytes furnished the chief means of attack. The function of the antipneumococcus serum, therefore, was to stimulate the leucocytes. This agent thus far did not hold a fixed place in our armamentarium. The tuberculins could neutralize only a few of the many toxins of the bacillus tuberculosis, and their action was therefore limited. The antirabic serum of Tizzoni had not been a success. The toxins of bacillus prodigiosus and of bacillus erysipelatis gave good promise. In closing he spoke very forcibly of the slanderous rumors derogatory to the officers of this section that had been circulated throughout the country.

Dr. A. M. Lyons, of Detroit, outlined the policy of the American Pharmaceutical Association, of which he was a delegate. He advised a censorship over all of the papers and advertisements in the medical journals.

Treatment of Acute Alcoholism by Large Doses of Digitalis; A Clinical Study Based on Cases in the Alcoholic Wards of Bellevue Hospital.—Dr. Henry P. Loomis, of New York, read this paper. He said that this agent was largely employed for this purpose in England. One observer reports seventy successful cases. It was generally agreed that there was a great tolerance of this agent in acute alcoholism. He administered it in ten cases. There were two deaths, only one of which could in any way be attributed to the drug. One-half ounce of the tincture was given every four hours for three doses; if this was not effectual he waited six hours and repeated the procedure. The effects observed were a better pulse, the skin became warm, the temperature fell, and the patient went to sleep. Recovery was much more rapid than with any other treatment. The speaker, however, cautioned against the indiscriminate use of such large doses, and thought they should be given only to robust young people. If after three doses the narcotic effect was not evident, it was better to desist.

Dr. O. T. Osborn, of New Haven, said that the vessels of the stomach in cases of acute alcoholism were in a state of vasodilatation, and, therefore, absorption from the stomach was very slight. This was the reason why such large doses of so powerful an agent produced so little effect.

Some Dangers from the Use of Narcotics in Young Persons.—This paper was read by Dr. T. D. Crothers, of Hartford, Conn. He said that when opiates were administered to some people for a limited period a diathesis was established which cropped out late in life if the subject was given opium again. The patient often did not know that the drug was administered before. In some individuals a repugnance was established with the first administration, which continued ever after. When opium did not cause nausea and disagreeable after-effects there was a predisposition toward the habit. A child born of a woman who was addicted to its use was irritable, and this irritability was often only overcome by the use of opium.

Dr. W. B. Hill spoke of the possibility of the cells being stimulated to produce a kind of antitoxin to neutralize the effect of the opium toxin, and thought that when the opium was discontinued the cells continued to produce the antitoxin, thus creating a demand or craving for the toxin.

Dr. J. N. Upshur, of Richmond, Va., deprecated the advice of college professors to students to use morphine for all pains. The students should be taught the responsibility of using narcotics.

Dr. Crothers in closing pointed out the difference between the opium and morphine habits, and said that both alcohol and opium habits were often the result of a psychosis inherited or acquired.

Therapeutic Progress.—Dr. I. Tracy Melvin, of Saguache, Colo., read this paper. He spoke of the uselessness of the knowledge of an accurate description of medicinal plants as far as the physician was concerned. The active principle was all that he needed. The Galenical preparations of the crude drug were too uncertain to be of any scientific value. The effects of soil, climate, and variety were so great that it was impossible that any two samples of a crude drug should possess the same effect. They often varied as much as three hundred per cent. in their percentage of alkaloids. He believed that the alkaloid should be prescribed in preference to the crude drug preparations.

Dr. N. S. Davis said that the physiological effects of many drugs could not be got from the use of their alkaloids. He believed in a proper combination of medicinal agents in many cases, and that the effect was really more simple than if a single agent was prescribed for each symptom.

Dr. F. Woodbury, of Philadelphia, believed that the scientific attitude toward all new remedies was that of scepticism until their value was clearly determined.

Plea for Greater Simplicity in Therapeutics.—Dr. L. Faugères Bishop, of New York, read this paper. He said that a small number of drugs well understood tended to clearness of thought and definiteness of purpose in therapeutic measures. Often a single ingredient of a complicated mixture caused injurious effects which were attributed to the course of the disease. He would advise young men to use a few drugs which they knew well, and to rely on hygiene for the rest of the treatment. He strongly protested against the use of proprietary combinations, the ingredients of which could not be varied and in many cases were not even known definitely.

Dietetic Treatment of Diabetes.—This paper was read by Dr. N. S. Davis, Jr., of Chicago. He said that in mild cases patients would cease to pass sugar when the sugars and most of the starches were withheld from the dietary. In cases of moderate severity improvement would take place as soon as both sugar and starches were entirely stopped. The sugar would not disappear from the urine in severe cases under this regimen. Even the amount of albumin ingested must be limited. The carbohydrates should not be stopped at once. It was wise to do this gradually. Very rarely could any diabetic patient take more than three and one-half ounces of carbohydrates in twenty-four hours. Fats should be taken liberally. Meat, milk, and eggs were the staple articles of food for most diabetics. In ordinary cases of patients who had improved sufficiently to take regular food again, a day of fasting should be observed about once a week, when the patient should return to the diabetic regimen.

Coma Diabeticum and its Treatment.—This paper was read by Dr. Heinrich Stern, of New York. In an analysis by the author of the number of deaths in Manhattan and the Bronx for the past year, there were two hundred and six cases of death in which diabetes was the cause. Sixty cases terminated in coma. He did not believe that it was true diabetic coma, however. There were two forms of diabetic coma—the true, and the pseudo-diabetic or coma due to an intercurrent affection. In true diabetic coma there was a regular dyspnœa, without any apparent cause, present in the lungs. Cyanosis was rare. The pulse was weak and the temperature low. After the onset the quantity of urine became much less; it generally contained albumin; glucose was absent in sixty per cent. of the cases examined by the writer. Before the coma occurred there was sometimes a diminished alkalescence of the blood. In some cases casts were found. When these were present they were absolutely diagnostic of diabetic coma. They were short, smooth, and broad, and of a pale hyaline appearance. There was no reliable symptom to warn one of the approach of coma. Usually death occurred in twenty-four hours. As a preventive alkalies in large doses afforded the best results. When coma occurred they were useless. Two cases were reported by the writer in which he saved the patient's life by the use of precipitated calcium carbonate. It was administered per rectum.

GENERAL SESSIONS.

Second Day—Wednesday, June 6th.

Address on Surgery.—Dr. W. L. Rodman, of Philadelphia, delivered this address, taking for his subject "Gastric Hemorrhage."

Gastric hemorrhage of whatever nature was, until recently, looked upon as strictly a medical affection, and was treated upon the same general principles as those which underlay that of many other internal hemorrhages. This was still true of many cases of gastrorrhagia, but not of others which were treated by a combination of medical and surgical means, and of others still which should be met by prompt operative procedure. Hæmatemesis, he said, might result from ulcer of the stomach, duodenal ulcer, gastric carcinoma, cirrhosis of the liver, vicarious menstruation, post-operative hæmatemesis, purpura hæmorrhagica, miliary aneurisms, aneurisms of the aorta and other vessels, leukæmia, typhoid, yellow, and other infectious fevers, valvular disease of the heart, and various kinds of traumatism. Gastric ulcer was the most common disease of the stomach producing hemorrhage —occurring in five per cent. of the entire population, according to Ewald and others. Hemorrhage occurred in at least fifty per cent. of all cases of gastric ulcer, and many authorities estimated it as present in eighty per cent. It was, too, fatal in eight per cent. of the cases in which it occurred, according to the conservative estimate of Leube, and it was indirectly fatal in a much greater number of cases by anæmia and its remote consequences. The character and amount of the ejected blood, however, would usually give prompt and positive evidence of its source and the cause underlying it. Bleeding in carcinoma was rarely so free as in ulcer; the amount of blood lost being small in quantity, and of the characteristic coffee-grounds appearance. It did not resemble pure blood, as it did in ulcer even though mixed with food. The presence of hydrochloric acid in the ejected matter was as characteristic of ulcer as its absence and the presence of lactic acid were of carcinoma. Ulcer was more frequent in women under the age of forty, whereas carcinoma occurred more commonly in men past middle life. Formerly the treatment of hemorrhage from gastric ulcer was uniformly by ice, astringents, and opium, combined, of course, with rest. This should properly be the treatment still for the first hemorrhage in all cases; for the second, possibly; but not for subsequent ones—for recurring hemorrhage, like appendicitis, would sooner or later prove fatal, and should, like that affection, be treated radically; and to carry the parallelism further, the best time to operate was between attacks. With two hemorrhages coming close together we might assume that as in appendicitis there would be a third attack, and if anything was to be attempted surgically it should be done when the patient was in fairly good condition, and not in the collapse of hemorrhage. The speaker said that better results would be secured by judicious interference than by the policy of inaction hitherto invariably followed, though he would not be understood as advocating interference in every case. Up to a certain point there was substantial agreement between physicians and surgeons, and, indeed, the idea of arresting hemorrhage from gastric ulcer by surgical means occurred to a physician and a surgeon at the same time. The results of operations for chronic hemorrhage were most encouraging. There had been thirty-one operations for frequently recurring, or what might be called chronic, hemorrhage, with six deaths, or a mortality of 19.3 per cent. Mr. Robson had reported one hundred and eighty-eight operations for gastric ulcer (non-hemorrhagic and non-perforating) with a mortality of 16.4 per cent., which was about the same percentage found by Heydenreich, Tricomi, and others. The good showing now made for recurring hemorrhage would be still better when physicians generally recognized that if delayed operations were justifiable, early ones were better, and should, therefore, be encouraged at a time when the chances of success were correspondingly brighter. While hemorrhage *per se* as a symptom of gastric carcinoma had not yet, Dr. Rodman said, led to an operation, he thought that in certain cases it might be either so free or of such frequent recurrence as to make one desirable. Resection would be the best procedure, but gastro-enterostomy would not only arrest the bleeding, but usually delay the inevitable end, and bring about a decided amelioration of all the distressing symptoms. Indicated as it often was in advanced carcinoma without hemorrhage, the presence of the latter as a symptom should be an additional reason for surgical intervention. Hemorrhage into the stomach was a frequent symptom in cirrhosis of the liver. The diagnosis of cirrhosis could be made in only one-third of the cases at the time of the first hemorrhage. A study of Preble's cases along with those collected by Savariaud showed the possibility of an unexpected and fatal gastric hemorrhage in the course of cirrhosis of the liver. Several of the cases reported as having been operated upon for diffused or capillary hemorrhage complicating ulcer were really, the speaker held, instances of venous hemorrhage into the stomach on account of an obstructed portal circulation due to cirrhosis. It was quite certain that operation for gastric hemorrhage in cirrhosis had a less promising future than the same procedure in bleeding ulcer; for in the former there was, in addition, that general hemorrhagic tendency that made bleeding from any situation most difficult to arrest. No operation had as yet been deliberately performed in cases in which the diagnosis of cirrhosis had been made, although some of the cases reported and operated as hemorrhagic ulcers might have been instances of cirrhosis.

Vicarious Menstruation.—There was a more or less general belief that vicarious menstruation might manifest itself in the way of hæmatemesis. If this did happen, one would naturally think that it should do so in young women whose ovaries and tubes had been removed, or in women submitted to hysterectomy, the appendages being left, and who could not therefore menstruate in the natural way. The speaker said he had written to fifty prominent gynæcologists and surgeons to learn if they had seen, and if so how frequently, instances of vicarious menstruation showing itself by hæmatemesis following removal of the appendages, uterus, or both. Nearly all answered, and only two reported (each a single case) affirmatively. Many of the writers expressed a positive conviction that vicarious menstruation did not occur.

Post-operative Hæmatemesis is rare. Mayo Robson, in his Hunterian Lectures, states that he has encountered it in seven cases of his own, two being fatal, and refers to a similar experience of Eiselberg, who reported to the Surgical Society in Berlin the details of six cases. It is significant that nearly all of the cases reported by Robson and Eiselberg were instances of operations on the intestines, omentum, and structures adjacent to the stomach. Robson stated that in six of the cases the omentum was ligated, and in another it was probably contused. He also said that "in an experiment on an animal multiple hemorrhages into the stomach followed twisting of the omentum." The speaker gave details of four experiments upon dogs to determine whether it was possible to cause hemorrhage into the stomach by rapid and severe traumatism not applied to the stomach itself. In none of the experiments was any hemorrhage noted. He also wrote to fifty surgeons, of whom only nine replied that they had seen operative hæmatemesis. He made particular inquiries as to the frequency of hæmatemesis after hernia operations as Robson and Eiselberg had both seen it. Of the fifty surgeons written to, only two had encountered it, and one of the cases was a strangulated hernia with general peritonitis. The other was a case operated upon for ventral hernia, and in which death occurred from a demonstrated duodenal ulcer. In more than a hundred herniotomies—strangulated and non-strangulated cases—Dr. Rodman himself had never encountered gastric hemorrhage. The sum total of all the hernia operations done by these fifty surgeons was undoubtedly many thousands, and yet but two cases of post-operative hæmatemesis were reported, and each was satisfactorily explained—one patient dying of general peritonitis following strangulated hernia, the other from a duodenal ulcer demonstrated at autopsy. All of the cases seen by Robson and Eiselberg followed intra-abdominal operations, such being also the case with all post-operative hæmatemeses reported by American surgeons, excepting two cases in which nephrorrhaphy had been done. In doing nephrorrhaphy, the peritoneum might, in the first place, be incautiously opened by the most careful operator, and secondly there was always a considerable amount of traumatism necessary to force the kidney into the lumbar incision. It is not, therefore, difficult to understand how a hæmatoma might easily be produced by the great abdominal pressure oftentimes necessary to bring the kidney into view, and how, furthermore, this extravasation might occasionally cause sapræmia, septicæmia, or peritonitis, according to circumstances. All septic conditions favored disintegration of the blood corpuscles, and predisposed to hemorrhage from mucous surfaces. The gastric mucosa was particularly liable to congestion in conditions of sepsis, both on account of the marked tendency of the thin and more or less disintegrated blood to settle in the internal organs, and on account of the vomiting and retching so frequently present. This would give, the speaker said, a satisfactory explanation of the rare hæmatemeses following abdominal operations. The experiments upon dogs had shown that even violent traumatism to the omentum, intestines, spleen, pancreas, and liver did not produce immediate hemorrhage into the stomach; and it did not seem unreasonable to suppose that delayed hæmatemesis would usually depend upon disintegration of the blood due to sepsis.

Oration on State Medicine: Typhoid Fever among American Soldiers. — Dr. Victor C. Vaughan, of Ann Arbor, Mich., delivered this address, presenting therein some of the more important conclusions reached after a study of typhoid fever among the American soldiers in 1898. He said that in August of that year a board, consisting of Major Walter Reed, U.S.A., Major E. O. Shakespeare, U.S.V., and himself, was appointed at the request of the surgeon-general of the United States army for the purpose of ascertaining the causes of the existence and spread of typhoid fever in the national encampments, and of suggesting means for its abatement. After completing the tour of inspection, this board spent about eighteen months in going over the medical records of the various commands. The first conclusion arrived at was that every regiment in the United States service in 1898 developed one or more cases of typhoid fever, statements to the contrary notwithstanding. More than ninety per cent. of the volunteer regiments developed this disease within eight weeks after assembling in the State encampments, and most of the regular regiments—probably all—developed it in less than that time. Typhoid fever was so widely distributed in this country that one or more cases were likely to appear in any regiment within eight weeks after assembling. When war with Spain was proclaimed, the total strength of the standing army of the United States was twenty-seven thousand, scattered in about one hundred military garrisons, and with no epidemic at any post. Typhoid fever not only appeared in every regiment in the service, but became epidemic in the small as well as in the large encampments. There was abundant proof that the prevalence of typhoid fever among these troops was not due to geographical location. The chance of infected men being found in each regiment was shown by the following figures: In New York City, which is unusually free from typhoid fever, it was calculated that there were 3,986 cases of this disease in 1897. As at least four-fifths of the cases occurred in those of military age—eighteen to forty-five years—there were among this class in New York City 3,188 cases. Assuming the population to be 2,000,000, and that the number of persons of military age was one-half of the population, it followed that if these people were divided up into regiments of 1,300 each, they would have furnished 769 commands. If the estimated 3,188 cases of typhoid fever had been evenly divided among these regiments, each command would have contained at least four persons who, in all probability, would develop typhoid fever during the year. Another point, which the speaker substantiated by quotations from military authors, was that typhoid fever usually appeared in military expeditions within eight weeks after assembly. As many intelligent medical officers still clung to the old miasmatic theory of typhoid fever, it was worthy of note that this investigation brought out no fact more prominently than the demonstration that locality was not responsible for the epidemics. Neither was any support found for the pathogenic theory. Translated into terms of modern medicine, this theory was founded on the belief that the colon germ might undergo a ripening process by means of which its virulence was so increased and altered that it might be converted into the typhoid bacillus, or, at least, might become the active agent in the causation of typhoid fever. Moreover, all the known facts of experimental bacteriology were at variance with this theory. This investigation also made it clear that there was no ground for the belief that simple diarrhœa might develop into typhoid fever, or predispose to it—indeed, the men who had simple diarrhœa did not, as a rule, subsequently develop typhoid fever. Typhoid fever was disseminated by the transference of the excretions of an infected individual to the alimentary canals of others. It was more likely to become epidemic in camps than in civil life, because of the greater difficulty of disposing of the excretions from the human body. More than this, a man infected with typhoid fever might scatter the infection in every latrine of a regiment before the disease was recognized in himself. As it was probable that typhoid bacilli were eliminated from the bowels as soon as infection began, it was reasonable to assume that throughout the entire period of incubation an individual might be a source of danger to others. If this was true, the only way in which typhoid fever could be with certainty prevented in armies was by the complete disinfection of the stools of all, both the sick and the well. Camp pollution was the greatest sin committed by the troops in 1898. Some commands were also unwisely located, as, for example, at Chickamauga, where certain regiments were so placed that they received the drainage of other regimental camps. In some instances the space allotted the regiments was inadequate, and many commands were allowed to remain on one site too long. The placing of the regiments in unsanitary positions was done by the superior line officers, sometimes in the face of protests from the medical officers. As the medical officer could only recommend, the line officer having the authority to command, it did seem right that the line officers should at least know enough of this subject to be able to recognize the importance of reasonable requests and recommendations made by medical officers. It also seemed proper and expedient that greater authority should be given medical officers in matters relating to the hygiene of camps. A significant statement made by Dr. Vaughan was that, in a general way, the number of cases of typhoid fever in the different camps varied with the method of disposing of excretions. Thus, during a part of the stay of the First Division of the Seventh Army Corps at Miami, and during the entire period of its encampment at Jacksonville, water carriage was employed for the disposal of fecal matter. In the Second Division the tub system was employed, and by it the fecal matter was scattered all through the camp. In the Third division regulation pits were used. The number of cases of typhoid fever was smallest in the First Division and greatest in the Second Division. The tub system should be condemned, and the regulation pit system was far from satisfactory, particularly in hot weather. He was convinced that if epidemics of typhoid fever were to be prevented, some other method of disposing of fecal matter in camps occupied for a week or longer must be resorted to. The board of inspection recommended that in permanent camps, where water carriage could not be secured, all fecal matter should be disinfected, and then carted away from camp. Galvanized iron troughs containing milk of lime should be used for the reception of the fecal matter, and their contents should be removed daily by means of the portable odorless evacuator. The investigation showed that infected water was not an important factor in the spread of typhoid in the camps in 1898. The greater prevalence of typhoid fever in the Third Army Corps was attributed to the fact that the camp-sites furnished many wet-weather springs, thus favoring infection. These undoubtedly served as carriers of the infection, either by mechanically transporting adherent and infected fecal matter, or by the men swallowing the typhoid bacilli and voiding them afterward with the encrement. It was more than likely that the men transported infected material on their persons or in their clothing, and personal contact was undoubtedly one of the means by which the infection was spread. Blankets and tentage became soiled with typhoid discharges, and in this way the disease was carried by the command wherever it went. It was probable also that the infection was disseminated to some extent through the air in the form of dust. Men inhaled the fine dust from the roads, or it was deposited on their food and was then eaten. It was true that complete desiccation soon destroyed the typhoid germ, but dust was not always completely desiccated. It should be borne in mind that a badly infected command did not lose the infection by simply changing location, though such a step was desirable. Even an ocean voyage did not relieve an infected command of its infection, as was well shown in the case of infected regiments going from Chickamauga to Porto Rico. Except in cases of most urgent military necessity, one command should not be located on a site recently vacated by another, and the fact that a command expected to change its location did not justify a neglect of proper policing of the ground up to the very moment of vacating it. In some of the encampments the tents were too close together, and there were too many men in each tent. Malaria was not found to be a prevalent disease among the troops that remained in the United States, and the malaria that did exist in the camps in this country yielded readily to quinine. The continued fever that prevailed among the soldiers in this country in 1898 was typhoid fever. What was designated as a distinct disease under the name of "Chickamauga fever" had the typical temperature curve of typhoid fever and the death rate of that disease; the fever was not arrested by quinine, and in cases coming to autopsy the characteristic lesions of typhoid fever were found. While the investigations of the board showed that coincident infection with malaria and typhoid fever might occur, the resulting complex of symptoms did not seem to be sufficiently well defined and uniform to be recognized as a separate disease. About one-fifth of the soldiers in the national encampments in the United States in 1898 developed typhoid fever. Of the 9,660 cases of probable typhoid studied at Chickamauga, 4,068, or a little less than half, were diagnosed by army surgeons as typhoid fever. Of these 9,660 cases, 713 resulted fatally, giving a death rate of 7.38 per cent. It was probable that when a command was thoroughly saturated with typhoid, one-third to one-quarter of the men would be found susceptible to the disease. In military practice typhoid fever was often an intermittent disease. No support was found for the belief that errors in diet, with consequent gastric and intestinal catarrh, induced typhoid fever or predisposed to it. More than eighty per cent. of the men who developed typhoid fever had no preceding intestinal disorder. The deaths from typhoid fever were more than eighty per cent. of the total mortality. The shortest period of incubation in typhoid was probably something under eight days. One who had lived in a camp in which typhoid fever was prevalent was liable to develop this disease any time within eight weeks after leaving such a camp. The proof of this last statement was to be found in the history of the Fifth Pennsylvania.

Change in Name of Section.—The name of the Section on State Medicine was changed to Section of Hygiene and Sanitary Science.

A New Section Formed.—In accordance with the suggestion of the president, the association formally authorized the establishment of the Section on Pathology and Bacteriology.

A Permanent Committee on Exhibit.—Acting upon another timely suggestion in the president's address, it was voted to establish a permanent committee on exhibit, composed of five members, electing each year a chairman residing at the place selected for the next annual meeting of the association.

Report of the Board of Trustees.—This report showed the total receipts for the year 1899 to have been the largest in the history of the association, *i.e.*, $109,115.33. The total expenses of the *Journal* were $77,641.01, and of the treasurer's office $15,968.39, making the total disbursements $93,609.40.

American Medical Association Medal.—Dr. George M. Gould, of Philadelphia, presented the report of the committee having this matter in charge. He stated that the committee had carefully examined the six essays submitted, and had unanimously voted to award the prize to Dr. A. L. Benedict, of Buffalo, N. Y., for the essay entitled, "Quantitative Tests for Proteolysis." The gold medal was of about the diameter of a United States twenty-dollar coin, and about twice as thick, and was of handsome design.

The Senn Medal.—Dr. W. L. Rodman reported for this committee that this prize had been awarded to the author of an essay entitled "Exstrophy of the Bladder," and requested President Keen to break the seal and announce the name. This was done, and the author was found to be Dr. F. Gregory Connell, of Chicago. Dr. Keen, in presenting the medal to Dr. Connel, took occasion to thank him for the high standard of excellence which characterized this important contribution to surgery.

Rush Monument Fund.—Dr. James C. Wilson, of Philadelphia, reported that the contributions for the year amounted to $938.20, making the total fund at the present time $11,330.05. Drs. Billings, Bulkley, and Rodman were added to the committee.

New Officers.—The nominating committee selected the following officers to serve the association the coming year: *President*, Dr. C. A. L. Reed, of Ohio; *First Vice-President*, Dr. A. W. Calhoun, of Georgia; *Second Vice-President*, Col. Alfred A. Woodhull, U.S.A.; *Third Vice-President*, Dr. Philip Marvel, of New Jersey; *Fourth Vice-President*, Dr. W. E. Quine, of Illinois; *Treasurer*, Dr. H. P. Newman, of Illinois; *Secretary and Editor*, Dr. George H. Simmons, of Illinois; *Trustees*, Drs. M. F. Porter, of Indiana, E. Fletcher Ingals, of Illinois, W. L. Rodman, of Pennsylvania, and J. A. Matthews, of Kentucky.

Dr. John A. Wyeth, of New York, was mentioned as the one who is to deliver the oration on Surgery next year, and Dr. N. S. Davis, Jr., of Illinois, for the oration on State Medicine.

SECTION ON PRACTICE OF MEDICINE.

Second Day—Wednesday, June 6th.

Pseudo or Modified Smallpox.—Dr. T. J. Happel, of Trenton, Tenn., read this paper, in which he reviewed the salient points in the course of a normal case of variola vera, giving data to show that it could be prevented by vaccination. The clinical history of pseudo-variola was given, showing absence of a pustular stage and of secondary fever often occurring in those successfully vaccinated; the vesicles desiccating without crusting or scabbing, and not being followed by pitting. Vaccination seemed to give no protection, and in some instances vaccination was successful after the disease had run its course. The report was based upon an epidemic extending to about three hundred patients, mostly negroes; white patients seemed to suffer more. The eruption was unattended by itching. There were no swelling and no mortality. The disease ran such a mild course that it was preferred to vaccination, the early backache and headache being the chief subjective symptoms. There were no complications nor sequelæ, and no medicines were administered.

Dr. Walsh, of New York, thought the observation valuable as showing a connecting link between variola and varicella, observers now coming to acknowledge the connection between these extremes.

Dr. James, of Missouri, said that in Missouri they had had an exaggerated form of the same affection, which he thought was mild or modified or discrete smallpox. There had been over three thousand cases of a mild form of variola often mistaken for chickenpox.

Dr. Chapman, of Ohio, said that for a year or two an epidemic of this disease had existed; a third of the adult population of a region being sick at the same time. Vaccination had been practised in infancy in almost all cases. He had found vaccination successful, and in this he took exception to Dr. Happel's views. The disease was not varicella, which was not an adult disease. He had seen a number of deaths. Health officers should vaccinate and isolate and stamp out this affection just as though it were more virulent. It was smallpox.

Dr. Corlett, of Ohio, said different epidemics differed in virulency. In Cleveland a number of cases had proven fatal. The distinction between variola and varicella could usually be made readily. Vaccination was the only safeguard.

Dr. Woodward, of Ohio, spoke of one hundred and twenty-five cases with one death. Vaccination seemed to protect; the one vaccinated in one family escaping, and seven others not vaccinated contracting it. Some epidemics were as mild as chickenpox.

Dr. Stewart, of Philadelphia, said that the evidence presented did not show that the epidemic was either variola, or varioloid, or varicella. He thought it might be some exanthem.

Dr. McCormack, of Kentucky, offered a resolution expressing the sense of the section that the epidemic described was one of modified variola. The cases he had seen coming from Tennessee were variola.

The resolution was declared out of order, and this decision was loudly applauded.

Yellow Fever: Its Nature and its Cause.—Dr. Eugene Wasdin, surgeon in the United States Marine-Hospital service, went over the natural history of the disease, describing its endemic presence in some Southern cities and in inter-tropical countries; its epidemic invasion of more temperate climes, and its disappearance from these regions with the cessation of the epidemic at the advent of frost. The clinical features marking the disease as an entity and distinguishing it at certain stages were described. The variations of temperature giving the three characteristic stages furnished the chief distinctive feature of the affection. The organisms at different times charged with being causative had been shown by Sternberg to be without sufficient evidence to support them. There was at present sufficient evidence to establish the claims made for the bacillus icteroides discovered by Sanarelli. It was found in half the cases, and was pathogenic to animals when introduced experimentally into the blood. It explained the natural peculiarities of the disease, satisfactorily explained its clinical phenomena, and fulfilled the demands of modern bacteriology to warrant its acceptance as the true and proved cause of the disease. It attenuated rapidly in cold and lost its virulence at a temperature below zero, explaining the disappearance of epidemic disease at the onset of frost. It was first colonized in the respiratory tract, giving the first paroxysm. Invasion of the blood gave the second, and septicity the third stage. Domestic animals were susceptible. Recrudescence might be attributed at times to them. America had furnished the proofs and the scientific explanation of Sanarelli's important discovery.

Dr. Flexner, of Philadelphia, said Sanarelli had done much in the discovery, in the bodies of subjects dead of yellow fever, of a hitherto undescribed organism. He did not know that all the conclusions arrived at by the reader could be accepted, but the observations opened the way for further experimentation and confirmation. The mode of invasion must still be regarded in the light of hypothesis.

Dr. Gerry, of Boston, asked whether one who had had yellow fever was really immune. This was not true for variola.

Dr. Wasdin said in closing that he felt convinced that further investigation would prove the value of Sanarelli's bacillus. Animals reacted to small amounts and were not overwhelmed by large quantities of the bacillus, so that the experiments approximated a natural process. The conditions required by Koch, Sternberg, and others were fulfilled in the animal inoculations, so that they must be accepted. Black vomit and characteristic changes were present to prove the truth of the specific nature of the bacillus icteroides. He did not believe absolute immunity was conferred by one attack.

Resolutions of regret at the death of Dr. Whitaker, of Cincinnati, were offered by Dr. Osler and accepted by the section.

In opening a symposium on malaria the secretary read a paper presented by Dr. Jesse W. Lazear, U.S.A., of Havana, Cuba, with the following title:

Pathology of Malarial Fevers; Structure of the Parasites and Changes in the Tissues.—The methods of preparation of the blood and staining with methylene blue, the Romanowsky method and its modifications, were first given. The cycles of development of the parasites were described. The structure of gameti or sexually ripe parasites was given, together with the formation of crescentic bodies.

The Etiology of Malaria, with Especial Reference to Mosquitos.—This paper was read by Dr. W. S. Thayer, of Baltimore. He described experiments carried on along the eastern shore of Maryland, where malaria prevailed, and where mosquitos abounded. One variety of mosquito, the Culex, abounded in high regions where there was no malaria. Another variety, the Anopheles, on the other hand, was found where the disease prevailed. It had been proved that the malarial parasite possessed an extracorporeal cycle which took place in the mosquito just as was the case in birds. A single bite would transmit the disease, and when fed upon the parasites the mosquito would transmit the particular form (quotidian, tertian, or quartan) with which it had been originally fed. The speaker believed that mosquitos acquired the parasite exclusively from man. While there might be other methods of transmission by mosquito bites, this was the only one proven. It is highly probable that where Anopheles abounded malaria would prevail. In prophylaxis the mosquitos must be killed in their larval stage. Patients should be treated, in relapses, under mosquito netting.

The Structural and Other Differences between the Several Mosquitos of North America.—Dr. L. O. Howard, of the Department of Agriculture, gave a screen demonstration showing the differentiation between the Culex and the Anopheles, the latter being the transmitters of malaria. They were to be distinguished in the larval stage in their mode of development, and when fully developed. The wings of the Anopheles were spotted; those of the Culex were plain; the "feelers" protruding from the head of the Culex were much shorter than those of the Anopheles. The singing note of the Anopheles was not so high as that of the Culex; this was well appreciated by collecting a number of each variety in a jar and listening to their buzzing when the jar was tapped upon.

Inoculation of Malarial Fever through the Agency of the Mosquito.—Dr. A. E. Woldert, of Philadelphia, read this paper. The natural order, general species, and modes of identification and of distinguishing the male from the female mosquito were given, based upon sections, dissections, and gross study. He said that the Culex pungens was not capable of inoculating a human being with malaria, but the reasons for this were not known. The different species of Anopheles, however, did transmit the disease. The Anopheles maculipennis or claviger was of doubtful occurrence here, and there was no example in any museum. The speaker went over the cultivation of zygotes of proteosoma in the dapple-winged mosquito as described by Ross. He also discussed the etiology of malaria based upon studies made in the South.

SECTION ON SURGERY.

Second Day—Wednesday, June 6th.

Colostomy for Permanent Fecal Fistula.—Dr. John A. Wyeth, of New York, read this paper. He laid particular emphasis on the desirability of forming an artificial sigmoid. It was the natural storehouse of the rectum, and its presence, in great measure, did away with the fifteen-minute dejections and the tenesmus so distressing in the older form of operation. The technique of the operation, which was in part suggested by his former assistant, Dr. Bodine, was as follows: As much as ten inches of the sigmoid and descending colon was dragged into the wound, and two running sutures, four inches long, were passed from the enterostomy site down the bowel wall. Traction was made on the lower gut, so that there might be no slack whatsoever to the rectum. The knuckle was held in place by sutures—he believed these to be preferable to the glass rod.

Present Status of the Murphy Button, and Report of 1,620 Cases.—Dr. J. B. Murphy, of Chicago, presented this paper. Just eight years ago he used the button on the first human case. He cited many statistics showing the influence of the button in lowering the mortality of all anastomotic work. In detail, he considered then as follows: Entero-enterostomy, which formerly yielded a mortality of from fifty to one hundred per cent., now showed a mortality of but 19.7 per cent. This seemed to Dr. Murphy to demonstrate the great value of his button in gangrenous hernia when the mortality reached the ebb-figure of fourteen per cent. It was for the operation of cholecystenterostomy that the button was first devised. Prior to its introduction there had been but eleven cases recorded. While formerly he recommended it in every gall-bladder case, he would now restrict its use to conditions in which there was permanent obstruction to the common duct. The mortality was 14.7 per cent. Gastro-enterostomy and uretero-enterostomy presented very favorable statistics. Reviewing the history of gut approximation, he spoke of the early efforts of the French, as far back as 1802, and said that Senn's classic paper in 1888 gave a tremendous impetus to bowel surgery. In the eight years during which the button had been used, the following conclusions regarding it had been reached: (1) It approximated without suture. (2) The time of operation was much shortened. (3) The union was ideal. (4) There was no contraction of the scar. (5) The physiological function of the gut was not interrupted at any time. There were two great classes of objections to the use of the button: (1) The opening might be occluded by food or other particles, prior to the sloughing of its attachment. (2) There might be prolonged retention of the button in the gut or abdominal cavity. Both these matters were of small moment, there having been but three fatal cases, in the 1,620 considered, traceable to such causes. It was of little consequence whether the button was passed or not. The portions of the canal in which it had been found retained were enumerated as follows. in the stomach, 22 times; colon, 5 times; ileum, 2 times; jejunum, 1 time; cæcum, 2 times; rectum, 4 times.

The Treatment of Obstinate Constipation Based on New Points in the Anatomy and Histology of the Rectum and Colon.—Dr. J. R. Pennington, of Chicago, read this paper. He spoke of the great variability of the position of the sigmoid which, when distended, frequently extended to the right iliac fossa. Numerous paraffin casts, both of the adult and of the child, together with a series of charts, fully supported this statement. They also illustrated the depth to which Heuston's valves frequently indented this portion of the great intestine. Of the histological anatomy of these valves he spoke at length and showed the numerous epithelial glands which found a foothold within their walls. These valves seemed to him to be very potent factors in the etiology of chronic constipation, when, their epithelium diseased and their tissues sclerosed and thickened, they presented firm barriers to the passage of fecal matter. The speaker showed a specially contrived chair for the examination and operation of rectal cases, and a contrivance whereby a clamp could be attached to a portion of the offending valve by means of a sigmoidscope. In time the portion bitten upon sloughed away and was thus removed without fear of hemorrhage.

Dr. Tuttle, of New York, opened the discussion. He wished to say, in support of Dr. Murphy, that he recalled five cases in which the button had not been recovered, in all of which no ill effects had resulted. He emphasized the necessity of using Dr. Wyeth's operation only in those cases in which a permanent anus was to be established. Colostomy for transient conditions called for as much slack in the rectum as could possibly be obtained, and, furthermore, a fistula once established by Wyeth's method was exceedingly difficult to close. Indeed, in those cases in which resection of the spur was necessary, statistics showed a mortality of thirty-one per cent. But for a permanent anus Wyeth's operation was ideal, particularly when combined with one of the modern methods of making a new sphincter. He recommended a rectangular incision through the oblique muscles, and the carrying of the gut between the skin and the external oblique to an opening just below Poupart's ligament. Over the collapsed gut, and upon the firm surface of the abdominal wall, a truss pad could be applied with such success that the patient could not pass even gas without lifting the pad. By a union of these methods a patient could be made absolutely comfortable. He differed from Wyeth in that he always used the glass rod, rarely introducing a suture, for he believed that the suture alone was very apt to yield and allow prolapse, which was a frequent cause of death.

Repair After Resection of the Intestine.—Dr. W. A. Evans, of Chicago, read this paper. It consisted of a discussion of the histological characteristics of the scars in end-to-end anastomoses by the use of Murphy buttons and other methods. Dr. Evans dwelt on the rarity of strictures after such anastomoses, and said that if they were destined to appear, it would be before the tenth month. In those few cases in which stricture had been studied in the small gut, it had been found to be composed exclusively of circular fibres. He cited at length the histological arrangement of the gut elements. In intestinal scars the amount of cicatricial tissue was small; the fibres were very generally in one direction only, and bridged the wound. The important factor was, that they never ran circularly. There was a law that governed the direction of the fibres of scar tissue: they always ran in the direction of greatest tension. Of the small number of strictures which had been found in the lesser gut, the great majority were due to tuberculous lesions. Strictures due to other causes, however, were common in the greater gut, in the œsophagus, and in the urethra. Why? Probably because there was in these passages a lack of the longitudinal tension which was ever acting in the lesser gut. He advised the approximation of the deeper coats as well as of the serous, believing that a union so produced must be stronger. The Czerny-Lembert suture often resulted in the formation of a diaphragm which might produce obstruction, but we should not forget that these valves were physiological, at least in the lower gut. Concluding, he said that his investigations showed that the scar formation in these cases was so light and so harmless as in no case to contraindicate end-to-end anastomosis.

Dr. Wiggin, of New York, opened the discussion. He said that he cordially agreed with Dr. Evans as to the infrequency of scars in end-to-end anastomoses. He had watched patients for many years on whom he had operated when these procedures were still in their infancy. Years ago he had experimented on animals, using both the button and Monsel's suture. In some which were killed from one to nine months later, he had experienced the utmost difficulty in discovering the point of union. He strongly advised the use of horsehair in the Monsel operation, because of its elasticity. This factor obviated the danger of the stitches cutting through. He no longer invaginated the intestine, preferring to pass through and through, from inside to inside. This seemed undoubtedly the safest procedure.

Dr. Evans, in closing, said that much needless stress had been laid on scar formation after the button operation, but he now felt that this danger was much exaggerated.

Appendicitis: Colitis as an Etiological Factor, and the Operation of Removing the Appendix in All Cases Operated on.—Dr. Miles S. Porter, of Fort Wayne, Ind., read this paper. His special aim was to draw attention to the etiological relationship existing between constipation, colitis, and appendicitis. He cited a number of cases in which the appendicitis had been ushered in by an acute colitis, in many of which cases chronic constipation had long been a symptom. The second part of his paper treated of the important question whether or not incision and drainage, without removal of the appendix, was the operation of choice. He agreed that the appendix should be removed in a great majority of cases, but advocated a simple incision, with drainage, when speed was demanded and shock particularly to be avoided. Of two hundred and two cases thus treated, recurrence had been found in but thirteen per cent. In conclusion he said that no operator could do appendectomy in every case without raising the percentage of mortality.

Appendiceal Fistulæ.—This paper was read by Dr. J. B. Deaver, of Philadelphia. He spoke of the unfortunate frequency of this condition; important because of its sequelæ. Fecal fistulæ should be considered under two heads: the external, which might be simple or fecal, and the internal. The simple external fistula was readily cured by the removal of the gauze left by accident in the wound. Those fistulæ which discharged fæces were either in direct connection with a loop of the bowel or cæcum, or connected with the intestine via the lumen of the appendix. Pus was not essential to the formation of a fistula; microorganisms were important, while drainage tubes often caused it to persist. Speaking of internal fistulæ, he strenuously objected to the view that a happy outcome of an appendicitis was to have the pus cavity evacuate into the gut, and deplored the lack of surgical intervention which made such a condition possible. He tabulated the etiology of fistula as follows: (1) Abscess formation; (2) migration of bacillus coli communis; (3) separation of the appendix; (4) the use of too many sutures; (5) the prolonged use of the drainage tube; (6) pressure necrosis. He continued by urging the abolition of those factors, which could largely be accomplished by immediate action. The treatment of fistulæ was largely dietetic. They should not be frequently washed out, but left severely alone. In closing, he summarized as follows: (1) Fistula was one of the most important sequelæ of appendicitis. (2) Some cases closed spontaneously. (3) When they produced marked symptoms they should be operated on. (4) They should be avoided by early operation. (5) Fistulæ were generally curable by dietetics. (6) They did not always occur soon after the operation, but might come late in the convalescence.

Dr. Senn, of Chicago, opened the discussion. He said that operation should be considered as a preventive and as a curative measure. Both the immediate and the remote causes should be removed. He felt that Dr. Deaver was an extremist, who, while he had done incalculable good, had probably wrought greater harm. Fortunate it was that Dr. Deaver did not teach. He advanced the expectant treatment; eighty per cent. of cases so governed resulted in recovery. Fistulæ operations were extremely dangerous. He urged the subperitoneal method of enucleation. Lastly, he urged the section to beware of operating in those cases in which one had reason to suspect that the abscess had opened internally.

Dr. Mordecai Price, of Philadelphia, was glad to take Dr. Deaver's side. He opposed Dr. Senn's view very strongly, and felt that he had treated the very class of cases to which Senn referred. But twice in one hundred and twenty-five cases had he operated without pus, and he had yet to repent in a single case. His method was, not to close the head of the bowel if it was badly broken through. He simply opened the pus cavity, washed it out, and broke down adhesions. The most important part of his technique he felt to be the placing of the ruptured colon deep in the wound, and the use of gauze dressing. He operated on everything that would leave the table alive. He disagreed with Porter's statement that appendicitis was common in children, having found it most frequent after the age of twenty-one.

Dr. Dawbarn, of New York, regretted the futility of the discussion, which he felt would be repeated for the next twenty-five years without show of progress. At least that long would the archaic side persist which opposed early operation. He called particular attention to the prevention of fistulæ, believing them to be due, in almost all cases, to faulty technique. In those cases in which the cæcum was gangrenous, he cut away the appendix, and, without waiting to invaginate the stump, cast a purse-string suture about the gangrenous area and quickly inverted this, together with the stump, into the copious lumen of the cæcum. This procedure, repeated at all points of weakness in the gut, precluded the possibility of fistulæ.

Dr. Hamilton, of Columbus, said that no sweeping rules could be established. He criticised Dr. Price's method of breaking down adhesions and washing, believing it to be permissible in very infected cases only. Fistulæ usually yielded to medical treatment. He referred to what Dr. Senn had said as to the frequent posterior position of the abscess, and advocated a backward draining through the loin.

Dr. Mynter, of Buffalo, was first, last, and at all times with Dr. Deaver. He was surprised at Dr. Senn's point of view. He should have said that eighty per cent. of the cases end in recovery in spite of medical treatment. He thought incision and drainage the proper course in most cases after the sixth day. He found that fistulæ healed in most cases without intervention, and noted that, should operation be necessary, Dr. Deaver's method of curettage would not cure. End-to-end anastomosis was necessary.

Dr. Keen, of Philadelphia, said that, like the poor, we have appendicitis always with us. The two important questions were: (1) Should we operate coincident with diagnosing? (2) Should the appendix always be removed? He felt that we should not try to practise surgery by aphorisms. Dr. Deaver, he was sure, in spite of his theoretical assertions, did not operate in every case. He urged a conservative course: no case should be allowed to pass beyond the second attack. He pointed out that the section was making surgical standards for the country, and feared that evil would result from its taking a too radical stand. In general, operation was best. In general, removal was best. Fistulæ healed, as a rule, spontaneously. This failing, he advocated excision of the tract, invagination of the stump, and gauze dressing in the wound.

Dr. McCrae, of Atlanta, Ga., urged the removal of the appendix. Otherwise seventy-five per cent. either recurred or had fistula. He criticised very emphatically Dr. Price's suggestion that the abdominal cavity should be washed out, as very dangerous to life. He used the purse-string suture for closing fistulæ.

Dr. Murphy congratulated Dr. Deaver on his point of view. Granted that eighty per cent. resulted in recovery when medically treated; was there any operation with a mortality of twenty per cent. of which surgeons spoke with pride? He used to operate on all cases. Now, however, those already moribund he left to the physician who caused them. Diagnosis should be made within the first twenty-four hours. In these early cases the mortality of one per cent. was due entirely to fulminating cases which had perforated.

Dr. W. H. Walthen, of Louisville, advocated the conservative course.

Dr. Grey, of Jersey City, said he had had seven fatal cases out of one hundred and seventy-five. This experience had taught him to operate early and to excise the appendix.

Dr. Hall, of Cincinnati, felt that the discussion should not be closed without protesting against the advice of Dr. Murphy, who leaves the moribund cases in the hands of those who allowed them to fall into that state. Simple incision might here save a life.

Dr. Boldt, of New York, agreed with Dr. Murphy in every detail.

Dr. Fenger, of Chicago, urged the conservative treatment, agreeing with Dr. Senn.

Dr. W. E. Ashton, of Philadelphia, agreed with Dr. Deaver, for no one could foretell the pathological changes which come so quickly in the appendix.

Dr. La Place, of Philadelphia, said that in every fatal case there had been a moment when operation was indicated. Either the physician or the surgeon was directly responsible for this death. He felt that we should have to turn to the physiological chemist, who might one day reach a method of determining conditions by an analysis of the relationship between the effects on the heart and temperature of the toxins of the different germs causing the disease, thus reaching an early diagnosis.

Dr. Ochsner, of Chicago, made special reference to the importance of maintaining absolute rest for the bowel until the omental and other adhesions had become firmly fixed. To this end he would forbid all food by mouth and all cathartics.

Dr. Porter said, in closing, that incision and drainage were sometimes absolutely necessary. He criticised Price's method of irrigation very keenly. He would also try to save the moribund cases.

Dr. Deaver said that if he looked tired he only showed what he felt. It was distressing in this advanced age to listen to those who opposed the radical view. He was glad and proud to be an extremist in so good a cause. He claimed but two points: (1) that the diagnosis could be made early; (2) that this once established, the appendix should come out.

Officers Elected.—The officers chosen at the close of the meeting were: *Chairman*, Dr. A. J. Ochsner, of Chicago; *Secretary*, Dr. Martin B. Tinker, of Philadelphia.

(To be concluded.)

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, May 28, 1900.

George B. Fowler, M.D., Chairman.

Dr. William E. Bullard resigned the secretaryship of the society on account of absence from the city. Dr. J. V. D. Young, the assistant secretary, was appointed to the position of secretary for the remainder of the year.

The Governor and his Staff: Being a Glance at the Personnel of a Modern Hospital, and a Plea for a Permanent Resident Staff.—Dr. Thomas J. Hillis read a paper with this title. He dwelt principally upon the incompetency of the internes, ridiculing the hospital governor and his staff, but he failed to offer any remedies for the alleged evils.

Infantile Amaurotic Family Idiocy.—Dr. John Claiborne read this paper. In 1881 Tay, of England, described a case of symmetrical changes in the macula lutea. The child held itself upright with difficulty. Intellectual development was very backward. At the first examination the optic disc was normal, but at the macula there was a white, more or less round, area in the centre of which was a brown spot. The picture was similar to that seen in embolism of the central artery of the retina. Tay at first thought it was a congenital change. Five months later he noticed the optic disc was atrophied. Three months later he observed three other cases in the same family. In all the ophthalmoscopic picture was the same, and all these persons died before the end of the second year of the disease. Between the years 1885 and 1886 the same ophthalmoscopic picture was described by Magnus, Knapp, and others. In 1887 Dr. Sachs reported a case which impressed him as being one of idiocy; this was particularly interesting on account of the changes observed in the cortical cells. The family character of the affection was suggested to him after observing four cases in two families. Kingden, of England, published a case and showed a picture which eye surgeons said belonged to the disease which Sachs had elucidated. In 1898 Sachs reviewed the subject, tabulating twenty-nine cases. The speaker's analysis was based on ten cases. Six cases observed tallied nearly with those of Sachs. At birth and for days and weeks after the children were apparently normal: at the age of nine months they ceased to take any interest in their surroundings. The eyes seemed to roll about; they could not hold up their heads; there were purposeless movements of the head and body; there was a great tendency to sleeplessness. The children either fell forward or slipped down on their backs when the parents attempted to make them sit in the lap. The children slid backward more often than forward. The appearance of the fingers suggested the notion of athetosis. He laid stress on the fact that somnolence was more marked than idiocy. In one case he observed distinct hydrocephalus. There was weakness of the extremities which seemed to increase slowly until diplegia appeared. The electric excitability of the nerves and muscles, as a rule, was normal, although Koplik reported the reaction to the faradic current to be slightly diminished. By the end of a year these children were totally blind; the optic nerve was dead and idiocy was pronounced; at the end of two years marasmus usually closed the scene. He did not agree with Sachs that the change in the macula was the most striking symptom; idiocy was the most striking. Yet the existence of the macular changes was necessary to establish the diagnosis. In January, 1898, Chamberlain referred to the case of D. D——, a female, aged eleven months, upon whom the diagnosis was made and treatment carried out for double ophthalmoplegia completa of the third nerve. The mother was healthy, but the father was tuberculous. There was no consanguinity. The child was carried to the ninth month and delivered normally. Nine months after birth the mother noticed that the left eye turned outward and the upper lid drooped. Three weeks later Dr. Chamberlain saw that the right eye turned outward and the lid drooped. Both pupils were moderately dilated. Both optic discs were normal. The child was given mercury by inunction, and the patient was brought again to the doctor a trifle less than four months after the first visit. After the use of the inunctions the lids elevated and the eyes became straighter. Then there developed great somnolency and nervous movements of the head and body. In each eye were marked areas, more or less round, in the centre of each macula lutea, showing as cherry-red points. The intelligence of the child diminished. Amaurotic idiocy was diagnosed and an unfavorable prognosis given. The doctor left the city for six months. On his return, May 5, 1899, the child died with symptoms that pointed to tumor of the brain. There was found a tuberculous tumor of the tubercula quadrigemina the size of a hickory-nut, and various organs were affected.

Dr. Pooly related a case of a child eight months of age. Soon after birth the eyes began to twitch and move constantly. Within three months, however, this improved. The intelligence was very backward. There was great restlessness. There was constant nystagmus. The pupils were contracted. There was a cherry-red spot in each eye. The optic disc was yellowish-white. Carter was the first to point out the fact that the victims of this disease were children of Hebrew origin. Sachs corroborated this view. It had been suggested that blood-relationship, trauma at child-birth, etc., might lie at the bottom of the affair. Sachs' and Tay's cases lent considerable color to this view. The speaker's own case showed very conclusively that the disease was associated with tuberculous tumor of the tubercula quadrigemina, with tuberculous deposits in the bronchial glands, the liver, the spleen, and the kidneys; in short, a general tuberculosis. Similar changes were found in the central nervous system. He failed to find grounds for the statement that syphilis might lie at the root of the trouble. So far as he was aware no one had suggested tuberculosis as a possible cause. Similarly hereditary spastic paralysis had been mentioned. The fundus picture tended to settle the diagnosis. He thought it was only just to regard the matter as yet *sub judice*. Many doubted that the marasmus of tuberculosis was a factor. Pathologically we were directed to the central nervous system. According to Sachs the external configuration of the brain exhibited a distinct picture of a lower order of development. He thought it was a question whether these changes were to be considered as primary degenerations or due to an arrest in development. In the speaker's opinion they were due to an arrest of development in the central nervous system, which invariably led to a fatal termination. The clinical features were rather clearly outlined, and he thought a name should be applied to the disease which indicated clinical features. The name "infantile cerebral degeneration" was not satisfactory. Sachs suggested the name "amaurotic family idiocy." In view of the blindness that follows, amaurotic was distinctive and correct. A better name he thought would be "infantile amaurotic family idiocy." The disease, in a large number of instances, occurred in more than one member of a family. Among twenty-seven of Sachs' cases seventeen occurred in families in which there had been other cases. Tay recorded three cases in the same family. The definition of the condition of idiocy should be one thing when applied to adults and another when applied to infants. Idiocy, when applied to adults, was a mental condition characterized by more or less complete abolition of intelligence and moral faculties. Among infants there must be some modification either in the direction of excess or in diminution of instinctive and physical reflexes. In 1895 Sachs tabulated twenty-eight cases. At the Vanderbilt Clinic seven cases were seen. Five of these the speaker had seen. The disease was not so rare as it was supposed to be. All cases brought to the Vanderbilt Clinic were Polish-Jew in origin. In studying this disease certain features had been grouped which were distinctive. Children at birth were apparently healthy and remained so for several months. Then the parents noticed that the children were sleepless and could not hold themselves erect on the lap; they fell forward or backward. Purposeless movements of the head, body, and legs were noted, which increased as the disease progressed. There was found in the macula of each eye a picture strongly resembling embolism of the central artery of the retina. Around the central artery there was a grayish-white area the edges of which were not sharply outlined; in the centre of each macula there was a cherry-red spot in blonds, but slightly different in color in brunettes. The disc was normal at first but later became atrophied. Nystagmus, hyperacusis, double third-nerve paralysis, etc., were concomitants. A fatal termination occurred before the end of the second year. The majority of cases occurred in children of Hebrew parentage, though a number did occur among those of Polish-Hebrew blood. A number of cases had been shown among members of the same family. The macroscopical and microscopical examination directed attention to the central nervous system. The brain seemed to be in an arrest of development. The microscopical examination showed changes in the pyramidal cells; changes were also found in the retina and in the spinal cord. It was reasonable to regard the alterations that occurred in the central nervous system as due to an arrest of development. The etiology of the disease was not established. From the findings in the case he reported, in which there was found a tuberculous tumor in the tubercula quadrigemina, tuberculosis might be considered a causal agent.

Dr. Henry Koplik said he had had experience with eight cases, and that very little had been added to the clinical picture that was described by Tay. These cases came under observation for blindness. He agreed that it was not the ocular symptoms but the other symptoms that were the most striking. The mother brought the child with the story that she noticed the baby was stupid and could not hold its head up, could not sit up; but the doctor noticed nothing. The clinician then had the child taken to the oculist. In one case the child cried incessantly, and the physician in charge thought the child had an ordinary colic. The mother called attention to the fact that the child did not notice anything; that he could not sit up, that he did not play. This was a case of amaurotic idiocy. On the other hand, cases that were well marked did not show changes in the macula lutea. Dr. Sachs called attention to those cases which seemed to develop very late. The speaker had seen three such cases. In regard to the tuberculous element, there were no marked cases of tuberculous meningitis in which the changes in the fundus resembled those seen in amaurotic idiocy; the fundus examination often confirmed the diagnosis of meningitis. He did not think tuberculosis was a causal element in these cases; it might be accidental complication.

Dr. William Hirsch said that two years ago he published the findings in an autopsy on one case in which he could prove that the disease was not confined to the cortical cells; but he could prove exclusively that the entire nervous system was affected in a somewhat typical manner. In 1898 specimens were obtained that showed that all the nerve cells of the spinal cord, in the anterior as well as the posterior horns, all the nerve cells of the pons, the medulla, the optic thalamus, the corpus striatum, and all the cells of the cortex had the same typical changes. The changes that took place in the cells were such that they were immensely enlarged; they were not only enlarged but showed very marked changes in the nasal bodies; the nucleus was invariably displaced, and in a great many cases it was pushed entirely out of the cell. This enormous increase and enlargement of all the nerve cells of the spinal cord gave an appearance as if there was an increase in the cells in vast numbers. In a great many instances these cells appeared as large white masses without any configuration at all, and often the nucleus belonging to one cell was found in other sections. The same changes described in the spinal cord and brain took place in the cells of the retina, and so gave the picture on the retina of a white rounded area with a red spot in the centre. Besides these changes there were absolutely no other alterations. The internal organs were found to be perfectly normal. The blood-vessels and other parts of the nervous system were also perfectly normal; so syphilis and tuberculosis and other diseases of this kind could be excluded. There was a theory that, in these instances, there was an intoxication of some kind; the reason for this theory was that there was an affection of all the nerve cells, and nothing else but nerve cells. The anatomical picture of the nerve cells resembled the picture which was to be seen in experimental poisoning. This was offered as a theory as yet to be substantiated. Children were never born, he said, with changes in the macula lutea. There was no one special part affected, but the entire nervous system was involved. We had to deal, not with an arrest of development, but with an acquired disease. He considered tuberculosis to be but an accidental complication.

The Effect of Summer Heat upon the Public Health.—Dr. Henry Dwight Chapin read this paper (see page 984).

Dr. Abraham Jacobi said there was one part of the subject that he wished to allude to, and one that he believed Dr. Chapin had meant to avoid. Certainly commercial enterprises should not be debarred; but, when commercial enterprise went so far as to endanger public health and destroy lives, then it was a danger to the community and should be interfered with. When commercial enterprise killed thousands of children and adults, it should not be considered legitimate, and should be interfered with. Here the doctors should be politicians, they should be statesmen, or else they could not be good citizens. It was true that our professional duties prevented us from taking part in the primaries, but doctors should raise their voices in protest when any obstacle is placed in the way of pure milk and plenty of ice reaching the poor of this great city.

THE NEW YORK PATHOLOGICAL SOCIETY.

Special Meeting, March 29, 1900.

Eugene Hodenpyl, M.D., President.

A Case of Epithelioma of the Œsophagus with Stenosis of the Trachea and Suffocation.—Dr. J. H. Larkin presented specimens removed from a man, sixty-three years of age, who had always been in excellent health up to five days before operation. At that time he had experienced a slight dyspnœa at first, and this had increased rapidly until at the time of his admission he was deeply cyanosed. Tracheotomy had been done immediately. On opening the trachea and endeavoring to pass in a tube, some difficulty had been encountered. A small tube had been passed without giving him much relief. On the following day the tube had caused so much distress that it had had to be removed. The man only lived forty-eight hours after the tracheotomy. At the autopsy all of the abdominal viscera had been found normal, and the lungs also with the exception of a slight œdema. About three inches above the cardiac end of the œsophagus was a small, slightly raised area which, on microscopical examination, showed epithelioma. High up in the trachea, and about one inch below the tracheotomy wound, and about one inch and a half above the bifurcation of the bronchi, was a marked stenosis of the trachea. The cause of this was a tracheal lymph node which had enlarged and grown through the tracheal rings and had occluded the trachea at that point. Microscopical examination had shown this to be a metastatic epithelioma of the lymph node. On account of the pressure on, and erosion of, the tracheal rings a secondary suppurative process had taken place in the lymph node. Death had resulted from slow asphyxia and œdema of the lungs.

Osteocarcinoma of the Breast.—Dr. Larkin also presented a tumor which had been removed from a woman of middle age by Dr. Kammerer. Five months ago she had first noticed a slight enlargement of the breast. At the time of the operation the growth was supposed to be carcinoma, but after its removal it was found exceedingly difficult to cut into the tumor. Further examination showed the tumor to be a well-circumscribed growth, and to have a limiting wall. At the periphery it was somewhat spongy, but toward the centre was a large and somewhat grayish elastic area which was undoubtedly cartilage. In the centre were nodules made up of true bone. Microscopical examination showed at the periphery a typical picture of carcinoma, but the carcinomatous element diminished as one proceeded toward the centre. In the latter location were bone and cartilage. A search through the literature showed that few tumors of this kind had been reported. The speaker said that cases of calcification of tumors of the breast had been reported in Virchow's *Archiv* for 18[illegible]7. Osteosarcomata of the breast had also been described, but very few osteocarcinomata had been reported. Coën, of Boulogne, had reported a case almost identical with the one just described. In that case the woman was forty-five years of age, and the clinical history had presented nothing unusual. A case of osteochondrocarcinoma had been reported by Hacke. Lesser had also reported a similar case, as had Leon, of Paris. Astley Cooper, in his book on "Diseases of the Breast," also reported such a case, but there was some doubt about the correctness of the diagnosis. Dr. Larkin raised the question as to whether this tumor had been at first an osteochondroma, or a combined growth of carcinoma with a secondary metaplasia of the stroma into osteoid tissue. As in the periphery metaplastic changes could be seen in the alveoli, it seemed to him reasonable to look upon this tumor as having been first a carcinoma, and that secondarily there had been a metaplasia of the fibrous tissue, resulting first in cartilage, and ultimately in bone.

Dr. Lartigau said that pathologists had hesitated to accept the belief that true osteoid tumors of the breast existed primarily as such. The tendency was to regard these neoformations as ossifying enchondromata. A study of the literature showed that enchondromata were very common in the mammæ of bitches.

A Case of Actinomycosis.—Dr. F. S. Mandlebaum exhibited under the microscope a section from a case of actinomycosis removed from a woman of thirty-four years, a Russian, who had been admitted to hospital on January 25, 1900, with a history dating back five months, and beginning with the development of two localized points of tenderness on the back to the right of the spine. Three months after the onset of pain, small swellings without redness had appeared at these points. Three weeks later, or five weeks before admission, these had been excised, and in one week a swelling had appeared in the right axilla and above the clavicle on the same side. On admission, these tumors had been the size of a small apple, and tender and painful, but the skin had not apparently been involved. Near the right scapula was a discharging sinus, and two inches below this another sinus. The entire supraclavicular triangle was occupied by a mass, in places fluctuating. Physical examination of the chest showed anteriorly dulness over the first right interspace, with exaggerated breathing, and posteriorly marked dulness and tenderness on percussion from the apex downward to the spine of the scapula. Over this vocal fremitus was increased. The woman was emaciated and was six months pregnant. One week after admission abscesses in the neck and axilla had been incised, and a large quantity of pus, streaked with blood and containing numerous small, yellowish particles, had been evacuated. She had received iodide of potassium internally, and had improved considerably while in the hospital. Dr. Mandlebaum said that he had taken small drops of the pus and fixed them in five-per-cent. formalin solution. The small pieces were then hardened in alcohol, embedded in celloidin, and sections made. The microscope showed these small particles to be actinomyces. He had stained them with many different stains, and had found that the best results were obtained with Plant's stain. This consists in staining the section for ten to fifteen minutes in a solution of carbol-fuchsin; then washing in water; transferring to a saturated alcoholic solution of picric acid for five minutes; decolorizing in fifty-per-cent. alcohol for fifteen minutes, and finally passing through absolute alcohol, oil of cloves, and into balsam. With the Gram method in only one instance had he been able to demonstrate the clubbing, although this was brought out well by following with eosin. The teeth and mouth were normal, and the primary focus was supposed to have been somewhere in the chest.

Hæmatoma of the Right Suprarenal and Rupture into the Peritoneum in a Child of Ten Days, with a Patent Foramen Ovale, Patulous Ductus Arteriosus, and Stenosis Isthmi Aortæ.—Dr. Charles Norris reported this case. The child had been brought to Bellevue Hospital with no further history than that it had been blue since birth. It had died very suddenly a few minutes after entering the hospital. On autopsy, the abdominal cavity had been found filled with blood, and the intestines all matted together by fairly firm adhesions. On the superior surface of the suprarenal, represented by a more or less organized blood-clot of a considerable size, was an opening two inches in diameter, through which the blood had escaped into the abdominal cavity. On examining the foramen ovale it had been found nearly closed. The ductus arteriosus as it entered the aorta presented a funnel-shaped opening. The speaker said that hæmatomata of the suprarenal were rarely as large as the one just presented. This was the second case of the kind that he had met with. He had been able to find only one or two instances reported in the literature in which rupture had taken place into the peritoneal cavity. One observer had reported twenty-six cases in which there had been small hemorrhages into the suprarenal in a series of over one hundred autopsies on still-born infants. In two of the cases the hemorrhage had started in the cortex. The blood more commonly escaped into the perinephritic tissues. It was more often met with after pelvic than podalic presentations, and after difficult labor.

Dr. Larkin said that having had an opportunity of examining a number of still-born children he had met with four or five such hæmatomata. His experience confirmed what had been said about their being more frequent after difficult labors, and with pelvic presentations. He had never before seen one rupture into the peritoneum, but had seen the blood escape behind the peritoneum, and had dissected out the latter down as far as the bladder.

Dr. E. Hodenpyl presented several specimens, as follows:

A Portion of the Œsophagus Showing Varicose Dilatation of the Veins.—This specimen had been taken from a man who was suffering from cirrhosis of the liver, and who died of a profuse gastro-intestinal hemorrhage. The œsophagus in the fresh state showed a number of very large and tortuous veins in the lower portion, at least one of which was ruptured. Preble, of Chicago, had found that in about eighty cases of fatal hemorrhage occurring in the course of cirrhosis of the liver, the bleeding arose from the varicose veins in the lower two-thirds of the œsophagus. This accident occurred in atrophic cirrhosis rather than when the liver was of normal size or enlarged. Attention was called to the fact that the venous circulation of the œsophagus was part of the systemic circulation, while that of the cardiac end of the stomach belonged to the portal system, and that there was a poor collateral circulation between the two. There might also be a negative pressure on the œsophageal veins during expiration.

Pneumothorax.—The next specimen had been taken from the gripman of a car who had been suddenly seized with severe pain in the right chest while at his work. He had been hurriedly removed to a hospital, and examination had revealed the presence of air in the right pleural cavity. He had died in a few hours. In spite of the man's excellent physique the autopsy showed quite advanced tuberculosis of both lungs, and the kidneys were studded with miliary tubercles. There was also a moderate tuberculous enteritis. The liver was found forced almost entirely below the free border of the ribs, and the diaphragm bulged downward. On puncture of the diaphragm below a water level, a considerable quantity of air escaped. The right lung was forced into the bottom of the pleural cavity against the vertebral column. This lung was entirely free from adhesions, although the pleura over the posterior portion of the apex was markedly thickened. The opening was so minute as to be discoverable only after forcing air through the bronchi.

A Tuberculous Appendix.—The third specimen had been taken from a man who had died of pulmonary tuberculosis with quite marked tuberculosis of the intestine. The latter was very markedly dilated, and it was so dark as to suggest gangrene. There were two constrictions in it. The miliary tubercles could be distinctly seen through the serosa. In tuberculosis of the appendix, as well as in typhoid ulceration of the appendix, the speaker said, it was worthy of note that the usual symptoms of appendicitis were not present.

Primary Carcinoma of the Pancreas with Secondary Carcinomatous Nodules in the Liver.—The specimens from this case had been taken from a person who had suffered but slightly, and had been ill only a few weeks. He was an alcoholic subject who had presented but few symptoms, but had died shortly after entering the hospital. At the autopsy immense deposits of fat were found throughout the body. Occupying the head of the pancreas was a large carcinomatous mass. The liver was studded with carcinomatous nodules. Examination of the heart showed dilatation of the right side of this organ and incompetence of the tricuspid valve.

Two Cases of Multiple Spurious Diverticula of the Intestine.—The specimens from two cases of this kind were exhibited. In the first, the duodenum and upper portion of the jejunum was the seat of a number of thin-walled cysts varying in size from that of a pea to that of an egg. The second specimen was from a case of papilloma of the peritoneal cavity. There were strictured areas in various parts of the colon, and seventy-nine diverticula were found in the intestine, principally in the lower end of the colon. Roth, in 1872, had described five cases of diverticula of the duodenum, in all of which the diverticula had been small and not over three in number. In 1894, an article on this subject had been published in Virchow's *Archiv* by Edel. Here the cases had been divided into two classes—congenital and acquired. Meckel's diverticulum alone constituted the first class. All three coats were present in the congenital form, whereas the muscular coat was missing in the acquired variety. The most common situation for these false diverticula was in the colon; next in order of frequency, and usually along the attached border, came the duodenum. The number of these diverticula varied from one up to two hundred or more. As a rule, they were small. The cause of the condition seemed to be a separation of the fibres of the muscular coat, so that, in one sense, they might be regarded as herniæ of the mucous membrane into the serosa. The pressure of scybalous masses, the presence of gall stones, circumscribed or diffuse peritonitis, constipation, and carcinoma were all causes. It had been noted that these diverticula were almost always found empty at autopsy.

Hypertrophic Tuberculosis of the Intestine.—Dr. A. J. Lartigau read a paper on this subject. He said that very few cases of hypertrophic tuberculosis had been studied outside of the ileo-cæcal region. In 1888 Hacker had reported a tuberculosis of the ileo-cæcal region simulating a tumor mass, and leading to operation. The new formation proved to be tuberculous. In 1893, twenty-one cases had been collected. In almost all of these cases the clinical diagnosis had been carcinoma. The amount of reduction of the intestinal lumen was quite variable, and was not in proportion to the increase in the size of the intestinal wall. The author then reported a case of this affection. According to the clinical history there had been brown pigmentation of the skin without vomiting, and slightly failing health. The bronzing was most marked on the exposed surfaces. The left adrenal gland was enlarged and soft, and contained a small cavity filled with brownish fluid. The right adrenal gland was also enlarged, and showed a diffuse tuberculous lesion. The retroperitoneal and mesenteric glands were enlarged and caseous. The mucous membrane of the duodenum and jejunum was normal, while that of the ileum showed thickening, increasing from above downward. In the lower two or three feet of the ileum the lumen was reduced to about one-third. The cæcum was thickened, and its walls measured 1.5 cm. The thickening in the colon was noticeable, but diminished until it became normal at the sigmoid. Tubercle bacilli were found in great numbers throughout the intestinal wall. Small round-cell infiltration was present in the submucosa. This case was undoubtedly one of primary tuberculosis of the intestine in an adult.

Stated Meeting, April 11, 1900.

EUGENE HODENPYL, M.D., PRESIDENT.

A Pronounced Case of Arterio-Sclerosis.—DR. D. H. MCALPIN, JR., presented specimens from a patient who had been admitted to hospital on March 19th suffering from dyspnœa and pain in the epigastrium. He was fifty-four years of age, and had been a sailor until a short time ago, when he had been compelled to give up this occupation because of shortness of breath. His past history was not a good one, having had syphilis and gonorrhœa, and having been accustomed to indulge in alcoholics to excess. Ten years previously he had fallen from a height and had fractured his clavicle. The present illness had begun with pain in the stomach and continued vomiting, shortness of breath, and some cough. Shortly after admission he had become delirious and had remained so until death. A few hours before death there had been complete suppression of urine. His temperature had ranged between 100° and 102° F.; the pulse had been 80, and the respirations between 28 and 40. There had been signs of consolidation of the lungs, and the apex of the heart was at the sixth interspace, to the left of the nipple line. There was a murmur heard indicating aortic insufficiency. The diagnosis had been chronic endocarditis and nephritis, pneumonia or possibly infarctions of the lungs, and arterio-sclerosis. At the autopsy, on opening the chest the heart had been found greatly enlarged. It weighed nearly fifty ounces. All of its cavities were greatly distended, and contained large, dark clots, and the coronary vessels stood out very prominently but were not tortuous. On opening the heart, several thrombi were found at the apex of the left ventricle, and a number of thrombi were attached behind the columnæ carnæ. The mitral orifice admitted four fingers, yet the valve curtains were greatly enlarged and appeared to be perfectly competent. The aortic orifice was very large, and the curtains of the valve were also very large and free. There was calcification of the aorta beyond the aortic valve, but no visible disease of the curtains. The walls were considerable hypertrophied, and the cavities greatly dilated. On the right side there appeared to be no disease of the valves. The foramen ovale was patent. The liver was about normal in size, and on section it showed a distinctly nutmeg character. There was an immense amount of passive congestion in the central zone of the lobule. The small hepatic arteries and hepatic veins were very thick and easily seen. The kidneys were of the characteristic stony hardness of the cardiac kidney. The small arteries were very prominent. The lungs exhibited areas which were firm, more or less granular, and of a gray color. The vessel walls were greatly thickened. The same uniform thickening of the vessels was observed in the brain.

A Case of Perforation of the Stomach by a Toothpick.—Dr. McAlpin also presented the case of a man, aged fifty years, a chronic alcoholic. Four months before admission he had been hit in the epigastrium with a base-ball. Two months later his abdomen had begun to swell, and he had then begun to lose flesh very perceptibly. His temperature on admission had been 100° F., but had quickly fallen to normal. The abdomen had been found distended with fluid; the heart was normal; the lungs were the seat of emphysema. On February 15th he had been so much better that he had left the hospital for the day, and had not returned until March 10th. At that time he had been jaundiced and feverish, and his urine showed hyaline and granular casts. He had died on March 14th, three hours after one gallon of dark, foul-smelling fluid had been removed from his abdomen. This fluid contained a variety of germs and leucocytes. At the autopsy, the intestines had been found greatly distended and heavily coated with fibrin, and the omentum hemorrhagic and drawn over the liver. The starting-point of the peritonitis had been traced to a point underneath the liver. On separating the adhesions here, a cavity one and a half inches in diameter had been laid open. This cavity was formed by the stomach and the liver. It contained dark greenish, viscid pus. In this cavity, sticking into the stomach, was a piece of a wooden toothpick, one inch in length. The opening through which the wooden spicula had entered the peritoneal cavity could not be found, evidently having closed by muscular contraction as soon as the wood had passed.

A Specimen of Uterine Mole.—DR. F. R. BAILEY presented this specimen, which had been removed from a colored woman, about fifty-five years of age. She had been married about five years, and had had no children and no miscarriages. Her last menstruation had been on July 17, 1899. On November 29th she had had a severe hemorrhage, and on February 1, 1900, she had had what she called a miscarriage, *i.e.*, a discharge of a fœtus of five or six weeks embedded in a mass of tissue, for the most part placental.

The Duration of Life of Typhoid Bacilli in Ice.—DR. W. H. PARK said that he had been making some experiments on the duration of life of typhoid bacilli in ice. He had been led to do this because of some statements made recently by Dr. Sedgwick as to the rapidity with which death occurred. He had experimented with twenty cultures. They had been made from twenty-four-hour agar cultures, one loop of each culture being put in a separate lot of 300 c.c. of filtered Croton water. The average number of bacilli in the water of the twenty lots was 2,500,000 in 1 c.c. At the end of three days' freezing the average number was 1,089,000; at the end of one week, 361,000; at the end of two weeks, 203,000; at the end of three weeks, 10,000; at the end of four weeks, 4,000; at the end of five weeks, 3,000; at the end of seven weeks, 2,000; at the end of nine weeks, 127. Three of the cultures had become sterile at this time. In general, then, it might be said that at the end of nine weeks the ice from a certain proportion of the cultures was sterile and the living bacilli from all the cultures were greatly reduced in number.

DR. T. M. PRUDDEN asked if any cultures older than twenty-four hours had been tested. He asked this because he thought it not improbable that at this age the bacilli were more vulnerable than older ones.

DR. PARK replied that the cultures differed greatly as to the lapse of time since they were obtained from the case. Of some interest was the fact that in thirty specimens of ice taken at random neither colon nor typhoid bacilli had been found, though the ice was the ordinary ice found in the market.

DR. A. J. LARTIGAU said that last year he had had occasion to investigate the ice supply of the city of Albany. From one specimen he had obtained an organism which responded to all of the culture tests for the typhoid bacillus. Unfortunately this specimen had been destroyed before it could be tested with typhoid serum. There was every reason to believe that this ice was over three months old. He had tested pure cultures of typhoid bacilli at various temperatures. At the end of twenty-four hours nearly fifty per cent. had been destroyed—in some specimens a still higher percentage were killed—and at the end of ten to eighteen days practically all had been destroyed (ninety-seven to ninety-eight per cent.). The water used was the Hudson River water. He had also tested the viability of the bacilli in water just above the freezing-point, and had found this temperature about as effective as when the water had been frozen. Alternate freezing and thawing had been somewhat more destructive to the life of the bacilli.

A Peculiar Streptococcus.—Dr. E. Libman presented a streptococcus which had been isolated from the stools of a child suffering acute entero-colitis. The stools had been placed in sugar bouillon for twenty-four hours, and this had yielded a pure culture of this organism. This streptococcus was peculiar especially in one respect. In its growth on lactose agar and glucose agar it made the medium white, which it did not do in its growth on the other preparations of agar. The peculiar action was found to be due to a precipitation of the albumin in the medium by the acid formed by the splitting up of the sugar. The organism was pathogenic for mice.

Sarcoma of the Small Intestine with Special Reference to Cases Resembling Appendicitis.—Dr. E. Libman said that he had seen four cases of intestinal sarcoma, notwithstanding the comparative rarity of the disease. Compared to carcinoma of the intestine sarcoma was uncommon. Sarcomata had their seat by preference in the small intestine. They might occur at any age, cases having been recorded from the age of five days up to seventy years. In a series of thirty-four cases he had found twenty-one males and thirteen females. These sarcomata might be single or multiple, and might be localized or diffused. The lymphosarcomata were the most common. In most cases the growth was confined to the mucosa and muscularis. The latter was early infiltrated and paralyzed, and the intestine was then dilated by the fæces. Spindle-celled sarcomata had very few metastases. In intestinal sarcomata the superficial nodes were not usually involved. The growth showed a marked tendency to extension to the pelvis, or to the formation of metastases there. Ulceration was very common, and might result in perforation, or in exposure of the vessels. The vena cava, bile ducts, pancreatic ducts, or the ureters might be obstructed by the growth. An important point was the frequency of the association of lymphosarcoma with tuberculosis. If the sarcoma was in the small intestine, there was very early a marked affection of the whole system, with but few local symptoms. At first, there were pain in the abdomen, loss of appetite, nausea, and vomiting, and the abdomen was distended. A tumor was found in most of the cases. The duration of the disease was from a few weeks to one year and a quarter, though most patients succumbed in nine months. The first case was that of a boy who had had pain in the abdomen to the right of and below the umbilicus. In a few days the abdomen had become distended; then the pain had increased and the constipation had been obstinate. The operation had been done on October 1st by the late Dr. Van Arsdale. It had revealed a large growth in the duodenum, encircling the gut and projecting into its lumen, and there were nodules in the mesentery, omentum, spleen, pancreas, and liver. The tumor was a lymphosarcoma beginning in the submucosa. The case had been sent to the hospital as one of appendicitis. The second case was that of a boy three and a half years old, and the symptoms were of eight days' standing. On the right side of the abdomen was an irregular-shaped mass. On January 5th an operation had been done by Dr. Gerster. This had shown a thickening of the peritoneum and omentum, and the intestine was infiltrated with new growth. The patient died in twenty-four hours. The autopsy showed the main tumor mass to be situated in the beginning of the ileum. Mesentery, omentum, intra-abdominal lymphatics, spleen, gall bladder, pancreas, and bronchial lymph nodes were also infiltrated. The left adrenal was almost replaced by a new growth. The microscope showed it to be a lymphosarcoma. The third case was that of a boy aged eighteen years, and the illness had begun with an attack of pain and vomiting. The pulse was rapid, small, and weak; the abdomen hard and tympanitic. It was thought to be a case of perforation of the appendix. The patient was almost moribund, so an infusion was given, but he died shortly afterward. Near the duodenum was found a perforation the result of an infiltration by a new growth. The latter was white and soft on section. Microscopical examination showed the growth to be lymphosarcoma. The fourth case was that of a man forty-two years of age, who came with a history of two weeks of irregular abdominal pain. Four days before admission there had been violent and diffuse abdominal pain. There was an irregular, hard, and sensitive tumor in the hypogastric region, especially on the right side. The operation was done by Dr. Brewer, and revealed a very large hemorrhagic tumor springing from the ileum about 70 cm. from the valve. The patient died three days later from acute peritonitis. The tumor measured 15 by 13 cm. It had begun in the submucosa and reached to the mucosa. Microscopical examination showed the growth to be a spindle-cell sarcoma. This clinically resembled a subacute appendicitis.

Dr. Harlow Brooks said that he had seen only one case of this kind, occurring in a stoker on an ocean steamer. He had felt slightly ill on reaching port, and had gone to St. Vincent's Hospital, where he died three days later. The autopsy had shown a very extensive involvement of the small intestine, and some involvement of the liver.

Notes on Acid Intoxications.—Drs. C. A. Herter and A. J. Wakeman presented a paper on this subject, which was read by Dr. Herter.

Treatment of Epilepsy in its Incipiency.—W. P. Spratling concludes as follows: (1) Make an early differentiation of the type of epilepsy from which the patient is suffering. (2) If it be reflex epilepsy, or if the child be suffering from epileptic phenomena, the chances of cure are much greater than if the case be one of genuine epilepsy. (3) If genuine epilepsy be present we are in a position to give a much more accurate prognosis as to the ultimate outcome and to apply better principles in the treatment of the case. (4) Remove as far as possible parental sympathy from the treatment of the child, for if allowed to assert its way this usually does more harm to the child than good. (5) Endeavor to keep from the young epileptic the many patent nostrums that, when taken by him, only aggravate the disease by first masking the true symptoms of the same; second, by destroying or impairing the functions of the gastro-intestinal tract. (6) If the seizures are localized and a given part of the body is chiefly involved at the time of convulsive phenomena, and suffers therefore exhaustion or partial paralysis as the result of same, apply physical means for its correction as soon as possible, for it will only be by these means that such a difficulty can be overcome. (7) We must learn to place great value on little things in studying the etiology and treatment of this obstinate malady, as, for instance, the occurrence of capillary hemorrhages in the brain.—*Buffalo Medical Journal*, June, 1900.

MEDICAL RECORD:
A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM WOOD & CO., 51 Fifth Avenue.

New York, June 9, 1900.

THE SIGNIFICANCE OF THE DIAZO REACTION IN CASES OF TUBERCULOSIS.

ALTHOUGH the property of diazo bodies to yield striking color reactions with organic substances had been noted previously, Ehrlich was the first, nearly twenty years ago, to apply this principle practically in clinical diagnosis. It was found that this diazo reaction was yielded by the urine only in disease and not in health, and then only in connection with certain diseases and under certain conditions. It is rarely present in cases of chronic visceral disease, but it is with especial frequency a concomitant of typhoid fever and of measles. It does not occur, as a rule, in cases of uncomplicated diphtheria and pneumonia, and its presence under such conditions is rather of grave prognostic omen. The reaction has been found to be of considerable diagnostic significance in cases of tuberculosis, and in cases of pulmonary tuberculosis it is of grave prognostic significance. It is not dependent upon fever, as it has been marked in cases without fever.

The reaction consists in the development of a rose or a red color when urine and the test agent are shaken together. Two test solutions are prepared and should always be fresh, one consisting of 0.5-per-cent. solution of sulphanilic acid in a five-per-cent. solution of hydrochloric acid, and the other of a 0.5-per-cent. solution of sodium nitrite. When used, one part of the latter is added to forty-nine parts of the former. To equal parts of urine and this mixture is added ammonia in the proportion of 1 to 10, and the whole is agitated.

Michaelis (*Berliner klinische Wochenschrift*, 1900, No. 13), who has devoted special attention to the test for the past five years at the clinic of Professor Leyden in Berlin, speaks most highly of its diagnostic and prognostic utility, particularly in cases of tuberculosis. The occurrence of the reaction is independent of fever, of the number of tubercle bacilli present in and the amount of the sputum, but often a parallelism is observed among all of these. The reaction cannot be obtained, as a rule, in mild cases, although it does appear when acute complicating infections supervene that do not themselves give rise to the reaction, such as pleurisy, pneumonia, and influenza. When the reaction is marked in cases of incipient tuberculosis, the disease must be considered serious and the prognosis grave. On the other hand, in advanced cases even with cavities, when the reaction is absent the course of the disease appears to be stationary or slow. The reaction may disappear after it has been pronounced and the condition of the patient has improved, but usually subsequent aggravation takes place. The administration of preparations containing tannic acid or gallic acid interferes with the development of the reaction, but without influencing the prognosis. Among 167 cases of pulmonary tuberculosis in which the diazo reaction was studied it was found present in 111 patients and absent in 56. Of the latter 5 patients were discharged cured, 43 improved, 5 not cured, and 3 died; while of the former none was cured, 15 improved, 3 were transferred, 13 were not cured, and 80 died.

THE PUBLIC-HOLIDAY QUESTION.

EVERY worker, be it with brain or hand, requires occasionally a change. Indeed a break in the monotony of every-day existence and a cessation, however brief, from toil and worry are absolutely essential to the health of those who live under the high-pressure conditions of this twentieth-century age. Time was when civilized life was not so strenuous as now, and when, in the opinion of many, the manner in which men passed through their earthly pilgrimage was more in accordance with the laws of nature and the rules of common sense. But even in the far-back days the necessity of a periodical term of intermission from labor was clearly recognized, and thus it came about that—putting aside the religious aspect of the question—the Mosaic law appointed for the Jews one day of rest in seven. The strain placed upon the mental and physical resources by the exigencies of our present-time mode of living have rendered more frequent and more lengthened intervals of relaxation indispensable.

These remarks apply with especial force to brain workers, and if such a course be not pursued a complete collapse of the vital powers must be the inevitable result. However, it is not only those who use their brains to an excessive degree who stand in need of recreation from time to time, but also those unfortunates who are cooped within the four walls of a factory or store, or condemned to sit upon an office stool ten hours in the day throughout the week, and who in too many instances earn scarcely enough to keep themselves and family from the grip of want. These are the people who are really deserving of the most sympathy and for whose benefit public holidays were mainly instituted. The presumable object, then, of a holiday is to recuperate exhausted energies and to relieve the sameness of ordinary daily life, and the outcome anticipated is that it will fit a person better to fulfil his duties. In fact a holiday may be rightly designated as a requisite safety valve.

In the case of public holidays there is a serious doubt if this result is often attained. Rather than being utilized as a means of gaining health they are, it is to be feared, more frequently made the excuse for indulging in disgraceful orgies, with the consequence that instead of being invigorated by his outing the worker returns to his appointed task with aching head and impaired digestion, a sadder if not a wiser man. Of course among the young of this class released from grinding toil on such rare occasions some exuberance may be forgiven, but when this superfluity of animal spirits is caused by an over-indulgence in strong drinks and takes the forms of obscenity and of objectionable horseplay, the questions may be fairly asked whether public holidays are an undeniable good or whether they are as beneficial as their founders expected to that grade of workers for whose especial behalf they were instituted. It must not be supposed that in saying this there is any intention to rail against public holidays; it is only against their abuse that a protest is made. With the advance of education, with a wider knowledge of sanitary laws, and above all with the creation of better homes, will come a more intelligent understanding of the advantages to be derived from spending the public holidays in a rational and healthful manner.

DECISION IN THE CASE OF WARD *VS.* ST. VINCENT'S HOSPITAL.

On May 12th ult., in the supreme court, before Justice Gildersleeve, the suit of Ward *vs.* St. Vincent's Hospital resulted in a verdict for the plaintiff with damages of $10,000. This case has been noticed editorially in the Medical Record (August 12, 1899, and again on December 23, 1899), but as the matter is one of the very greatest interest to the medical profession, and as by the verdict a precedent has been established, it may be as well to run over briefly the leading facts. In February, 1894, Miss Ward entered St. Vincent's Hospital as a pay patient in order to have an operation performed. The sister in charge, at Miss Ward's request, agreed to provide a skilled nurse at $3 a day, which charge was additional to that asked for the room. While she was still under the influence of ether an unsheathed hot-water bottle was applied to Miss Ward's leg, injuring that member to such an extent that she has been more or less lame since. After this accident had occurred the discovery was made that the person who laid on the bottle was not a trained nurse, but a pupil in the defendant's training-school.

An action was brought against the hospital for large damages. In the first trial Justice Cohen decided that a hospital was not liable for damages sustained through negligence of its servants. The appellate division of the supreme court reversed this decision, taking the common-sense view that if a charity hospital takes in paying patients, furnishing them with private rooms and nurses, it enters into an express contract, and for any breach of that contract the sufferer thereby is entitled to the same damages as though the action had been for negligence pure and simple, and is entitled to an adequate compensation for injuries. The person furnished as a nurse in Miss Ward's case not being trained, it was for the jury to say whether in furnishing a careless pupil of limited experience the defendant fulfilled its contract obligation to the plaintiff, and if it did not, and injury resulted from the breach of contract, to award the adequate compensation for such injury.

In the following trial before Judge Leventritt, the jury failed to agree, one man standing out for the hospital upon the grounds that there had been no contract made, but, as before stated, the supreme court on May 12th decided for the plaintiff with damages. This ruling appears to be a perfectly sound one. The mere fact of accepting money for services rendered implies in itself that a contract has been entered into, carrying with it pecuniary obligations for a breach thereof. If the hospital had been purely and solely a charitable institution no suit could have been brought against it, for the simple reason that, only a moral obligation being involved, and money not entering into the question, it would be impossible to make a contract incurring pecuniary responsibility. While sympathizing with St. Vincent's Hospital for the loss it has sustained, we cannot but think it is well that the matter of liability of pay hospitals should be established.

News of the Week.

Yellow Fever in Manila?—The *Boston Medical and Surgical Journal* states that there have been only three months in the past ten years in which there were no deaths from yellow fever in Manila. Our esteemed contemporary has been misinformed, for whatever drawbacks there may be to a residence in Manila, the prevalence of yellow fever is certainly not one of them.

The Pan-American Medical Congress.—The international executive commission of the Pan-American Medical Congress announces that the third meeting of that body will be held in Havana, Cuba, on the 26th, 27th, 28th, and 29th of December, 1900. The original intention was to hold the congress at Caracas, Venezuela, in December, 1899, but on account of the disturbed political conditions in that country the medical profession there first advised that the meeting be postponed to December of this year, and now have requested that some other country be selected. Owing to the lack of adequate hotel accommodation in Havana, it has been suggested that an entire hotel be reserved for the foreign visitors, especially those from this country and Canada, of whom it is believed many will be in attendance. The second congress of Cuban physicians, which was to have been held this year, will probably be postponed to some time in 1902.

Inspection of the City Hospitals.—The grand jury on May 23d made a tour of inspection of Bellevue Hospital, the Morgue, the City Hospital, the New York City Training-School for Nurses, the County Penitentiary, the Workhouse, the Almshouse, and the other public institutions on Blackwell's and Randall's islands. "Without a single exception," the report says, "the various buildings, outhouses, and offices connected with all these institutions were found to be in an exceedingly good condition. In the hospitals, the patients appeared to be well cared for, and the sanitary conditions of the hospitals were as nearly perfect as modern appliances could make them." The grand jurors also visited the Harlem Hospital and Dispensary, and found less to praise there. They report that the dispensary is absolutely unfitted for the use to which it is put, and that the hospital accommodations are inadequate to the great demands made upon them. In concluding their report, the grand jurors "congratulate the people of the city of New York upon the admirable way in which the interests and welfare of the poor and unfortunate of this great city are protected."

The Associated Physicians of Long Island.—The spring meeting of the "Associated Physicians of Long Island" will be held June 16th at Northport, L. I. The association will be the guests at dinner of the Northport Yacht Club and the village of Northport.

Omega Upsilon Phi.—The annual banquet of the Epsilon chapter, at the University and Bellevue Hospital Medical College, of the Omega Upsilon Phi Medical Fraternity, was held May 28th at the Hotel Marlborough.

The Maine Medical Association.—The forty-eighth annual meeting of this association will be held at Portland, Me., on Wednesday, Thursday, and Friday, June 13th, 14th, and 15th, under the presidency of Dr. B. T. Sanborn, of Augusta. The annual oration will be delivered by Dr. J. Collins Warren, of Boston, the subject being "The Etiology of Cancer."

The Medical Club of Philadelphia gives a reception at the Hotel Bellevue on Saturday evening, June 9th, in honor of Drs. Abraham Jacobi, of New York, Alonzo Garcelon, of Maine, George H. Simmons, editor of the *Journal of the American Medical Association*, James Morrison Bodine, of Louisville, Frank Billings, of Chicago, and the president-elect of the American Medical Association.

The American Academy of Medicine.—At the annual meeting of this society, held at Atlantic City on June 2d and 4th, the following officers were elected to serve for the ensuing year: *President*, Dr. Samuel D. Risley, of Philadelphia; *Vice-Presidents*, Drs. C. M. McCulver, of Albany, N. Y., Rosa Engell, of Chicago, Ill., G. G. Graff, of San Juan, Porto Rico, Charles T. McClintock, of Detroit, Mich.; *Secretary and Treasurer*, Dr. Charles McIntyre, of Easton, Pa.; *Assistant Secretary*, Dr. Alexander R. Craig, of Columbia, Pa.

A Chicago Diploma Mill, known variously as the Metropolitan Medical College, the Independent Medical College, and the National Law School, was raided on Monday by agents of the Post-Office Department, and four of the "professors" were arrested. The charge was that of using the mails to defraud. The diplomas of medicine or law were sold at prices varying from $3 to $200, according to the amount that could be squeezed out of the candidate in each individual case. The mill was grinding out "physicians" at the rate of ten or twelve a day. The diplomas contained an array of names of the learned men who constituted the faculty, but all the signatures were made by two young women who were employed for their ability to vary their handwriting to fit each name.

The Electrocution of Germs.—It is reported that a Viennese dentist has discovered a means of killing bacteria in a human body by a current of electricity so weak as to be barely perceptible.

An Ambulance Makes Patients.—An ambulance racing at high speed, early one evening last week, ran into a crowd of people who did not hear the gong, and knocked a number of them down. Two were so severely injured as to require the attention of the surgeon of the ambulance that ran over them.

Attack on a Dispensary.—A mob recently attacked a Chicago dispensary and nearly demolished the building before the rioters were dispersed by the police. The disturbance was caused by a story being circulated to the effect that the physicians had carried a neighbor's child into the dispensary and were cutting him to pieces for medical purposes. After the disturbance the missing child was found. The rioters were mostly ignorant Bohemians and Lithuanians who had been worked up to a high pitch of excitement by stories of dissections at dead of night and experiments upon kidnapped children.

The Beth Israel Hospital.—The ceremony of laying the corner-stone of the new Beth Israel Hospital, at the corner of Cherry and Jefferson streets, took place last week. The programme of exercises consisted of an opening prayer and address by the Rev. Dr. Bernard Drachman; the laying of the corner-stone by Harris Cohen, president of the Beth Israel Hospital; a dedicatory prayer by the Rev. Dr. G. Gottheil; and addresses by Kaufman Mandell, Abraham Nelson, the Rev. Samuel Schulman, the Rev. Dr. H. Pereira Mendes, Randolph Guggenheimer, John W. Keller, Isidor Straus, Dr. Abraham Jacobi, the Rev. L. Zinsler, and the Rev. Philip Jaches. The hospital building is to be seventy-eight by one hundred and twelve feet on the ground, five stories high, in the Renaissance style of architecture, and is to be of steel and buff brick, with trimmings of Vermont marble and terra cotta. It will be completed by January 1st next, and will contain one hundred beds.

The American Association for the Advancement of Science, which includes many of the most important non-medical scientific societies in America, will meet in this city during the last week in June. The general meetings will be held at Columbia University. On Saturday afternoon, June 23d, the annual meeting of the association council will be held at the Hotel Majestic, and a second meeting will be held early on Monday morning in Schermerhorn Hall, Columbia University. The general meeting will be opened on Monday by President G. K. Gilbert, of Washington, D. C., who will introduce Prof. Robert Simpson

Woodward, of Columbia, the president-elect. Governor Roosevelt will then deliver the address of welcome, and President Seth Low, of Columbia, will follow him. Dr. Woodward will then reply for the association. A general session will again be held on Tuesday evening in the American Museum of Natural History, at which President Gilbert will deliver his retiring address, after which a general reception will be held for the members of the association and invited guests. General sessions will be held on every succeeding morning during the week at 11 o'clock, and on Thursday evening the general committee will meet at the Hotel Majestic for the election of officers and the determination of the time and place of the next convention.

Succi, the Italian Faster, has been declared to be insane and is now under confinement in an asylum.

The Plague.—Six new cases of bubonic plague and two deaths were reported in Cairo on June 4th. In San Francisco a case is reported from time to time, and the quarantine of Chinatown is still maintained. In Sydney, N. S. W., the disease is believed to be well under control.

Cape May County (N. J.) Medical Society.—At a stated meeting held at Cape May on June 1st. the following officers were elected: *President*, Dr. A. L. Leach; *Vice-President*, Dr. J. S. Douglas, of Tuckahoe; *Treasurer*, Dr. Randolph Marshall, of Tuckahoe; *Secretary*, Dr. C. B. Corson, of Seaville.

Association of Baltimore and Ohio Railway Surgeons.—At the annual meeting of this association, held at Atlantic City on June 2d, the following officers were elected: *President*, Dr. R. B. Short, of Union Mills, Ind.; *First Vice-President*, Dr. F. J. Evans, of Chester, Pa.; *Second Vice-President*, Dr. J. W. Hays, of Albion, Ind.; *Secretary and Treasurer*, Dr. G. A. Davis, of Summit, W. Va.; *Assistant Secretary*, Dr. W. A. Bailey, of Leisenring, Pa.; *Executive Committee*, Drs. John E. Russell, of Mount Vernon, Ohio, and W. W. Weaver, of Philadelphia.

The Association of Military Surgeons of the United States met in their ninth annual session at the Academy of Medicine in this city on May 31st and June 1st and 2d, under the presidency of Col. Charles H. Alden, of the Army Medical Corps. The address of welcome was made by Dr. Albert H. Briggs, of Buffalo, major and surgeon of the Sixty-fifth New York Regiment. Dr. Alden, in the presidential address, suggested the advisability of the publication of a medico-military journal under the auspices of the association. Such a publication, he said, could be made self-supporting, and could be made a magazine for the permanent preservation of many facts that had been gathered by army surgeons during the wars in Cuba and in the Philippines. On motion of Dr. Daly, of Pittsburg, a committee was appointed to take steps toward the establishment of such a journal. The award of the gold medal offered by Dr. Eno Sanders, of St. Louis, for the best essay on "military surgery" was made to Capt. W. C. Borden, assistant surgeon United States army. Among those present were Major Narciso del Rio, surgeon in the Mexican army and delegate from the government of Mexico, and Colonel-Surgeon W. McWatters, of the British army. The following officers were elected: *President*, Brig.-Gen. A. J. Stone, of Minnesota; *First Vice-President*, Medical Inspector John G. Wise, of Washington, D. C.; *Second Vice-President*, J. F. Calef, of Connecticut; *Secretary*, Col. Charles Adams, of Illinois; *Treasurer*, Lieut. Herbert A. Arnold, of Pennsylvania. St. Paul, Minn., was selected as the next place of meeting, and it was recommended that the meeting for 1902 be held in San Francisco. A motion was made and adopted that all ex-surgeons of the Civil War, both Federals and Confederates, be eligible for membership in the association.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending June 2, 1900. May 2d.—Assistant Surgeon W. H. Barber detached from the *Alliance* when placed out of commission, and ordered to duty at the naval hospital, New York. May 31st.—Assistant Surgeon C. N. Fisk commissioned assistant surgeon from May 15, 1900. Surgeon O. D. Norton detached from the *Monadnock* and ordered to the *Bennington*. Assistant Surgeon J. S. Taylor detached from the *New Orleans* and ordered to the *Culgoa*. Assistant Surgeon F. J. Grow detached from the *Richmond* and ordered to the *Monadnock*.

Obituary Notes.—Dr. Truman W. Miller died at his home in Chicago on June 1st, of sequelæ of influenza. He was born in Seneca, N. Y., March 2, 1840. He attended Hobart College, and later studied at the Geneva Medical College, where he received his degree in 1863. He was connected with the United States army medical staff during the Civil War, and became post-examining surgeon at Chicago in 1864. From 1877 to 1886 he was surgeon in charge of the Marine Hospital at Chicago, and was for six years surgeon at the Cook County Hospital. He was professor of general and genito-urinary surgery at the Chicago Policlinic, and was surgeon to several hospitals and railways.

Dr. Joseph Davis Osborne, of Newark, died in that city on June 2d, at the age of sixty-seven years. He was born in Morris County, N. J., and was graduated from the College of Physicians and Surgeons in this city in the class of 1859, subsequently studying under Dr. Abram Coles, of Newark. He was a surgeon in the Fourth New Jersey Volunteers during the Civil War. A widow and two daughters survive him.

Dr. Theodore Menges, a well-known dentist in Chicago, is dead as the result of an operation for appendicitis. Dr. Menges was secretary of the faculty of the Northwestern University Dental School.

Dr. Gerald C. Hopkins died at Philadelphia on May 27th at the age of thirty-six years. He was graduated from the medical department of the University of Pennsylvania in 1886.

Dr. Edwin O. Shakespeare died at Philadelphia on June 1st, of angina pectoris, at the age of fifty-four years. He was born at Dover, Del., where he obtained his preliminary education. He subsequently entered Dickinson College and received the degree of bachelor of arts in 1867, and of master of arts in 1870. He was graduated from the medical department of the University of Pennsylvania in 1869. In 1885 he was commissioned by President Cleveland to investigate the cholera in India, and he devoted a year to the study. His report, a voluminous one, was published in 1889. In 1898 he was appointed a brigade surgeon with the rank of major of volunteers, and at the time of his death he was a member of a commission appointed by the surgeon-general to investigate the causes of typhoid fever in the army.

Progress of Medical Science.

New York Medical Journal, June 2, 1900.

On a Little-Known Method of Treatment of Furunculosis.—G. Langmann believes that the growth of boils as commonly seen is the result of a trophoneurotic disturbance. He advocates for purposes of treatment the galvanic current, describing his method in the following words: "The cathode, exhibiting more intense reaction upon the tissue, is placed upon the furuncle, the anode somewhere in the neighborhood, and a current of about two to five milliamperes is applied for from five to ten minutes. As a rule, one sitting daily is sufficient. The intensity of the current ought to vary both with the stage of development of the boil (the earlier stages being more sensitive) and with individual sensitiveness. Whoever has no galvanometer on his battery may regulate the current according to the sensations of the patient; the feeling of a lively sting, entering, as it were, the centre of the boil, just enough to be tolerated, indicates about the proper strength of the current."

Microbes—What Are They?—H. G. Graham details a series of experiments undertaken upon the lower forms of life in order to determine the nature of microbes. He comes to the conclusion that bacteria are low forms of life derived from the protozoa, and that in turn they are also elementary forms of higher organisms. Protozoa are constantly being taken into the body, and the possible fact of their becoming virulent is conditioned on two things: (1) whether they will by their own motile powers penetrate the walls of the alimentary tract and so reach tissue beyond; (2) whether they will adapt themselves to a new and ever-changing environment that gradually becomes more and more toxic for the host.

The Diseases of the Blood in their Relation to Surgery and their Treatment.—G. C. Van Schaick makes a plea for the systematic examination of the blood in all cases requiring surgical intervention in which the nature of the patient's malady does not require immediate operation. If a condition of anæmia is found, the patient should first be brought up to a proper blood condition. He thinks it is generally possible to do this by the administration of a certain organic preparation of iron now on the market.

A Case of Mediastinal Growth with Subsequent Tuberculous Disorganization Mistaken for Aneurism of the Arch of the Aorta.—This case is reported by F. Griffith. His patient was a woman aged seventy years. The nature of the case is sufficiently indicated in the title. The author discusses the question of differential diagnosis between the two conditions suggested therein.

Æstivo-Autumnal Fever in New Orleans, Summer and Autumn, 1899.—By H. A. Veazie.

Some Desultory Remarks concerning Diphtheria.—By J. W. Jervey.

Philadelphia Medical Journal, June 2, 1900.

Asthma.—Richard B. Faulkner defines asthma as a condition of spasm of the bronchial tubes with bronchial and peribronchial hyperæmia, approaching or amounting to inflammation, accompanied by râles upon both inspiration and expiration, with great difficulty in breathing. A second form exists as an affection of the vagus, either at its root or at some remote part of its course, or of the fibres of other nerves that connect with the vagus, without apparent bronchial lesion or other lesion. In the treatment of the paroxysm he advises counter-irritation over the course of the vagus, and also the use of strychnine. For the general condition and to prevent a return of the paroxysms he advises exercises adapted to the physique of the patient. To prevent the return of the paroxysms, other important indications are: (1) Removal of all exciting causes; (2) removal of all toxic influences, rheumatic, gouty, renal, malarial, irritating plants (ragweed, goldenrod, ailanthus, honeysuckle), irritating dust (hay, feathers, Chinese matting, ipecac), irritating animal odors (horses, dogs, cats, rabbits), acid fumes, the atmosphere of close, warm rooms; (3) restoration of general good physiological conditions of digestion, respiration, circulation, nervous system, cutaneous surface; (4) removal of reflex irritations, nasal, rectal, uterine; (5) relief of bronchial hyperæmia, bronchitis; (6) repair of emphysema; (7) climatic suggestions.

Prognosis in Fractures.—Clinton B. Herrick insists upon the importance, in every case of fracture, of making the patient acquainted with the exact state of affairs at the outset, and also aware of the complications, in order that a perfect understanding may exist and the possibilities of censuring the surgeon may be eliminated. He hold that fractures should take their place with the more serious, rather than be classed as simple injuries, for if so regarded an increased degree of diligence will be accorded, results will be improved, and the odium of failure will be removed. He refers to the various complications and sequelæ that may occur, from slight atrophy even to death, and says that the surgeon should in every instance give a guarded prognosis to the end that the patient and his friends may understand the uncertainty of a positive result, and the surgeon preserve his reputation against distrust, censure, and malpractice suits. Especially should the surgeon refrain from saying to the patient that his leg or his arm will be just as good as ever, for that cannot be and will not be.

Some Advances in Medical Instruction.—President C. W. Eliot of Harvard, in an article entitled "The Inductive Method Applied to Medicine," says that education in general comprehends just three things: accurate observation, the foundation of all; an exact record, and the exactly limited inference from recorded facts. The lecture system in medicine has been greatly modified, and is now mixed with question and answer, with conference, and with the writing of themes and theses. Another improvement should be made at once in preparatory medical education, and that is, a study of animal life. We have found out that diseases are pretty well mixed up between animals and man; we know that the sources of some diseases that afflict human beings are to be found in animals, and that some diseases are transmitted through animals to man; and also we know happily that we can get treatment for some human diseases out of animals. We should do well to secure to the medical student a comparative study of medicine in other animals as well as in man.

William J. Councilman, speaking of "The Course in Pathology at the Harvard Medical School," says that certain things which seem evident have been brought out in this course: (1) That the mind of the student must be active and not passive; that he can acquire knowledge only by his own powers of observation and deduction; he cannot acquire it by being told things. (2) That teaching should be individual as far as possible; that the central idea should be to give opportunities to the student, and to assist him in the effort which he himself makes. (3) That medical education should not be directed solely to teaching the medical art, but education in its true sense, the development of the individual, must not be lost sight of.

Discussing "The Case System in Medicine," W. B. Cannon speaks of the practicability of the method; its value from the point of view of the medical student; and what seems to the author its place in a medical curriculum. As to the first point, in the past two years he and other instructors have used printed records of cases as centres of interest in the study of medicine, and there has not been the slightest difficulty in applying the plan. As to its value, it arouses much enthusiasm in the students; teaches them the judgment of clinical data, the estimation of the value of evidence, fixes symptoms in the mind by their vivid presentation, and gives the students a training in being required to adapt themselves to actual difficulties in practice. The place in the curriculum of the study of case histories is in the central position between the scientific work of the first two years of training which provides principles and theories, and the practical work of dealing with actual problems.

Giving "A Personal Experience in the Teaching of Surgery," Herbert L. Burrell thoroughly indorses Mr. Cannon's suggestion of the case method of teaching systematic medicine. In surgery he considers it imperative. There is a tendency for surgeons to work more with their hands than with their heads—which is fraught with danger to the true advancement of surgery on a secure scientific basis. The "case-method" system and sectional teaching will counteract this danger and will oblige students to use their brains. The advance of teaching in the first and second years has been along the lines of concentration and sequence. The advance of teaching in the third and fourth years should be along the same lines, plus electives and coordination of teaching subjects. The students are taught in their case-taking and section work continually to go back to the foundation principles of anatomy, physiology, and pathology, in interpreting clinical phenomena. This will make a race of physicians whose knowledge is drawn from known scientific facts, and not mechanical operators, or "up-to-date," "last-remedy" practitioners.

A. H. Wentworth answers the objections made to "section teaching" and considers its advantages. Its chief aim should be to oblige the students to do most of the work. They should learn systematic methods of physical examination, and should be required to state the results of their examinations. They ought to be able to make provisional diagnoses and to give their reasons for the same. The instructors should correct and criticise, and the entire section should take part in the discussion. One of the best ways for gaining a clear idea of a subject is to try and explain it to some one else. It stimulates ideas and teaches accuracy and clearness in description. The students take the greatest interest in the work and improve with wonderful rapidity.

Journal of the American Medical Ass'n, June 2, 1900.

Removal of the Cervical Sympathetic in Glaucoma and Optic-Nerve Atrophy.—James Moores Ball reports several cases of this operation and discusses its technique. From a study of the cases of sympathectomy made by Jonnesco and others, and from the observation of his own cases, he reaches the conclusions that excision of the superior cervical ganglion is a valuable procedure in glaucoma, more so in glaucoma simplex than in inflammatory glaucoma. In inflammatory glaucoma, when iridectomy has been done without benefit, this operation should be tried. In cases of absolute glaucoma with pain, sympathectomy is to be tried before any operation on the eyeball. In simple optic-nerve atrophy, the operation may possibly be beneficial if done before vision is entirely lost. In unilateral glaucoma excision of the sympathetic ganglion is to be done only on the corresponding side. In the hands of a careful operator, excision of the superior and middle ganglia is a safe operation, but removal of the inferior ganglion can be done safely only by the most skilful surgeons. The fact that glaucoma is improved by sympathectomy and the finding of pathological changes in the excised ganglia suggest that this affection is due either to a permanent irritation of the cervical sympathetic, or to an irritation located elsewhere and transmitted by means of this nerve.

Intralaryngeal Insufflation for the Relief of Acute Surgical Pneumothorax.—Rudolph Matas refers to the danger of opening the pleural cavity and thereby inducing acute collapse of the lung, and reviews the methods which have been employed to counteract the disastrous effects of acute pneumothorax so brought about. The most effective of these procedures, he says, is artificial inflation of the lungs and the rhythmical maintenance of artificial respiration by a tube inserted in the glottis and directly connected with the bellows of an air-pump. The idea of insufflation of the lungs is an old one, the author says, although its application for the maintenance of the pulmonary function in thoracic operation is an essentially modern and very recent conception. The article is a continued one.

Gastro-enterostomy for Carcinoma of the Pylorus.—J. Henry Barbat reports a case of this operation performed on a woman forty-five years old. She had a tumor at the pylorus which was found at the time of the operation to be so extensively bound by adhesions to neighboring parts as to make removal impossible. The author then resorted at once to a gastro-enterostomy. The result was brilliantly successful, the patient being, at the time of the report, able to eat and digest large quantities of food. Before the operation the woman weighed eighty-three pounds, and six weeks later her weight was one hundred and one pounds, and was constantly increasing.

The Sanatorium Treatment of Incipient Pulmonary Tuberculosis and its Results.—E. L. Trudeau describes his method of combined climatic and sanatorium treatment. A study of the gross results in the twelve hundred patients admitted during the past fifteen years shows the result to be as follows: Twenty-three per cent. were discharged as apparently cured; fifty-six per cent. were discharged with the disease arrested or much improved; nineteen per cent. were discharged stationary or unimproved; two per cent. died in the institution. Of the eleven hundred and seventy-six patients discharged alive, about one-half are still living, and one-half of this number have been heard from as being perfectly well. The permanency of the recoveries depends necessarily a good deal on the environment to which the patient returns. A laborious life and indoor occupation are more likely to bring a relapse than a good climate and outdoor exercise. The education which the patients receive at the sanatorium as to the nature of their disease and the methods of combating it is of the utmost value to themselves and to others.

Stump Pregnancy.—John C. Morfit describes a case, which convinced him that it was a variety of extra-uterine pregnancy that has never before been met with, which occurred in the remains of a tube, the proximal end of which he had not entirely removed. The absence of the ovary and most of the tube on the right side, the occlusion by ligature of the stump, the presence of a normal ovary and tube on the left side, and a large corpus luteum being present in the only ovary, led to but one possible conclusion. The fertilized ovum came from the left side, passed through the left tube and the uterine cavity up into the remains of the tube on the right side, where it began to develop, and finally ruptured the tube into the abdomen. This upsets the view that ectopic pregnancy is due to some mechanical or inflammatory hindrance to the normal downward passage of the fertilized ovum. The author believes that the ovum can travel in any direction before anchoring itself preparatory to development.

Hip-Joint Amputation.—William D. Hamilton describes five cases in which Wyeth's bloodless method of hip-joint amputation was used. Three of the operations were done by the writer, with one death and two recoveries. The other two patients were operated upon by Dr. Charles Hamilton, and both recovered. Of the last two, one had had a thigh amputation done by the writer, with early recurrence. There is no doubt as to the great value of Wyeth's bloodless method when it is applicable. A well-appointed hospital is the proper place for its performance. Then, too, shock can be more successfully combated in case it should occur.

The Prevention of Scarlet Fever.—By Floyd M. Crandall.

Treatment of Membranous Colitis.—By W. H. Thomson.

The Lancet, May 19 and 26, 1900.

Chronic Abscess of the Pericardium.—D. Hunter's patient was a man who was insane and had been a hard drinker. The clinical features of the case presented nothing out of the ordinary. Cardiac symptoms were feeble, with irregular and intermittent heart action without murmurs. Gradual asthenia supervened, and he died from cardiac failure. An attempt to open the pericardium at autopsy showed that much thickening existed and that the pericardial layers were firmly adherent. Continuing the incision round to the left side, a cavity was opened and some thick, creamy, greenish-yellow pus exuded. The heart and pericardium were removed *en masse*, and were found to weigh 530 gm. On dissection the cavity above mentioned was found to be over the wall of the left ventricle and to contain about four ounces of pus. The walls were thickened and lined with a definite pyogenic membrane. There was a smaller cavity over the left auricle containing thin ichorous pus, also with thick and velvety walls. The remainder of the pericardium showed considerable thickening, with complete firm adhesion between its layers. The wall of the left ventricle was hypertrophied, and the myocardium generally was of good color and consistence. The mitral orifice admitted the tips of two fingers only, and the tricuspid orifice was somewhat dilated, but there was no structural valvular disease. The base of the aorta showed two small atheromatous patches.

A Clinical Study of the Causes of the First Sound of the Heart.—A. Morrison concludes that the impulse given to the blood by the muscular action of the heart gives rise in it and in the vibratory structures containing it to vibrations of a certain quality which result in that tone which is synchronous with cardiac systole and usually called the first sound of the heart, and that the largest share in this result must be attributed to vibrations in the blood itself, to produce which at a normal rate valvular support of the vibrating blood columns is necessary. The study of some congenital cardiac malformations especially appears to support this conclusion, because with considerable parietal defects and bruits caused by such the sounds of the heart may be well heard so long as the division of the blood is fairly maintained by the valves.

A Fatty Tumor of the Ascending Colon; Enterectomy; Recovery.—The case reported by J. Bland-Sutton was that of a man aged forty-four years. He suffered from symptoms of intestinal obstruction, and on examination a sense of resistance could be made out between the cæcum and the umbilicus. A continuance of the symptoms led to cœliotomy. Two inches below the ileo-cæcal valve, a tumor was found in the colon, over which an incision was made. This mass was ovoid, one pole being embedded between the muscular and mucous coats; the remaining two-thirds of the tumor, covered with mucosa, projected into the lumen of the ascending colon. It proved to be a lobulated lipoma weighing two ounces.

Congenital Word Blindness.—J. H. Wood gives the histories of four cases, two occurriug in his own practice. Both patients were brought to him by medical attendants who suspected that difficulty in learning to read might be due to some cerebral cause. Wood regards the difficulty in these cases as due to some congenital defect in the visual memory centre for words and letters. Learning to read is a process of two stages: (1) the storing up in the visual memory of the individual letters of the alphabet; (2) the gradual acquirement and storage of the memory of words. This special function is localized in the angular and supramarginal gyri on the left side of the brain in right-handed people.

A Case of Multiple Papilloma of the Vaginal Surface of the Cervix Uteri.—J. Oliver records the case, the patient being a woman who had had two children, but had been a widow for ten years, being at the time of operation forty-one years old. The growth originated on the left half of the cervix, about three-eighths of an inch from the os. There was no evidence of surrounding infiltration. Two other smaller similar masses were also discovered. To include the bases of all three, a wedge-shaped piece was taken from the left half of the cervix and the edges of the incision were brought together with deep catgut sutures. Recovery was without incident.

The Incubation Period of the Plague.—From a study of various outbreaks of the plague, F. G. Clemow concludes that infection from inoculation, as in making an autopsy, has a regular incubation period of from two to three days. Under general circumstances the period runs from ten to twelve days, varying according to the mode of infection. In studying this question a distinction must be made between the time of exposure to infection and the onset of the disease, and the period between the reception of the bacillus into the tissues and the onset of the disease.

Simultaneous Excision of Both Mammæ for Cancer.—A case of this nature is reported by G. P. Newbolt, the patient being a woman aged sixty-four years, with mitral trouble and albuminuria. In spite of these handicaps, the surgical result was a successful one.

Berliner klinische Wochenschrift, May 14, 1900.

The Reflex Irritability of the Nasal Mucosa in Relation to Narcosis.—F. Bruck attacks the plan devised by Rosenberg, whereby the nasal mucosa is cocainized previous to chloroform inhalation. He asks: (1) Are the cocainized portions of the interior of the nose completely anæsthetized? (2) Does such a plan of local anæsthesia reach the entire nasal interior? To both of these questions he returns an emphatic "no." He believes that if the mouth is kept open and the tongue well forward during chloroform narcosis, there is a minimum of danger of failure of either heart or respiration, from reflex influences. Theoretically these should be abrogated by the local anæsthesia in the nose; practically, according to Bruck, this procedure renders the administration of chloroform more difficult.

Diagnostic Employment of Upper Bronchoscopy in Pulmonary Carcinoma.—G. Kilian records a case of hæmoptysis in which the usual methods of chest examination located some trouble in the right lung. Its exact nature could not be made out. An *x*-ray picture confirmed the location, but bronchoscopy enabled the observer to see the exact bronchial tube from which the bleeding proceeded. Kilian was able to study the ramifications of the bronchial tree, and makes some observations on the anatomical relations of the pulmonary interior.

Fundamental Views on Pathogenesis.—Fr. Martius reviews the changing views as to the pathogenesis of disease which have been current during the present century, paying special attention to Virchow's theory of cellular pathology.

The Origin and Secretion of Oxalic Acid.—By E. Salkowski.

Deutsche medicinische Wochenschrift, May 10, 1900.

The Diagnostic Significance of the Digestion of Carbohydrates in Gastric Hyperacidity.—L. Schüler says the definition of hyperacidity is not yet settled. For the diagnosis of this disease the qualitative examination of total acidity or that of free hydrochloric acid is not enough. There are cases of low total acidity with the clinical symptoms of hyperacidity. For this purpose it is necessary to inquire into the duration of the amylolytic stage of digestion, the quantity of the stomach contents after a test meal, and the specific gravity of the filtered digested fluid. The amylolytic stage is very much shortened in hyperacidity, and hence we will find large quantities of amidolin (proven by the action of Lugol's solution); the quantity of the stomach contents after the test meal is increased—about 200 c.c., while the normal amount is 150 c.c.—due to the hypersecretion of the stomach cells; the specific gravity is therefore low—1.110. Taking into consideration all those points, we are able to make a diagnosis even in so-called latent cases of gastric hyperacidity.

The Relation of Epileptic Convulsions and the Excretion of Urea.—By Dr. Garo.

Acute Dilatation of the Heart and Cor Bovimen.—By Dr. Hoffman.

Deutsche med. Wochenschrift, May 17 and 24, 1900.

The Blood Pressure in Neuropathic Children.—Paul Heim discusses the various apparatus for testing blood pressure, and favors the use of Gärtner's "tonometer" as giving the most accurate and constant results. But the physiological variations in the blood pressure cannot be obtained; the scale does not even read off the average, but merely the maximum, pressure at the height of the systolic pulse, and this finally is increased during the respiratory phase. For comparison with neuropathic children Heim examined about twenty-five normal children. These children were physically in no wise similar, but only such were chosen as were free from fever, nephritis, heart lesions, or icterus. He observed, even in normal children, that the first result obtained was always 10–20 mm. higher than succeeding ones, when taken from the same finger after a pause of about a quarter of an hour. Only after two, three, or at most four tests was a constant value observed, which varied between 80 and 90 mm.; as extremes he found twice a pressure of 75 mm., and in four instances 95 mm. He does not agree with Fraenkel that this difference between the first and subsequent tests is due to paralysis of the arterial muscle, as the variation is too great, but ascribes the heightened pressure to psychical influence, *i.e.*, excitation. Contrary to his expectations this variation was not so marked in neuropathic as in normal children. Only such children were classified as neuropathic who, without discoverable physical cause, complained of headache, stitches in the sides, loss of appetite, nausea, vomiting, dizziness, fainting-spells, cramps, or became easily fatigued at school. Anæmic children, children with defective refraction or other discoverable cause, were excluded. Neuropathic children are always in physical excitation, and this condition causes increased blood pressure, the same as it frequently causes pulse acceleration. Heim does not believe that there is any relation between the height of the blood pressure and the severity of the affection; the usual tension was between 130 and 150 mm. Nor is it possible to make a differential diagnosis of the different neuroses by measuring the arterial pressure, *i.e.*, we cannot say that hysteria causes a higher tension than neurasthenia or vice versa. He believes, however, that blood-pressure measurement is of considerable value in the diagnosis of neuroses in general, in differentiating neuropathic children from the non-neuropathic when suffering from similar symptoms.

Contribution to the Study of Kraurosis Vulvæ.—Ph. Yung discusses the various theories and gives the résumé of four cases of this disease. The appearance of the skin is as follows: it is white and dry, occasionally covered by thick, rough epidermis; the neighboring cutis is shiny, pale reddish-gray in color, covered by white spots and occasionally coursed by varicosed arterioles; sebaceous glands of the pudendal folds are very sparse. Except mild atrophy and atonicity, the remainder of the outer genitalia shows no constant changes. Histologically, connective tissue is very much atrophied and often presents a small-cell infiltration; the rete Malpighii is very thin; papillæ are small or entirely obliterated; in severe cases glands are more or less completely obliterated; no changes in the nerves. Elastic fibres are almost entirely absent. In the neighboring cutis there are sometimes hypertrophy and enlargement of the stratum cœnium, rete Malpighii, and papillæ, as well as small-celled infiltration of the papillæ and horny layer. The atrophy follows the hypertrophic stage. Anatomically, kraurosis is the result of "chronic dermatitis." As to the symptoms, in severe cases, there is a feeling of tension and rigidity, which sometimes entirely prevents coitus. There is also local pruritus and burning on urination. Some cases, however, are entirely symptomless and are discovered only accidentally. The disease may occur at all ages. Bacteriological examination is negative. In six of the sixty cases reported, carcinoma vulvæ was also present, the malignant disease probably finding its starting-point in the chronic inflammation present. The best procedure is excision and removal of the diseased areas. In only one case did a relapse take place. Those cases complicated by cancer naturally give a bad prognosis.

A Case of Glanders.—Zandy describes a case which occurred in a young man twenty-five years old. He was brought to the hospital with the history of having been sick fourteen days, suffering from headaches and weakness. There were no chills. The abdomen was tympanitic and distended, the spleen somewhat enlarged and palpable; there was no gurgling or abdominal pain. There was a doughy swelling in the left upper part of the face, partly covered with a number of small (size of millet seeds) whitish-yellow vesicles upon a bluish-red base. A number of red blotches and nodules were found on the upper arm and chest. Fetor from the mouth was present. His temperature was 39.5° C., pulse 156, respiration 40. The sensorium was free. The œdema of the face and hyperæmic nodules on the arm increased in area. The right lower arm now showed a diffuse swelling. The urine contained albumin and casts. No micro-organisms were found in the blood. Though the picture was not typical (no muscular abscesses, no typical exanthem, no nasal lesion), glanders was diagnosed by exclusion. The patient died after an illness of about three weeks. On the day before death cultures were made on glycerin-agar and on potato of the contents of the pustules, and animal inoculations were also carried out. All these showed the pathogenic glanders bacillus.

Three Cases of Fatal Parenchymatous Gastric Hemorrhage.—Reichard reports three cases of fatal parenchymatous bleeding from the stomach without discoverable anatomical lesion. In the first case, that of a man aged fifty-six years with a history of long-standing jaundice and pronounced icterus, indicating occlusion of the common bile duct, no obstruction could be found at the operation, though the bile channels were dilated. A cholecystenterostomy was performed. On the sixth day the patient passed a large quantity of fluid and clotted blood from the bowels, and died on the eighth day after operation. Reichard concedes that jaundice may have been an etiological factor. In the other two cases there was no jaundice. The patients were transferred to the surgical department on account of uncontrollable hæmatemesis with progressive anæmia. At the autopsy no lesion was found to explain the hemorrhage.

Contribution to the Pathology of the Blood.—Lipowski gives the history of a patient dying from an acute pernicious anæmia of toxic origin. There were continued hemorrhages from the gums and pharynx, as well as from the vagina. Examination of the blood showed slight poikilocytosis, no micro- or macrocytes, no nucleated erythrocytes; number of erythrocytes, 2,115,000; hæmoglobin, eighteen per cent. Death took place after two weeks. The specific toxin was not discovered. He cites another case of progressive anæmia in which its pernicious character was determined rather by the marked continued decrease of hæmoglobin and erythrocytes, the fever, subcutaneous hemorrhages, and changes in the background of the eye, than by the characteristic histological data derived from the blood examination.

Gastro-enterostomy, Gastrostomy, and their Relation to Gastro-enterostomosis Externa.—By O. Witzel and C. Hofmann.

Occupation Poisoning and Accident-Insurance Laws.—By L. Lewin.

Further Clinical Studies on Aspirin. — By Heem and Liesau.

French Journals.

A New Treatment for Alopecia Areata.—Scheffer finds that pilocarpine acts not only in increasing transpiration but produces also marked and persistent vaso-dilatation which increases the nutrition of the hair bulb. He employs the nitrate in solution of one-half per cent. mixed with 1:1,000 bichloride of mercury, by intradermic injection. Before injecting the plaque is rubbed with ninety per cent. alcohol. The syringe is filled three-quarters full by drawing in first ¼ c.c. of the mercurial solution, then ¼ c.c. of the pilocarpine solution, and finally ¼ c.c. of the mercurial solution. This makes the proper proportion. The injections are made just beneath the skin in as horizontal a manner as possible, 1 cm. apart, and repeated every four or five days. A patch the size of a dollar requires about twelve injections. After four or five sittings the hair begins to grow. In sixty cases treated over a period of three years there was no instance of failure. The extension of the plaque is at once arrested and new ones do not form.—*La Médecine Moderne*, May 19, 1900.

Clinical Pneumography.—E. Hirtz and G. Brouardel, in a study based upon extensive observations, describe normal pneumography, and that in the course of chronic pulmonary tuberculosis, and point out its importance in the early diagnosis of the latter. The subject is one which has hitherto received little attention excepting at the hands of one of the present writers. Many tracings from the same subject are required for approximately correct results. It is found that while the tracing for each normal respiration presents four lines, that from the onset of tuberculosis shows but three. This pneumographic formula of chronic tuberculosis persists in all periods and is not found in other pneumopathies.—*La Presse Médicale*, May 19, 1900.

Post-Operative Spontaneous Evisceration.—G. Chavannaz describes as a complication of laparotomy the spontaneous expulsion of a portion of the abdominal viscera through the various layers of the abdominal incision or alongside of the cicatrix. The paper is based on twenty-four cases of this rare accident, three of which are unpublished. In one instance of rupture of the cicatrix there was syncope. The treatment is preventive and curative. A well-applied bandage at first and caution against strain, etc., may act as preventive measures. Infection and shock are two elements to combat. In treatment alcohol, heat, caffeine, and artificial serum are precious resources.—*Le Bulletin Médical*, May 19, 1900.

Pediatrics, May 15, 1900.

The Present State of Our Knowledge of the Action of the Various Therapeutic Serums.—Antonio Fanoni reviews the development of orrhotherapy and strives to answer the question, "Are all these worthy of the confidence of the unbiassed practitioner?" Pane's serum he has employed with marked success in pneumonia in children. Maragliano's serum against tuberculosis has much in its favor. This latest expression of the *ars curandi*, "serum therapy," is gradually forcing itself upon us, and in the interests of humanity it is hoped there will soon be complete victory for its advocates.

A Case of Amnesia.—P. F. Barbour relates the case of a girl aged four years and three months, found in a stupor with apparent paralysis of the right upper and lower extremity. Memory was lost and not regained for several weeks. The writer looked upon the case as one of functional derangement of the intellectual centres such as may be produced by an interference with the nutrition of the frontal lobes, or with the general circulation in the brain, resulting most probably from an auto-toxæmia arising from the intestinal tract.

A Case of Peliosis Rheumatica Caused by Traumatism.—Louis Fischer differentiates peliosis from simple purpura by the fever, swelling, and tenderness in the joints plus subcutaneous hemorrhages. Cardiac lesions do not complicate the condition. A case of a boy of nine years is related, coming on after bicycle riding to excess, from which the writer feels justified in calling it peliosis rheumatica traumatica. The illustration does not do justice to the case.

Reviews and Notices.

HELEN KELLER SOUVENIR. Volta Bureau, Washington, D.C.

THIS handsomely prepared and illustrated volume commemorates the Harvard final examination for admission to Radcliffe College in June, 1899, of Miss Keller, a deaf girl who passed with distinction. This account of her instruction, with methods pursued, is circulated by the Volta bureau for the increase and diffusion of knowledge relating to the deaf, and as such is of the greatest interest to all instructors of deaf children and to those engaged in educational pursuits in general.

INDIGESTION—ITS CAUSES AND CURE. By JOHN H. CLARKE, Fellow of the British Homœopathic Society, etc. American edition, revised and enlarged from the fifth English edition. Philadelphia: Boericke & Tafel. 1900.

LITTLE alteration has been made in this American edition, since only a year has elapsed from the time of output of the last English. The work is very brief, but touches upon the various forms of faulty digestion and enumerates the homœopathic remedies.

A DIGEST OF EXTERNAL THERAPEUTICS, with Numerous Formulæ. Arranged for reference by EGBERT GUERNSEY RANKIN, A.M., M.D., physician to the Metropolitan Hospital, New York. Second edition, revised and enlarged. New York: Boericke & Runyon Company. 1900.

THE necessity for a new edition on March 1st speaks in itself for the reception this work has received. The authorities quoted are almost without exception old-school writers, Pepper, Allbutt, the Twentieth Century Practice, Bangs, Hardaway, Unna, Allen, Ingals, Roosa, Jacobi, et al. The work might have been written, selected, compiled, and arranged, and may be read by one of the regular quite as well as by one of the homœopathic school of medicine.

A HANDBOOK FOR NURSES. By J. K. WATSON, M.D. Edin., late house surgeon Essex and Colchester Hospital. American edition, under the supervision of A. A. STEVENS, A.M., M.D., professor of pathology in the Woman's Medical College of Pennsylvania. Philadelphia: W. B. Saunders. 1900.

THE excellent judgment displayed by the author in giving the essentials without trying to instruct nurses too deeply in the science of medicine has made an American edition of his work a thing to be desired, and the supervision has been in such hands as to give confidence that the work in its present form will be found most useful. The scheme of marginal subheadings has husbanded much space put to good use in making the reading-matter compact.

PLEA FOR A SIMPLER LIFE, AND FADS OF AN OLD PHYSICIAN. By GEORGE I. KEITH, M.D., LL.D., F.R.C.P.E. London: Adam & Charles Black. 1900.

THIS is an interesting and suggestive account of the author's long experience in the dietary treatment of many of the commoner diseases. He maintains that most of the latter owe their origin to excessive feeding, and advises extreme abstinence, especially in regard to red meats. Although confessedly an extremist, the majority of his arguments are eminently sound and will appeal to the good sense of practitioners generally. His style is charming and he has very winning ways in presenting his subject.

MT. SINAI HOSPITAL REPORTS; Volume I., for 1898. Edited for the medical board by PAUL F. MUNDÉ, M.D., LL.D. 1899.

THE institution publishing this work is to be congratulated upon its most interesting first volume. The more modern method of publishing articles upon the hospital experiences by the various chiefs of staff has been followed, and in so doing the board has given the medical public a far more interesting work and one much more apt to be read than if it were simply a mass of statistics. Among the noteworthy articles on medical subjects are those on typhoid fever, lobar pneumonia, and Widal reaction; from the surgical side, Dr. Gerster's general report, as well as numerous and thorough articles on special subjects. It is a most instructive and valuable collection.

PROCEEDINGS OF THE PATHOLOGICAL SOCIETY OF PHILADELPHIA. New Series, Vol. III., No. 4. February, 1900.

THE chief article of interest in this little pamphlet is the symposium on typhoid fever, discussed by Müsser, Flexner, Ashton, and McFarland. General tuberculosis and the method of staining the sporozoa of malaria are treated by Hand and Woldert respectively, and Lloyd describes a case of hæmatomyelia.

DISEASES OF THE STOMACH, their Special Pathology, Diagnosis, and Treatment, with Sections on Anatomy, Physiology, Chemical and Microscopical Examination of the Gastric Contents, Dietetics, Surgery of the Stomach, etc. By JOHN C. HEMMETER, M.D. Second enlarged and revised edition. Philadelphia: P. Blakiston's Son & Company. 1900.

THIS edition of Hemmeter's work on "Diseases of the Stomach" contains much new and important material. The following articles have been added: Hypertrophic stenosis of the pylorus, obstruction of the orifices, the use and abuse of rest and exercise in the treatment of digestive diseases. Part of the chapter on motor insufficiency, electro-diaphany, hemorrhage from the stomach, and the articles on gastroptosis and enteroptosis have been entirely rewritten. The present edition will undoubtedly gain as many friends as the first edition.

SKIN DISEASES: their Description, Etiology, Diagnosis, and Treatment according to the Law of the Similars. By M. E. DOUGLASS, M.D., lecturer on dermatology in the Southern Homœopathic Medical College of Baltimore. Philadelphia: Boericke & Tafel. 1900.

THE author states that he has been prompted to prepare this work by a conviction of the existence of an urgent demand for a work which should embody the advances recently made and set forth the distinctive characters of his school's therapeutics. He believes that in this department more than in any other we will find Hahnemann's rule, to treat the totality of the symptoms complained of by the patient, the only method by which we may cure our patient. The author states quite freely what those whom he is pleased to call "allopaths" advise in the various affections, and at times he makes statements concerning their views which carry one back toward the dark ages of dermatology. Unfortunately he does not give the source from which he derives his knowledge of old-school methods, there being no bibliographical references. Nor are there any acknowledgments concerning the source of the pictures, almost if not all of which are borrowed, with the exception perhaps of a print of eczema opposite page 165, which shows nothing of any value to the student and does not grace the book. The statement is made concerning impetigo contagiosa that pediculi capitis are rarely present, and the lymph which is poured out is said to be "splastic." After the statement that "the old school rely" on external measures, the author gives a list of twenty-five remedies for internal use from which the student is left to choose one or more, at times being guided by what the child may state as to the particular kind of irritation it feels at the time of his visit. In trying to learn dermatology the homœopathic student has as much right as any other to the best instruction he can get. There are plenty of good works on the subject. The therapy he can acquire after he has mastered diagnosis.

TRANSACTIONS OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION FOR 1899. New York: D. Appleton & Company. 1900.

THIS bound volume of Transactions is very neatly printed, and the papers are of the usual high order of excellence and interest. Henry Swain, of New Haven, is the secretary, to whom credit is probably due.

NEW, OLD, AND FORGOTTEN REMEDIES. Papers by Many Writers. Collected and arranged and edited by E. P. ANSHUTZ. Philadelphia: Boericke & Tafel. 1900.

THIS collection is intended to answer the question, "Where can the literature or description of such and such a drug be found?" The work represents much searching of old journal files and many hours spent on considering what to reject. The compiler deserves no little credit for the amount of careful work bestowed. The reader will find, at times, hidden among chaff, many grains of wisdom. The writings concern chiefly nature-given remedies rather than laboratory products.

THE INTERNATIONAL TEXT-BOOK OF SURGERY. By Amercan and British Authors. Edited by J. COLLINS WARREN, M.D., LL.D., etc., and A. PEARCE GOULD, M.S., F.R.C.S., etc. Volume I. General and Operative Surgery. With 458 illustrations in the text, and 9 full-page plates in colors. Philadelphia: W. B. Saunders. 1900.

IN this volume there are twenty-eight chapters, some authors having written several, and there are many illustrations. The subjects usually discussed under the head of general surgery, or the principles of surgery, occupy the first few hundred pages, and we find here bacteriology, inflammation, infection and its causes, the pathology of the blood, and various general and local diseases which are of surgical significance. There is much information which makes the book especially useful as a work of reference, but there will be few occasions upon which it will be necessary to do much memorizing by the medical student in these days of "compends." The chapter upon the technic of aseptic surgery is capital and contains all that is necessary for the novice or the expert, and the illustrations representing amputations and excisions are very satisfactory. A good diagram in this department of surgery often serves a better purpose than much text. The warning in regard to cocaine cannot be too often repeated. The chapter on "Tumors" is not as satisfactory as it might be. The descriptions are rather too brief, and the illustrations are not specially commendable. The subject of fractures and dislocations, we think, forms the most satisfactory section of the book, and here we find excellent explanatory illustrations. Cranial surgery, including fractures, is considered in a separate chapter, and is followed by one on the special surgery of the vertebral column and spinal cord. An attempt to suture a wound of the heart is advised in all cases in which there is time, but such cases are necessarily rare. The diseases of blood-vessels are disposed of in a rather short chapter, which includes treatment in a general way.

Anatomie Clinique des Centres Nerveux. Par Dr. Grasset. Paris: J. B. Baillière et Fils. 1900.

A most useful little book for every physician to read. After a short introduction on the neuron, and its groupings and connections, the author proceeds to discuss the special anatomy of the nervous mechanism of general motion and sensibility; secondly, of the special senses; thirdly, of speech; and, finally, of circulation, respiration, and digestion. In a comparatively small space the author has succeeded in clearly stating the most recent ideas as to centre, localization, and the paths of nervous impulses in the brain and spinal cord. The book will be of especial interest to the general physician who has not the time to devote to the more extensive works on this subject.

The Anatomy of the Brain. By R. W. Whitehead, M.D. New York: The F. A. Davis Company. 1900.

This book is intended as a text-book for students, and certainly fulfils the aim of the author. In clear, concise language he has described this complex portion of anatomy; by tracing only those fibres whose course is definitely known and omitting minutiæ of those tracts that are still *sub judice* as regards their exact relations and distribution, he has been enabled to present the subject in a comparatively small space. Its terseness, completeness, and compactness recommend it strongly to those for whose use it has been written. The illustrations are numerous and good.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

COMING EVENTS IN MEDICAL COUNCIL—MEDICAL SOCIETIES—BRITISH MEDICAL ASSOCIATION—GALL STONES—PNEUMOTHORAX IN HEALTHY PERSONS—ACUTE ENCEPHALITIS—CHANGES IN THE BLOOD IN DISEASE.

London, May 11, 1900.

Next week the Medical Council meets, and we shall have more dreary talk on many disputed projects. The midwives bill must, of course, be one, as the council cannot permit all their representations to be ignored without a protest, as the government asked for them, and the promoters of the bill have misrepresented their recommendations in the House.

We are also to have next week the conversazione of the Medical Society and the oration by Dr. Fowler. The Clinical, too, will hold its annual meeting, and the Medico-Chi will give us another evening on "The Wounded in the War," by Mr. Dent and Sir W. MacCormac. There will be an exhibition of specimens, bullets, etc. Lantern slides will be employed.

The conference at Manchester, of which I gave you some particulars last week, has given rise to some uneasy sensations. These seem to centre round the resolution to attempt to reform the British Medical Association and to open the campaign at Ipswich in July. If the reformers can only get a hearing we may expect a lively time. But the little clique which rules the association has never been at a loss to stifle unwelcome discussion, and is likely to make a strategic movement in an unexpected direction.

At the Clinical Society on Friday the chief interest was centred in some cases of gall stones. These concretions always excite interest on account of the excessive pain they sometimes give rise to and the slight symptoms in other cases. Thus in one case the diagnosis is evident and in another obscure. Besides, the secondary effects vary greatly and fresh difficulty arises. Mr. Battle related three cases. In one, a girl aged fourteen years had had severe attacks of abdominal pain with nausea and headaches. The pain was not well localized, but referred to the umbilicus and again to the left lumbar region. There were blood and albumin in the urine, but no casts. An x-ray examination was negative. A lumbar incision was made and the left kidney explored, but nothing was found. After convalescence another severe attack of the old pain occurred and an abdominal exploration was made. A gall stone was found in the cystic duct, the removal of which cured the patient, who continues well. Another of Mr. Battle's cases was of a girl aged sixteen years. The gall bladder could be felt, very hard as if contracted on some large stones. It contained none, but its wall was very thick. A stone was found in the common duct and extracted with a good result. The third case was that of a woman aged forty-nine years, who had had attacks of pain and vomiting extending over eighteen years. She had passed gall stones. She had jaundice; stones were found in the gall bladder and ducts and were removed through incisions, and the patient did well.

Mr. Bland-Sutton related a case in which on operation the stone was detected in the wall of the duodenum, impacted in the terminal segment of the common duct. It could not be moved in either direction, so the wall of the duodenum was incised and the papillæ were exposed, when the concretion could be seen at the orifice, and on nicking the edges it was extracted. The incision into the duodenum was sutured in two layers. The patient did well.

Dr. Weber said his house surgeon was palpating a large gall bladder when it disappeared under his fingers, and the stools, previously clayey, became colored. That seemed a case of distention with bile, but in another case when the bladder diminished suddenly a hard lump was felt, which proved to be a stone.

Mr. Symonds made some interesting remarks on the cases and mentioned others. He discussed the necessity of suturing the duct when it was incised, as if that could be dispensed with it would much facilitate operation.

Mr. Bland-Sutton, in his reply, said he had operated on a number of cases without suturing the duct since he reported one in the Transactions, vol. xxv. Though it was thought "risky" then, he never felt the least temptation to put in a suture—he merely drained.

Those curious cases of pneumothorax which now and then come on suddenly in healthy persons were the subject of some conversation at the society, Dr. Parkes Weber having related one at length and Dr. Percy Kidd another more briefly. All the recorded cases seem to have been in males and were probably caused by the bursting of an emphysematous bulla. A minute tuberculous nodule had also been found to open a communication between the air passages and pleura in a person who had given no previous signs of tubercle. Dr. West had such a case, but this cause must be rare, for in cases of sudden pneumothorax in healthy persons, recovery almost always takes place spontaneously.

Drs. Prickett and Batten read details of a case of acute encephalitis following influenza in a lad aged nine years. On the fourth day of the influenza he became paralytic and aphasic, passed into coma, and died in seventy-two hours.

The adjourned discussion at the Pathological Society on changes in the blood in disease was not so interesting nor yet so severely scientific as the earlier debate. Nevertheless there were many points deserving of consideration.

Professor Wright, of Netley, resumed the debate. He did not think much of enumeration of red or white cells, and asked if, after all, there were any diseases in which examination of the blood by current methods helped the diagnosis or prognosis. He thought the coagulability of the blood the most important point to estimate, and that we should watch whether the condition we wish to produce is brought about by our treatment. In aneurism it was wished to increase the coagulability, and starvation diet has been used. But in starvation the coagulability goes down and after a good meal goes up. In phthisis also the coagulability is reduced. Eating acid fruits reduces it to the extent sometimes of "serous hemorrhages"—urticaria. Lime salts increase it, and the professor has shown that they may be used for this purpose, and that decrease of them means diminution of coagulability. The investigation of the agglutinins is a promising field. In Malta fever slow development of agglutinins had been noticed as occurring in the more prolonged cases, and if after this fever or typhoid the agglutinin kept high a relapse was not likely to occur, but if low a relapse was probable.

Dr. Lorrain Smith confined his remarks to anæmia, on which he has made laborious researches. In anæmia from hemorrhage he finds there is a loss of oxygen capacity, *i.e.*, of hæmoglobin. It was not so in chlorosis. Many symptoms he finds due to increase of the volume of blood, and treatment should be directed to reducing it.

Dr. J. H. Drysdale said the red and white cells varied independently of each other, and protested against the common practice of comparative measurements. Percentages were useless. Blood from the periphery differed from that from the centre. Advance must come from clinicians rather than biologists.

Dr. William Hunter could not indorse Professor Wright's remarks on estimation of the corpuscles. Coagulation he admitted to be important, but so were other factors. He demonstrated by the lantern some of the changes he had investigated.

Dr. A. Whitfield said he had worked at the blood from the morphological standpoint, and he gave the results of his researches. He also referred to the work of Justus, who found that mercury given to syphilitics caused a sudden fall in hæmoglobin, followed by a steady rise to normal as the drug took effect. The fall did not occur in healthy subjects, so perhaps might serve as an aid to diagnosis. The statements of Justus had been confirmed by all who had experimentally investigated them.

THE FEEDING OF INTUBATION CASES.

To the Editor of the Medical Record.

Sir: Here is a difficulty: your patient coughs so much, the regurgitation is so great, that but little nourishment is retained; add to this the usual dislike for medicine, and it seems almost insurmountable. First, try this method, which, I think, when practicable, is always the best:

Lay the child on its back with the head hanging over the nurse's knee, or, if it is in bed, let the head hang over a pillow; then feed slowly with a spoon or medicine dropper; do not use a feeding-bottle unless the child has always used one, otherwise the nurse will first have to teach the child how to nurse from one, and time in those cases is always an object.

The purpose of feeding in this manner is simply this: The intubation tube is, of course, a foreign body, and the child in the act of swallowing cannot entirely close the epiglottis; hence the coughing, choking, and regurgitation caused by the fluids getting into the trachea. When the head is kept at a certain angle the food passes more directly into the œsophagus. Now this method, although very good, is not always successful; the choking and regurgitation may continue, and premature coughing up of the tube is a danger to be looked out for.

We have another resource—feeding by gavage. This method is really a life-saving one, but I hold it should be a last resource. A feeding-tube is used, which is similar to the tube used in giving enemata. Get a small rubber or glass funnel. Attach to it a piece of rubber tubing about four inches long, then a piece of glass tubing three inches long, and then the catheter. A rubber catheter, No. 7, is a good size unless the child is very young; then a smaller one may be used. The child is wrapped securely in a sheet and placed on its back on a table. Pass the catheter through the right or left nostril into the œsophagus, at the same time pinching the tube so as to exclude as much air as possible. This is not so difficult as it seems, if the child is held firmly and not allowed to struggle. Practice has proved that it is better to pass the tube through the nasal passage into the œsophagus than through the mouth. When the tube is passed through the mouth a gag has to be used, and the patient is likely to cough and struggle more. Do not pass the tube too slowly; remember how sensitive the parts are, and the tube causes a great deal of irritation, and passing it slowly only means prolonging the trouble.

Insert about eight inches of the catheter. The milk is used warm. Medicine may be given at the same time. When the fluid has passed below the glass tubing, pinch the catheter and withdraw it. The pinching prevents the small quantity of milk that has remained in the tube from dripping as it is withdrawn, and prevents further irritation.

Now it can be readily understood that this is not a pleasant operation for the patient, although I have seen children fed in this manner without the slightest resistance. The strongest argument in its favor is that it prevents the possibility of the fluid getting into the trachea and later on causing bronchial pneumonia; against it is the resistance of the patient and consequent exhaustion. Its use in private practice might be questioned, so for those reasons, unless it is a question of starvation, I advise other means being tried.

Never keep to any rule in those cases. Feed the child the way it takes it best. Every patient is a "law unto himself." There are children who have held the intubation tube for months, and were able to eat and drink as well as if the tube was not there. The patient is often able to swallow solid food when drinking is impossible. This is easily explained: dry particles of food cannot get into the trachea as readily as fluids.

Some one has suggested nutritive enemata. I say no. A nutritive enema can be given only to an intelligent patient, who knows why it is given and tries his or her utmost to retain it. M. D.

THE SALE OF PATENT MEDICINES.

To the Editor of the Medical Record.

Sir: Cannot some way be suggested for the concerted action of the medical profession against "patent medicines"? Their sale and the harm that they do are increasing every year, and, except for a feeble protest now and then from our superior medical periodicals, not a particle of resistance is attempted to the great inroads they are making upon the health of our citizens. It would be folly to introduce a bill into the legislature of any State governing the sale of patent medicines until the people are awakened to its necessity, and who is there to advise and admonish the people except the medical profession? As a profession should we not do all in our power to protect the public's health? Yet how many of your readers ever take the trouble to warn their patients of the dangers to be encountered in taking patent medicines, or any medicines, without the advice of a competent physician? Many physicians, I doubt not, laugh and joke and make light of patent medicines. Perhaps they think their levity will teach the absurdity of using them, but they are slighting their responsibilities when they let pass an opportunity to explain the innumerable dangers always risked by taking any drug, even a diarrhœa mixture, without being so advised by a physician.

The people of the State of New York, by their laws duly enacted at the capital and enforced at no little expense, demand to-day a thorough education in all the principles underlying the science and art of medicine and surgery before they grant a license to treat and prescribe for a patient, and if the same people knew the serious dangers of patent medicines would they not demand the laws and gladly expend as much from their treasury to prohibit the sale of such articles? If the public's attention was drawn to the fact that the laws protect them from ignorant doctors, but do not protect them from poisonous drugs or fraudulent medicines, would they not act, and act at once?

If as much ink as has lately been used by members of the profession in Pennsylvania in a controversy over whether the medical student should receive any credit for subjects pursued in an academic college, were used by these gentlemen in as able arguments for the protection of the public from the ignorant administration of drugs by means of patent medicines or by the drug clerks, much would be accomplished for the public safety.

Again, the profession would do the public and itself better service would it devote a little more exertion toward the regulating of the prescribing of drugs and medicines and a little less toward regulating the free dispensing of professional services.

The law at present upon the statutes of the State of New York, controlling the sale of poisonous drugs, even if enforced, is of little value. If a man has a pain, no matter where, or a cough, or trouble with his bowels or his kidneys, or in fact any trouble whatsoever with his bodily functions, he needs but to be able to go to the drug store, and his wants will be attended to by either the patent medicine bottle or some "just the thing" from the druggist's own bottles. Indeed a man confined to his bed may often receive treatment from a druggist by a friend's describing his ailment. What he receives may not be the direct cause of his death, and yet the delay in seeking professional aid may put him beyond the chance of recovery, and, furthermore, may have given him so many more hours in which to infect other people with typhoid or some other disease.

Since so much advertising is done in the interest of patent medicines, would it not be well to advertise more widely the ruin of health they may cause, and the dangers they exert in possibly inculcating opium, alcohol, or some other habit? A prize for the best article setting forth the dangers of using any drug, without first being advised by a physician, would call forth a number of publishable articles, which could be inserted in the newspapers and magazines. The medical societies could take this matter in hand and by systematic pamphleteering make such attacks as would demand attention from the public and result sooner or later in legislative action.

A suggestion which may be far from feasible, and yet may lead to some one offering a better idea, is this: Let a law be passed prohibiting the sale of any drug or combination of drugs for internal or external use, by any one whatsoever, except upon a written demand of a registered physician, a book of registered physicians to be kept by all druggists. The patent-medicine manufacturers would expend millions to defeat such a bill! Yes, but we are not afraid of the fight, when we are in the right. The druggists would combine against the passage of such a bill! Yes, probably. The people would say the profession was trying to form a trust! No, for the working of such a law would prove the contrary. The drug stores might each have a doctor, who would write for any drug desired! Well, he must be registered, and not many men so well educated as to have passed the necessary examinations would sell their services for dishonorable purposes; and if the drug stores kept proficient doctors behind their counters it would be a step forward at least. Prescriptions would be for sale at every drug store, all written and signed! Again, an educated, honorable man would not dare, or care to, sell a batch of prescriptions for indiscriminate distribution, and the law might be framed to forestall such an evasion.

One result that might accrue would be the customary practice for families, or even a houseful of boarders, hotels, etc., to have visiting physicians at a yearly rate, who would call regularly, practise prophylaxis, and advise upon all topics of health and hygiene. They would at times advise this or that member of the household to be examined by the oculist, aurist, the gynæcologist, or some other specialist. The specialties would be more popular, and the specialists would in consequence be more advanced. During severe illness the consultants would be more frequently called to the bedside. All headache powders, cathartics, etc., the family physicians would prescribe as needed, and no extra charge would be made. As the result of such a law, we would not take a prescription into a shop one quarter of which is given up to a soda-water and ice-cream counter, another quarter to toilet articles, and the shelves on both sides crowded with patent medicines. Pharmacy would become a much higher and more dignified profession than it is to-day, and the drug shop would be a much more respectable institution.

John Joseph Nutt, B.L., M.D.

San Diego, Cal.

RAIN BATHS.

To the Editor of the Medical Record.

Sir: In the issue of the Medical Record of May 12, 1900, I notice an editorial under the title of "An Absurd Claim and a Unique Exhibit," referring to spray or rain baths. Regarding the claims of Dr. Baruch or Mr. Goodwin Brown as to priority in the establishment of public baths I know nothing, but as perhaps pertinent to the subject I wish to make the following statement:

Soon after taking charge of the medical department of Clinton Prison, New York, in May, 1889, I became convinced that the only proper method for bathing a large number of persons was by means of the spray or rain bath, of which at that time I practically knew nothing. The idea was suggested to me by the necessity of preventing contamination from one person to another from tub bathing, especially when there was venereal disease; and also a necessity for a form of bath which would bring on rapid reaction, the circulation of confined men usually being of low pressure and altogether sluggish. I immediately began investigating the subject and agitating the necessity of constructing a bath-house in connection with this institution. Early in the year 1891 an appropriation of $18,500 was obtained from the legislature for the construction of a bath-house in connection with Clinton Prison. No sooner, however, did I attempt to introduce my ideas of spray and rain baths than I met with determined opposition on the part of some concerned in the construction of the building.

I could find no precedent to fortify my position, but fortunately for my cause I accidentally mentioned the subject to Mr. Goodwin Brown, who was then acting in the capacity of pardon clerk to Governor Hill. He immediately indorsed my idea as a feasible one, and stated that he was a warm advocate of this method for public baths. He gave me his earnest support in the matter, and the result was that a bath-house was constructed on the Roman plan of architecture and fitted up with nine rain baths and fifty individual sprays. The water for the sprays is driven with a pressure of eighty-seven pounds, and very finely subdivided; the spray rosette is large, giving a wide radius to the jet, and is attached to a flexible hose. The water is heated to any desired temperature by means of heaters attached to the water-supply pipe. The water used in bathing and all débris are washed down inclines to well-trapped sewers.

The bath proved to be a great success, and so far as I am able to learn is the first spray bath put into operation in connection with a public institution in this country. It attracted considerable attention, and many persons inspected it and approved the principle. Now I am aware that many similar baths are in operation in connection with institutions and are used for the purpose of public bathing.

I do not write this with the desire to prop up any claims of priority which Mr. Brown may have made, but simply in justice to the very efficient aid he gave me in this then experimental work.

J. B. Ransom,
Physician to Clinton Prison.

Dannemora, N. Y., May 21, 1900.

To the Editor of the Medical Record.

Sir: The articles on bathing recently appearing in the Medical Record, as to priority of public baths, whether shower or tub, might well be extended and thus put on record some other facts than have yet been published. The Charity Organization in October, 1893, opened its lodging-house at 516 West Twenty-eighth Street, and largely because of my personal insistence the baths were spray baths. We required also a system of disinfecting clothing, and determined upon constructing something quite different from any apparatus then to be seen. With the competent help in planning given me by our plumber, a hot-air chamber constructed after the manner of the cold-storage places (which gave me the idea) was put in and economically maintained at a temperature of 240° F. or more. All clothing was taken at the time the bather took it off and placed by him in netted bags designed for the purpose, and then the bags were hung on an elevated railway and pushed into the hot-air chamber, swinging perfectly free in the air. The clothing, after remaining there for at least two and one-half hours, was freed from vermin and vermin eggs.

To our minds no public baths are complete without such an arrangement for disinfecting the clothing. Our system of dry heat has been copied in several places outside the city, and has been always found satisfactory. It destroys all visible animal life. Two attempts to copy our system with modifications have been tried in this city, and have both proved dismal failures because of the introduction of steam into the process, thus wrinkling the clothing, because it is in those places (quarantine and department of charities) subjected to steam while under pressure. The result, besides the wrinkles, is to warm the eggs into life, and a worse condition than before obtains in forty-eight hours. With the dry heat, however, this is all avoided, and the bather is not only clean after his bath, but has a chance to remain so by putting on clothing that is also clean.

This is written more to place on record facts that may hereafter be of importance, than to claim any priority for any one.

Wickes Washburn.

Medical Items.

Sterilizing Water by Ozone.—In a method of sterilization of water by means of ozone described by Dr. Weyl, of Berlin, at the German scientific conference in 1899, water is pumped to the top of a tower and allowed to flow freely over stones, meeting as it falls a current of air charged with ozone. The process appears to be likewise effective in purifying peat and bog water, the solution of the iron of humic acid being decomposed and oxidized, and the brown color disappearing in consequence. The method, it is said, can be advantageously used in connection with filter beds. —*Appleton's Popular Science Monthly.*

Losses at Mafeking.—An official report from Mafeking as to the total casualties during the siege shows the following losses: Officers, 5 killed, 15 wounded, 1 missing; non-commissioned officers and privates, 51 killed, 103 wounded, and 25 missing. Of these 15 died from disease and 5 were accidentally wounded. Of Kaffirs 25 were killed and 58 wounded. Non-combatants, 4 killed, 5 wounded, and 32 died from disease. Among the natives 54 were killed and 117 wounded. The Baratongs had 128 killed and 122 wounded.

Military Surgery in the Boer Army.—The Berlin correspondent of *The Lancet* says that Professor von Esmarch has permitted the *Münchener medicinische Wochenschrift* to publish letters written by a former assistant, who is now medical officer to an ambulance with the Boer forces. Most of the wounds treated were caused by the Lee-Metford rifle. Simple wounds of the soft parts healed very well without suppuration except when the shot had been fired from a short distance. This seldom happened in fighting, but some Boers shot themselves wilfully with their own rifles to avoid military service. In these cases the wound of ingress was very small as in all other wounds of the soft parts; the wound of exit, however, was very large and the muscles were lacerated. It was an interesting fact, not from a surgical but from a psychological standpoint, that these accidents happened always a day before a battle was expected. Soldiers with wounds of the extremities continued to fight and were even able to ride to the dressing-tent without support. The majority of the Boers, however, when slightly wounded, seized the opportunity to withdraw from the battlefield. Dr. Küttner, another of the German surgeons at Jacobsdahl, in a letter addressed to Professor Bruns, of Tübingen, confirmed the opinion of the latter that the prognosis of the wounds inflicted by modern rifle bullets was good, and that conservative treatment was advisable. Wounds of the skull and brain were usually very serious and often required operative treatment, while wounds of the thorax healed very well. As to wounds of the abdomen, their prognosis was better than was supposed. A good many of them healed under expectant treatment without laparotomy, an experience in accord with that of MacCormac and Watson Cheyne. The results were not improved by laparotomy. Wounds of the liver were not observed at all, as the wounded died on the battlefield. Wounds of the kidney were more frequent and of a better prognosis. In a postscript the state of the wounded in General Cronje's laager after his surrender at Paardeberg is described. Owing to the want of surgical aid, the wounded had been ten days without dressings. The wounds were covered with tobacco leaf, and nearly all were septic. Many operations were, therefore, necessary, and there were many deaths from septicæmia and tetanus.

Number of Registered Physicians in the United States.—The actual number of registered physicians in the United States, according to the most recent count, shows an average for the whole of about one to 647 inhabitants, but the proportion in the States varies greatly. California appears to be the State which is most liberally supplied, the proportion there being one physician to 420 inhabitants, while in Iowa nearly the same conditions prevail. On the other hand, in North and South Dakota and New Mexico the proportion was respectively one to 1,285, 1,296, and 1,391 inhabitants.

Cremation in the United States.—Within the past twenty years the custom of cremating the bodies of the dead has obtained a considerable foothold in the United States, and several crematories have been built in different parts of the country. The first crematory was built by Dr. Julius T. Le Moyne, at Washington, Pa., in 1876, and was used for the disposal of his own remains. From that time to the present much has been written in America in relation to this safe and rational method of disposal. No more establishments for incineration were erected till 1884, but from 1884 to the present time twenty-six crematories have been established. In some instances laws have been enacted favoring the practice and placing it under proper restrictions. That the public sentiment in favor of incineration is steadily increasing is shown by the rapidly augmenting number of bodies submitted to this method of disposal. The following list furnished by Mr. Louis Lange, of New York City, shows the rapid progress which has been made in the establishment of crematories in the United States and in the number of persons whose remains have been incinerated in these since their introduction in 1876. In the eight years, 1876 to 1883, only twenty-five bodies had been disposed of in this manner, and all these were treated in the crematory built by Dr. Le Moyne at Washington, Pa. From that time the annual number increased to 1,699 in 1898, with a total of 8,885 in all up to the close of 1898, and at the present date the number has probably reached ten thousand.—"Public Hygiene and State Medicine in the United States," by SAMUEL W. ABBOTT.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended June 2, 1900:

THE OCCURRENCE OF MOULD IN THE STOMACH AND ITS PROBABLE SIGNIFICANCE.*

By MAX EINHORN, M.D.,

PROFESSOR IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, NEW YORK.

THE part which micro-organisms (bacteria and mould fungi) play in the occurrence of pathological processes in the stomach has been variously interpreted by authors. Most clinicians ascribe no special significance to them. Others, however, assign them a prominent place; thus, for example, Talma[1] maintains that the fermentation of carbohydrates induced by micro-organisms is the cause of hyperchlorhydria; others, again, place stress not so much upon the variety of these microbes as upon their ultimate number. Among these authors Naunyn[2] may be especially cited.

The mould fungus, as such, has been but little mentioned in the domain of gastric affections. In the following I shall give the different data which I have found in the literature:

Leube[3] writes as follows: "Usually yeast and mould fungi, sarcinæ, and the most diverse forms of bacteria are found. Inasmuch as all these fungi do not exert any direct deleterious influence upon the gastric mucous membrane, and as their presence in the diseased stomach does not materially interfere with a cure, the occurrence of fungi in the gastric contents must be regarded as rather accidental than as a symptom of certain pathological processes in the stomach. On the other hand, in very rare instances micro-organisms appear to be capable of exciting inflammation and ulceration of the stomach; but up to now so few observations from an anatomical standpoint have been made upon gastritis mycotica that it would be better to refrain from the exposition of a clinical picture and from a diagnosis of this condition."

De Bary[4] frequently examined the gastric contents for micro-organisms in seventeen patients suffering from gastric troubles, and found: thread fungi, oidium lactis (cases 1, 8); other forms, undetermined (cases 1, 3); mucor mycelia (cases 3, 4); leptothrix buccalis (cases 14, 17). In general, he determined that the thrush fungi and mould fungi are more infrequent.

Naunyn says: "I would mention the occurrence of mould fungi in the stomach, which I have found in two cases; one observation I made three years ago, the patient being a woman about forty years old with moderate dyspeptic disturbances and considerable increase in the width and depth of the stomach. After lavage had been performed twice the patient withdrew from treatment. The mould fungi, which were present profusely the first time, could be found only with difficulty in the wash-water the second time. The other case came under my observation about a year ago. Unfortunately I have not any notes in regard to it, and can only state that, if I recollect rightly, the mould fungi disappeared from the stomach contents after a single lavage, and that here no considerable mechanical gastrical insufficiency was present."

Boas[5] makes the following remarks relating to this subject: "Among the sprout fungi, the yeast fungi (at least in small quantity) are to be regarded as a normal constituent. The thrush fungus (oidium seu saccharomyces albicans), usually originating in the buccal cavity, is also occasionally met with. Furthermore, mould fungi (mucor forms) are found in small number, these being likewise of no essential pathognomonic significance."

The following pathological anatomical data found in Klebs' "Handbuch"[6] are also of interest: "A different condition prevailed in a mycosis of the stomach which was first observed by E. v. Wahl (*Virch. Arch.*, Bd. 21), then by Recklinghausen (*Virch. Arch.*, Bd. 30), since here the fungi penetrated into the ducts of the mucous glands. In the first case there were found, especially in the pyloric portion, numerous foci of the size of pin-heads, pustular nodules, partly of yellow and partly of red color, which occupied the glandular layer and extended to the submucosa; and in the second case there were in the fundus similar but somewhat larger foci with central necrosis. In this case the fungi were present both in the glandular tubercles as well as here and there in the tissue between them, so that they connected the ends of the tubes with one another. . . . In both instances the same variety of fungi was present, consisting of several fine threads, only rarely or not at all segmented, together with fine, minute granules occasionally arranged in rows in the form of a rosary—forms which therefore belong to the leptothrix group." Klebs attributes the necrosis to the proliferation of these fungi.

Eichhorst[7] expresses himself in a similar manner: "Oidium albicans does not frequently occur in the stomach. Reisz has described an instance in a girl eighteen years old. The mucous membrane was found to be covered with whitish, semiglobular granules up to a pin-head size, which at some points in the fundus ventriculi had coalesced into larger patches. Microscopically, the cylindrical epithelia were destroyed in some places, the mucous membrane being infiltrated by an abundance of round cells, but nowhere was there any entrance of the fungi into the blood-vessels. Besides the stomach, thrush fungi were found in the œsophagus. Rudnew has found penicillium glaucum in a woman who died from cholera, in the vicinity of the pylorus the fungi had penetrated abundantly into two small tumors. Naunyn also observed in two instances mould fungi in the stomach contents. Kundrat recently described, in the case of a man with favus universalis, the presence of favus colonies upon the mucous membrane of the stomach and colon, which had led to a croupous diphtheritic inflammation and to the formation of ulcers."

Grawitz[8] has succeeded by injections of aspergillus colonies into the blood-vessels in producing mycotic diseases of the kidney and liver. As regards the behavior of the fungi in the stomach, nothing, however, is mentioned in this work.

---

* Read before the American Gastro-Enterological Association on May 1, 1900, at Washington, D. C.

In all the literature cited, with the exception of the pathological anatomical data, the scant references to mould fungi in the stomach relate to the findings of microscopical examinations. Mould itself, recognizable by macroscopic examination, has, according to my knowledge, not as yet been observed clinically in the stomach. At any rate, no mention of this occurs in the literature. I have had occasion to observe several cases of mould formation in the stomach, and it seems to me worth the while to discuss the subject somewhat more fully. In the cases under my observation there were found in the wash-water of the empty stomach small, sometimes blackish-gray, and sometimes brownish-green flakes (2 to 5 mm. in diameter; see Fig. 1) in varying number (four to fifty and more). The microscopical examination showed that these flocculi consisted entirely of spores and mycelia and scarcely anything else. Similar flocculi were found in the same patients in the gastric contents after a test meal, and the microscope showed the same picture as in the flocculi from the empty stomach.

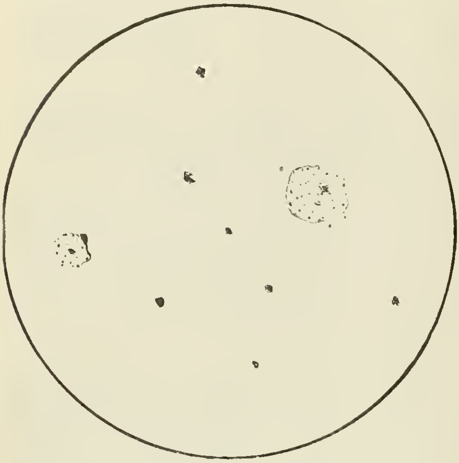

Fig. 1.—Small Pellicles of Mould found in the Stomach. (Natural size.)

Sometimes these blackish-gray masses are embedded in mucus. We then note besides these fungus colonies mucous corpuscles and numerous epithelial cells. This indicates an intimate connection between the fungus colonies and the surface of the mucous membrane. The former must adhere quite closely to the latter and perhaps even proliferate into the epithelial layer. This firm adhesion must be assumed for the following reasons: If the fungi were only an accidental admixture of the ingesta, that is introduced with the latter and then carried further onward, without there being any fungus proliferation, then they would be encountered only in the gastric contents after meals, but not in the fasting state of the patient, that is, when no food is found. As a matter of fact, however, in the cases referred to these flocculi occur in large number, principally in the empty stomach.

Are these mould fungi, present in the stomach, still in a living condition, or are they destroyed by the action of the gastric juice? In answer to this question it can be said that the mould colonies retain their full vitality and are capable of further development. If the flocculi are placed in some water or in the filtrate of the gastric contents of the patient it is soon noticed that there is a formation of whitish-gray clouds which are connected with the flocculi, and under the microscope we find spore colonies and mycelia very similar in character to the original mould.

After these introductory remarks permit me to describe in detail a few of the cases that have come under my observation.

Case I.—Hyperchlorhydria, with periodical continuous gastro-succorrhœa; October, 1899. William R——, thirty-eight years old, has suffered for four years with periodical vomiting of from two to four days' duration. While at first the attacks of vomiting occurred about once in four or five months, they increased to such an extent in the third year of the disease that they appeared every three to four weeks. Since then the patient has no longer felt well during the interval between the attacks, being constantly troubled, about two hours after meals, with intense heartburn and gastric pains; constipation was also present in a marked degree. The patient had lost about thirty pounds in weight. At this time he first came under my treatment. A careful examination showed the presence of hyperchlorhydria with continuous gastro-succorrhœa occurring periodically. He was placed upon proper diet and treated with sodium bromide and alkalies. During ten months he remained free from the attacks of vomiting, after which they recurred in the same manner as previously. The patient consulted me again during such an attack.

Status præsens: The patient appears well-nourished, but somewhat pale; nothing abnormal can be discovered in the thoracic organs; the gastric region is somewhat sensitive to pressure; the knee phenomenon is present; the urine is free from albumin and sugar. In the fasting state about 60 c.c. of gastric juice mixed with some bile is found. During the following irrigation of the stomach small greenish flakes in considerable number (about twenty to thirty) are observed in the wash-water. I first thought that these were small mucous flakes which had absorbed biliary coloring-matter, but the microscopical examination showed that this was not the case, but that the shreds consisted entirely of round spores and mycelia (Figs. 2 and 3).

Case II.—Hyperchlorhydria; February 18, 1900. T. M——, twenty-two years old, had suffered for six years with digestive disturbances; he was troubled with frequent belching; the tongue was always coated, and he often had a bad taste in the mouth in the morning. One-half to two hours after meals a feeling of burning frequently appeared in the pit of the stomach, and the patient had a sensation as if he had swallowed a foreign body. He also often experienced a raw feel-

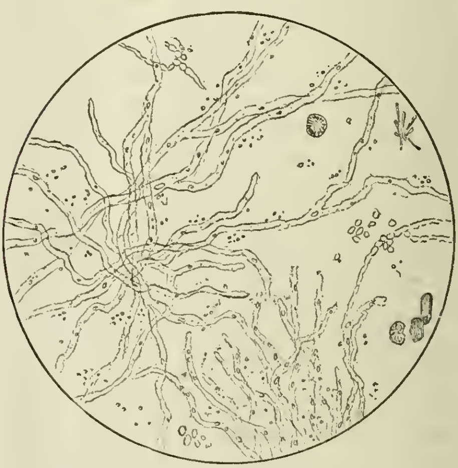

Fig. 2.—A Greenish Pellicle found in the Wash-water of the Stomach (of Wm. R——), in the fasting condition. Mycelia, free spores, and a few crystals are visible. × 240.

ing in the throat, with repeated hawking. The bowels were always regular; the appetite was good; there was no loss in weight.

Status præsens: The patient is of vigorous build and well nourished; the tongue is covered with a greenish-gray coating; the thoracic organs show normal conditions; in the abdomen nothing abnormal can be discovered; the knee phenomenon is intact; the urine is free from sugar and albumin.

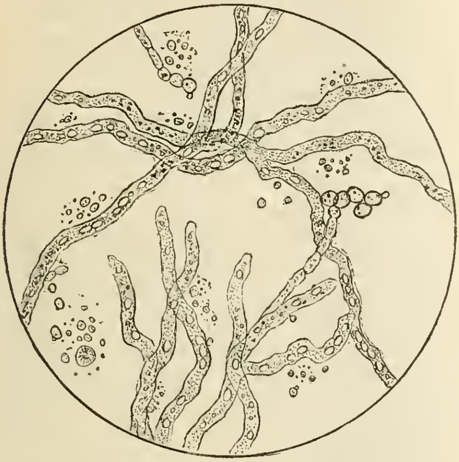

FIG. 3.—Same as Fig. 2, highly magnified. × 420.

Examination of the stomach one hour after the test breakfast shows: HCl +, acidity 76; free HCl, 56. The chyme contains small greenish flakes similar to parsley, in small number (about four such shreds on the filter). Macroscopically these presented the appearance of being either small particles of green vegetables or mucous flocculi which had taken up biliary coloring-matter. Microscopical examination showed, however, that these flakes represented mould fungi colonies, consisting of spores and mycelia (Fig. 4).

The patient was examined on the following morning in the fasting state; the stomach contained no ingesta, but a slight quantity (20 c.c.) of gastric juice. After lavage was performed the wash-water contained a considerable number (fifty to sixty) of the above-described greenish flakes; there was a small quantity of mucus.

The patient was treated with bicarbonate of sodium and with gastric irrigation, in connection with a spray of silver nitrate. His condition improved, that is, the subjective symptoms diminished, and about fourteen days after commencing treatment the irrigating-fluid contained either no greenish flakes or only a scanty number. A small amount of yellowish-brown mucus, however, is almost always present in the wash-water, and in this epithelial cells and spores (probably from fungi) can be demonstrated.

CASE III.—Hyperchlorhydria; March 15, 1900. George D——, forty-eight years old, had always enjoyed good health until about a year ago, when he began to suffer with digestive disturbances. At first the pains appeared some time after eating, and later they were now and then accompanied by vomiting. The appetite at the beginning was undisturbed, later impaired; the bowels were sluggish; frequently there was a sour taste in the mouth. During the course of the disease the patient had lost forty-five pounds in weight, and felt weak and restless.

Status præsens: The patient is of vigorous build, but appears pale and debilitated; the tongue is markedly coated; the thoracic organs are normal; examination of the abdomen discloses a slight sensitiveness to pressure in the gastric region, the presence of splashing sounds, which can be produced down to the navel, and the absence of any tumor. The knee reflexes are present; the urine contains neither sugar nor albumin.

Examination of the stomach one hour after the test breakfast shows: HCl +, acidity 104; free HCl, 80. In the fasting state the stomach is found empty. In the irrigating-water numerous mould flocculi are present, as determined microscopically.

The patient was treated for several days with gastric lavage and alkalies; in addition he was placed on a light diet, with frequent meals. His condition improved; the pains diminished; the vomiting ceased, and he began to gain in weight. After three weeks' treatment no mould pellicle can be discovered in the stomach.

CASE IV.—Gastritis glandularis chronica and gastric erosions; January 12, 1900. Leopold C——, twenty-nine years old, has been troubled for two years with dyspeptic symptoms, a feeling of pressure, and slight pains in the gastric region one-half hour after meals, frequent eructations and slight constipation. The patient has kept up a strict diet during this time, and has lost twenty pounds in weight, while the disturbances remained unchanged.

Status præsens: The patient appears pale; the mucous membrane of the lips and cheeks is anæmic; the tongue is only slightly coated; the thoracic organs are normal; palpation of the abdomen elicits a slight sensitiveness to pressure in the epigastric region.

Examination of the stomach one hour after the test breakfast shows: HCl +, acidity 24; a considerable quantity of mucus and two blackish-green flakes, which on microscopical examination are found to consist of spores and mould fungi. In the fasting state the stomach is found empty; the wash-water contains, however, an abundance of these mould floccules (twenty to thirty) (Fig. 5) and, besides, four small pieces of mucous membrane. The same finding was repeatedly determined, with the exception that after longer treatment, which consisted of gastric irrigation and spraying with silver-nitrate solutions, the mucous fragments and also the mould floccules appeared in lesser numbers.

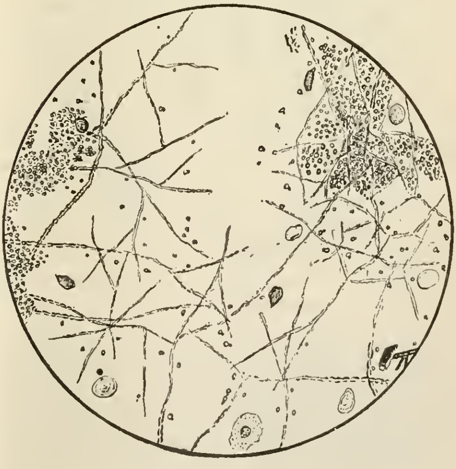

FIG. 4.—A Blackish Pellicle found in the Gastric Contents (of T. M——) after a Test Breakfast. Numerous spores, mycelia, a few crystals, starch granules, and epithelial cells are visible. × 140.

The patient felt better, was more vigorous, and experienced fewer disturbances. He is, however, not yet entirely free from his pains.

Aside from the above-described observations I have found mould in the stomach in two other instances: in one there was a decided hyperchlorhydria; in the other an atony of the stomach, with quite normal chemical processes and gastralgias. Both patients were not long under observation, so that I am not sufficiently informed as to the subsequent course of the cases.

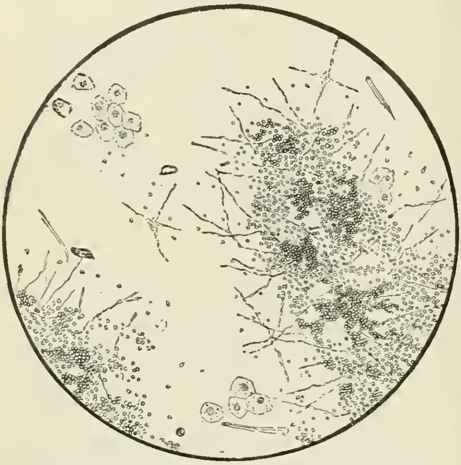

Fig. 5.—A Blackish Pellicle found in the Wash-water of the Stomach (L. C——), in the fasting condition. Numerous spore-colonies, mycelia, a few crystals, epithelial cells, and several algæ are visible. × 120.

That the grayish-green or grayish-black flakes, which were found, represented mould pellicles, was established beyond doubt by the microscopical examination. An extremely large number of spores and mycelia was always observed. In all my cases the microscopical picture was the same, and it can therefore be assumed that the mould fungi present belonged to one and the same species. In order to determine the latter point I gave a few of these greenish shreds to Dr. E. K. Dunham, and insert his report:

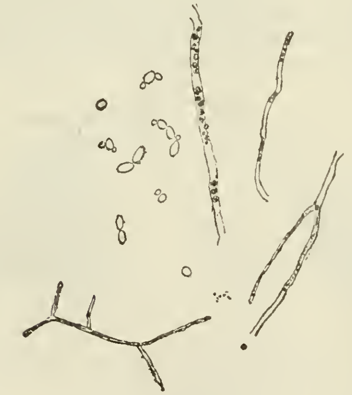

Fig. 6.—Oc. 2. Obj. $\frac{1}{12}$ oil, Leitz.

"New York University, Carnegie Laboratory, }
"New York, April 27, 1900. }

"Dear Doctor Einhorn: The specimen from stomach contents which you sent me for examination contained small particles of a dirty yellowish or greenish color. Under the microscope these particles contained granular material of indefinite character, from which mycelial threads projected into the surrounding liquid. The latter contained numerous round bodies which were considered to be the spores of some mould, but no signs of any fructification could be detected upon the mycelium. Attempts to cultivate the mycelium upon agar-agar, gelatin, milk-sugar, bouillon, and upon acidulated media yielded no fruiting mould. The original material was finally distributed over sterilized bread. Upon this medium, colonies of an aspergillus, a penicillium, and one colony of a mucor were obtained without difficulty. The penicillium appeared to be the common penicillium glaucum. The colonies of aspergillus were also green in color. Only the asexual spore-formation came under observation.

"I attach very little value to these observations, because bread cultures were not made until at least a week had elapsed after the material was received from you. There was a chance that the growths obtained were due to contamination of the material distributed upon the bread.

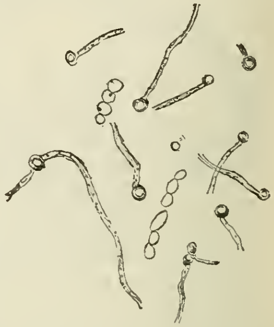

Fig. 7.—Oc. 2. Obj. $\frac{1}{12}$ oil.

"I enclose three drawings made from the original material with the aid of a camera lucida (Figs. 6, 7, 8).

"Yours very truly,
"Edward K. Dunham."

At this place I beg to express my indebtedness to Dr. E. K. Dunham as well as to Dr. Goldhorn for their labor.

If now we return to our cases in which mould fungi were frequently found in the stomach, the question comes up, What significance have these mould fungi in gastric pathology? Although isolated fungi may exist in the stomach for a short time without any detriment, they do not find in the normal organ favorable soil for further development. They are intimately mixed with the chyme and are carried onward, living or dead, through the pylorus. Entire colonies of fungi which are macroscopically perceptible are probably never to be found in the normal stomach. Any considerable growth of mould would be possible only if a colony of the fungi had infested a fold of the surface of the gastric mucous membrane and had become so firmly adherent that they were not carried along with the onward passage of the chyme. Under these circumstances a fungus colony may grow undisturbed, and considerable areas of the gastric mucosa may become covered with mould. In the above-described cases such a condition must have prevailed. In lavage of the stomach the inflowing current

Scale, 0.05 mm. Each division = 0.01 mm.

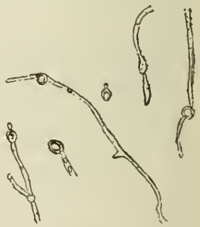

Fig. 8.—Oc. 2. Obj. $\frac{1}{12}$ oil.

of water exerts considerable force and tears many mould islets from their bases, so that they then appear in the wash-water.

It is scarcely conceivable that such a mould coating of certain zones of the gastric mucosa can be unattended with disturbances of the functions of the organ. Conditions of irritation as well as inflammatory processes might be expected *a priori* from the mechanical action of the mould.

After these theoretical conclusions it would be profitable to analyze more closely the cases that have been described, and to elucidate whether the mould formation was in a causative relationship to the symptoms of the disease. The decision of this question is, however, very difficult, because *post hoc* is not always the *ergo propter hoc.* I have met with the mould formation particularly in two groups of gastric affections: first, in cases of intense hyperchlorhydria (occasionally attended with hypersecretion and vomiting); and, second, in gastralgia with normal or reduced gastric secretion. It cannot be denied that in many of these cases the mould flakes became smaller in number or disappeared after gastric lavage followed by spraying with a one to two per mille solution of nitrate of silver. In connection with this a subjective improvement could be observed in the condition of the patient. Yet it cannot be said with certainty that the mould produced the existing pathological process in the stomach; for we find cases analogous in every respect without the presence of mould fungi. Notwithstanding this, it appears plausible that these mould fungi are connected to a certain extent with the above-mentioned abnormal conditions; and even if they are not the cause of these, they undoubtedly increase their severity.

The occurrence of mould in the stomach in large masses must, therefore, be considered of importance from a therapeutic standpoint; hence it must be our endeavor to free the stomach from them as soon as possible. This is best done by irrigation of the stomach in the fasting state of the patient. This acts in a purely mechanical manner, since the mould flakes are removed with the water. The use of the gastric douche might also have a favorable influence in this direction. Following this the application of an antiseptic solution of silver nitrate with a spray appears likewise of some utility. Aside from the therapeutic measures just described, the treatment of these cases must be directed in accordance with the special disease present.

Prostatectomy.—In lateral lobe enlargements, in perineal urethrotomy, a crescentic incision is made anterior to the rectum and well around it, the rectum being drawn backward and the prostate capsule incised. The prostate is drawn down into the wound by means of the finger and enucleation made with the finger of the other hand and scissors. The wound is packed, leaving in the bladder a large tube from the perineal wound for six days.—FREYER.

DIFFUSE SEPTIC PERITONITIS AND THE ELEVATED HEAD AND TRUNK POSTURE. A REPORT OF THREE ADDITIONAL CONSECUTIVE CASES OF RECOVERY.

By GEORGE RYERSON FOWLER, M.D.,
NEW YORK,
PROFESSOR OF SURGERY IN THE NEW YORK POLYCLINIC; SURGEON TO THE METHODIST EPISCOPAL HOSPITAL, ETC.

THE following is presented as an addendum to the report of nine consecutive cases of recovery of diffuse septic peritonitis published in the MEDICAL RECORD for April 14th, thus making twelve consecutive cases in which recovery has taken place under the combined treatment of cleansing the neighborhood of the original focus with hydrogen peroxide, through flushing of the abdomen with decinormal saline solution at 110° F., deep pelvic drainage, and the elevated head and trunk posture to facilitate the passage of fluids from the intestinal and diaphragmatic areas to the pelvic portion of the peritoneum. The special object to be accomplished by this posture, namely, that of removing the fluids from the dangerous areas mentioned to the comparatively safe region of the pelvis, together with the anatomical and physiological reasoning upon which this is based, are fully set forth in the article referred to.

CASE X.—March 15, 1900; Methodist Episcopal Hospital; female, aged seven years. The patient was admitted and operated upon on the tenth day of an attack of acute appendicitis. The expression was anxious. There were extreme abdominal distention and tenderness, with persistent vomiting. The conditions were believed to be complicated with intestinal obstruction of mechanical origin. A median incision was made. the operation revealed the small intestines deeply reddened and matted together with exudate; as these were separated large quantities of sero-purulent material flooded the peritoneal cavity. The appendix was gangrenous and perforated. It was excised; the primary focus was cleansed with partially neutralized hydrogen peroxide (diluted with equal parts of a saturated solution of sodium bicarbonate). The intestines were separated, cleared of lymph deposits wherever these were easily separable, and the peritoneal cavity was repeatedly flushed with large quantities of decinormal saline solution. A glass drainage tube was placed in the pelvis and led out of the lower angle of the incision.

After-treatment consisted of elevation of the head of the bed fifteen inches above the horizontal; an enema of saline solution every two hours. Vomiting ceased; flatus passed freely; the distention subsided. The glass drainage tube was removed on the sixth day, and substituted, on account of a reaccumulation in the pelvis, by one of rubber, which was finally removed on the fourteenth day. The head of the bed was lowered at the end of the second week. Recovery resulted.

CASE XI.—March 17, 1900; German Hospital; male, aged twenty-three years; perforative peritonitis of appendicular origin. The operation showed a large quantity of sero-purulent fluid; the peritoneum was deeply reddened, and extensive deposits of fibrinoplastic material were scattered over the entire area of the small intestine. The appendix was excised; the original septic focus was cleansed with partially neutralized peroxide-of-hydrogen solution; the lymph deposits were removed where easily detachable; the peritoneal cavity was flushed with decinormal saline solution at 110° F.; a glass drain was inserted in the pelvis.

After-treatment: The head of bed was elevated fifteen inches; stimulation with strychnine and caffeine; an enema of decinormal saline solution was given every two hours; fluids were administered by mouth *ad libitum.* No vomiting occurred after the patient was placed in bed. Flatus passed freely after six hours. The glass drain was forced out by an act of coughing at the end of twenty-four hours; it was not replaced. The elevated head and trunk position was maintained for six days. Staphylococcus was found in culture. Recovery resulted.

Case XII.—April 5, 1900; Methodist Episcopal Hospital; male, aged sixty-six years; perforative peritonitis of appendicular origin. Upon admission the patient presented the characteristic picture of diffuse septic peritonitis. Upon opening the abdomen, a quantity of sero-purulent fluid escaped from the peritoneal cavity. The intestinal coils were greatly distended, deeply reddened and mottled, and coated here and there with patches of fibrino-plastic exudate. It was with difficulty that spontaneous eventration through the abdominal wound was prevented. The appendix was perforated. Excision of the appendix was done; the original septic focus was cleansed with partially neutralized hydrogen dioxide; the peritoneal cavity was systematically flushed with decinormal saline solution. A quantity of the latter was permitted to remain in the cavity for the purpose of favoring peritoneal leucocytosis and immunity. A small supplementary opening was made through the abdominal wall in the left linea semilunaris, and through this a large and closely fitting glass drainage tube was passed to the bottom of the pelvis. The original operation wound was closed.

After-treatment: Elevation of the head of the bed eighteen inches; stimulation by strychnine and caffeine; aspiration of drainage tube every four hours; enemata of decinormal saline solution. Nausea and vomiting ceased at once; normal peristalsis was re-established and flatus expelled within twelve hours; a movement of the bowels was obtained by simple enema on the morning of the third day. The rigidity of the abdominal wall was replaced by the normal relaxed condition, and the peritonitic facies disappeared. The glass drain was removed on the fourth day, and its place supplied by a narrow gauze strip. Recovery ensued.

The following case is offered in addition. Especial points of interest present themselves in the case, for the reason that the abdominal symptoms absolutely disappeared, while a general septico-pyæmia persisted, which finally resulted in septic meningitis, from which the patient died on the thirteenth day following the operation. I am greatly indebted to Dr. H. A. Henriques, of Morristown, N. J., who, although not previously in attendance, assumed the care of the patient at my request, upon the supervention of the meningeal complication.

April 14, 1900; L. D——, aged fourteen years, of Morristown, N. J.; perforative appendicitis; third day of the disease. The patient presented the typical appearances of diffuse septic peritonitis, *i.e.*, anxious facial expression, purplish-red hue of surface (vasomotor paralysis), extreme distention, and rigid abdominal walls (barrel-shaped abdomen). There was paralysis of peristalsis. The stomach was absolutely intolerant; vomiting of brownish-green matter took place. The pulse was 160; temperature, 104° F. Abdominal section revealed deeply reddened coils of intestine floating about in a large amount of foul-smelling sero-purulent fluid with flakes of lymph; fibrino-plastic patches were present upon the intestinal serous surfaces. The appendix was gangrenous and perforated. Excision of the appendix was done; the region of the original focus of infection was cleansed with hydrogen dioxide undiluted, about twelve ounces being used. Considerable of the hydrogen-dioxide solution necessarily invaded the general peritoneal cavity. Forcible flushing was done with decinormal saline solution at 110° F. A large glass drainage tube was inserted to the bottom of the pelvis.

After-treatment: Elevated head and trunk posture; the glass drainage tube was aspirated every three hours until the third day, when it was removed, and a rubber drainage tube and a strip of iodoform gauze were substituted. Stimulation was effected by caffeine and strychnine. A saline enema was given every three hours; fluids *ad libitum.* The nausea and vomiting ceased at once. The bowels moved spontaneously three times within the first twelve hours, accompanied by the expulsion of large quantities of gas; the distention promptly diminished. The morale rapidly improved. The extensive general septic conditions which existed prior to the operation, however, persisted, although the abdominal symptoms rapidly subsided, save the occurrence of a small and well-walled-off secondary abscess in the left iliac region, which was evacuated by an incision in the left linea semilunaris on the ninth day. On the eleventh day symptoms of cerebral meningitis developed, with intolerance of light, vomiting, high fever, delirium, the temperature finally reaching 107.5° F.; there was stiffness of the neck due to contractions of the posterior muscles; alternate contraction and dilatation of the pupils occurred. The patient became comatose and remained so for forty-eight hours preceding the final lethal exit, which took place on the thirteenth day following the operation.

A word as to the method of flushing pursued in the last case: I believe, in spite of the assertion of Bode[1] to the contrary, that eventration or disembowelling adds increased risks to the operative procedure, and should be avoided, if possible. Heretofore the difficulty of reaching every portion of the peritoneal cavity with the irrigating-fluid and with the intestines *in situ* has been almost insurmountable. In the last case, I adopted an expedient for overcoming this difficulty by means of the following improvised means: The outlet tube of a large douche bag was cut away, and through the hole thus left in the bottom of the bag an ordinary curved and flanged abdominal glass drainage tube of large size was passed from inside the bag. The tube was then passed into the remoter portions of the peritoneal cavity at first, and, the bag being filled with the decinormal saline solution, the solution was forced from the bag by rolling the latter upon itself from above downward, the fluid rushing rapidly and forcibly from the end of the glass tube as this was moved about first in the region of the spleen and liver, and subsequently between the coils of intestine and about the root of the mesentery. Quantities of sero-purulent material, with flakes of lymph, were thus brought to the surface and flowed out of the operation wound with the returning fluid. The pelvic cavity was then flushed in a like manner, and finally a rapid washing away of what débris had been deposited about the wound itself followed. The bag was filled and then emptied again and again, until about eight gallons of the decinormal saline solution was used.

Finally, I desire to state that, in spite of the fact that the elevated head and trunk posture should, theoretically, throw additional work upon the heart in these desperate cases, this has not constituted a valid objection to its employment, in my experience. In case the patient fails to respond to the stimulation employed after the operation, however, there would be no objection to placing the bed in the horizontal position, or even elevating the foot of the bed during the first few hours, providing thorough cleansing of the peritoneal cavity had been done. Absorption of the relatively clean saline solution from the diaphragmatic and intestinal areas will do no harm, and may be of service in assisting the stimulation of the patient. A further argument in this connection is found in the fact that the presence of the saline solution in the peritoneal cavity favors a large local leucocytosis, which, according to the experiments of Durham and Issaeff,[1] results in a peritoneal immunity against pathogenic bacteria for a certain length of time. Unless persistent and progressive failure of the circulation is observed in spite of strychnine and caffeine stimulation combined with whiskey and saline enemas, however, it is better to place the patient in the elevated head and trunk posture from the commencement, since, in addition to its principal advantage, this posture secures early cessation of vomiting and the prompt expulsion of flatus.

DISEASE OF THE THORACIC DIVISION OF THE SYMPATHETIC CHAIN.[2]

By JOSEPH FRAENKEL, M.D.,

INSTRUCTOR IN NERVOUS DISEASES AT THE CORNELL UNIVERSITY MEDICAL SCHOOL; PHYSICIAN TO THE MONTEFIORE HOME; NEUROLOGIST TO THE CITY HOSPITAL.

THE physiology, pathology, and symptomatology of the sympathetic nervous system are admittedly still obscure. Undoubtedly some have found herein an inviting field for speculation, and others a not less welcome excuse for hasty and harsh criticism of attempts to elucidate the subject.

For centuries much ingenuity and labor have been spent upon this question by earnest investigators; but the results are so far very meagre indeed. The sum total of facts concerning the sympathetic nervous system that has been admitted into the text-books as permanent scientific acquisition is small. Most of the text-books refer to the sympathetic only incidentally and meagrely. In all, the familiar symptom groups of destruction or irritation of the cervical division of the sympathetic are described, with their bearing on the diagnosis and localization of disease of the nervous system. This last point is, however, often not so fully considered as it deserves to be.

Recently, affection of the abdominal division of the sympathetic chain has frequently been called upon to explain more or less obscure pathological states.

The discussion concerning the rôle that the abdominal sympathetic may play in the causation of Addison's disease, diabetes, colica mucosa, and similar obscure conditions is not yet settled.

Apparently the least is known about the thoracic part of the chain. It is known that from this part the great splanchnic nerve takes its origin, but the exact roots from which this nerve arises have not been definitely ascertained. Some writers (Quain, Gegenbauer) assign the origin to the fourth, fifth, or sixth dorsal, down to the ninth or tenth dorsal; others (Landois) to the sixth cervical down to the fifth dorsal ganglia. Further, it has been proven by experiments that lesion of the great splanchnic nerve may lead to death of the animal, through anæmia of the oblongata; the animal bleeding into its own blood-vessels as it were (Landois).

From a clinical standpoint, the only reference to the thoracic sympathetic to be found in the literature is in the first edition of Oppenheim's text-book, page 814, which reads: "In a very obscure case of abscess formation near the thoracic vertebral column, there was in life a unilateral œdema, which occupied the whole corresponding side."

The writer recently had the opportunity of observing a case, in many respects singular and remarkable, but particularly valuable as a contribution to the subject in question:

Mrs. B——, thirty-seven years old, married, was first seen July 25, 1898. She complained of headache, irregular sleep, pain in the upper part of the thorax of the left side and in the precordial region, and finally of attacks to be described more fully below. Her father died at the age of fifty-two years from Bright's disease; her mother is eighty years old and in good health, excepting occasional attacks of senile bronchitis. The other members of the patient's family, two sisters and two brothers, personally known to the writer, are in good health; all, as well as the patient herself, are somewhat undersized. Concerning the other branches of the patient's family, nothing definite is ascertainable.

Mrs. B—— was of temperate habits, rather reticent and quiet. When six years old, she fell from a second-story window, without apparent immediate or remote consequences. Menstruation began at the age of thirteen and had always been normal. The patient married at the age of twenty-three, against the wishes of her family, a man who shortly afterward began to ill-treat her, and who subsequently developed general paresis. Soon after her marriage, the patient claims to have "gone into a general decline," which the then attending physician called "uterine displacement and anæmia." Rest and treatment were followed by absolute cure after two months, and she remained well until the onset of the present disease, ten days previous to my first examination, *i.e.*, up to July 15, 1898.

The patient claims to have been free from venereal disease; she never had been pregnant; she states further that she was more or less nervous all her life, "as most women are," but emphatically denies ever having had what people call "hysterics." This latter statement is corroborated by the patient's sister.

The present disease developed without attributable cause, out of vague symptoms of general nervousness and irritability. These symptoms were unheeded, until a nocturnal attack frightened the patient and her family. About ten days previous to the date of her first visit, the patient awoke at midnight with a peculiar pain in the left upper extremity. This was soon followed by painful contraction of the muscles of this extremity, and later by contraction of the muscles of the left lower extremity. Then the right lower and finally the right upper extremities became painfully contracted. According to the patient's description, the hands assumed, during the spasm, the position characteristic of tetany.

The attack lasted about from three to six minutes, and terminated in a short laughing-spell; the patient felt exhausted and soon went to sleep again. Altogether three seizures of this type occurred during two weeks. Apparently there was nothing like an aura preceding these attacks. Furthermore the patient complained of headache, but of a different kind from those to which she had been subject during the greater part of her life. The latter headaches were apparently of a migrainous nature, coming once in six weeks, preceded by a general feeling of malaise that enabled the patient to foretell the attack, and most of the time accompanied by nausea and vomiting. These headaches were all over the skull, and of a throbbing character. During the few months preceding the illness which I am describing, this type of headache disappeared, and its place was taken by a more constant feeling of dull ache, with an occasional sharp paræsthesia on the top of the head (clavus—according to description). She has occasionally some paræsthesia of her throat; not distinctly a globus, though. The patient was nervous, depressed, and sleepless. She arose tired and claimed to be practically ailing all day; "if it's not one thing it's another." The appetite was whimsical, and occasionally attacks of uncontrollable vomiting occurred. Every autumn the patient used to cough for about two weeks, and she has a slight cough now. There were no hæmoptyses at any time; the bowels were and had always been regular. Micturition was normal. Menstruation was regular, copious, of three days' duration. There was no leucorrhœa. There were no subjective complaints of vision, although for some time she suspected that her headache might be caused by some ocular defect, and she was fitted with glasses.

---

[1] Byron Robinson: Annals of Surgery, vol. xxxi., No. 2, p. 223.

[2] Read before the New York Neurological Society, March 6, 1900.

Examination: The patient is of short stature, but otherwise well-built, without somatic signs of degeneracy. She is well nourished. The skin is of good color and free from scars. The hair is dark, streaked considerably with gray. The teeth are good. The pulse is 72, of normal qualities; respiration, 16; temperature, 98½° F. The tongue is clean, of normal shape and volume. Percussion and auscultation of thoracic organs, as well as percussion and palpation of abdominal and pelvic organs, reveal no noteworthy findings. Examination of urine and sputum is negative. Vision, hearing, smell, and taste are normal. The cranial nerves are normal. Motility and co-ordination of upper and lower extremities are undisturbed. Erb, Chvostek, or Trousseau phenomena could not be elicited. Scattered areas of analgesia and hypalgesia could be made out on the left side of the body, and a few areas of hypalgesia on the right side. Reflexes: chin and tendon reflexes of upper extremities were absent; patellar and Achilles jerks were present and fairly lively; interscapular and upper abdominal absent; lower abdominal and plantar present; pharyngeal reflex diminished; conjunctival and pupillary reflexes present.

The objective findings justified only one diagnosis; that is, hysteria. Accordingly this diagnosis was given to the patient and her family—although with very little satisfaction. It is the conviction of the writer that the simple clinical diagnosis, "hysteria," is often extremely unsatisfactory, as long as an organic point of exit is not detectable or there is not at least a sufficiently evident etiological factor upon which to rest an understanding of the condition. The therapy that the patient was advised to follow was, therefore, symptomatic and general only. She was advised to spend more time out-of-doors, to abstain from stimulants, to have a cold sponge bath daily, to avoid emotional excitement; and finally she was given a prescription for a mixture of bromide and valerian, to be taken internally.

After four weeks the patient returned, reporting slight improvement—in so far as only two other attacks had occurred since the last visit. Still she had many complaints. The search for the etiology was this time as futile as before, and thinking a premature menopause possibly at the bottom of the mischief, the valerian-bromide mixture was replaced by a mixture of bromide and ovarian extract.

On the 23d of September, the patient reported that she had been free from well-defined seizures, but that she was in general worse. Twitching and pain in the whole left side of the body were more or less constant, with considerable headache; sharp pain on the top of the head and over the left eye. This eye and the left side of face were swollen considerably on various occasions. Sleep was disturbed, and she was tired in the morning. She complained of pain around the heart, frequent and severe, and of "fainting-like feelings around the heart," with tingling and formication in the left upper extremity. Objective examination was as above.

Very little change occurred in the patient's condition until April, 1899; that is, nine months after the onset of the disease. She had called at my office from time to time, complaining constantly, and putting stress at one time upon the one and at another time upon several of the above-mentioned symptoms. The chief complaints were headaches, disturbed sleep, attacks of vomiting, pain in cardiac region, and attacks of stiffness in the left upper extremity. A variety of therapeutic procedures in vogue for these troubles were tried, but all in vain.

On April 17, 1899, the writer was summoned to the patient's house. She then was in bed, and stated that she had become very ill during the last few days. She was much prostrated and complained about everything in general, and in particular about considerable weakness, absolute loss of sleep during the last two nights, and very severe pain around the upper left thorax. The appetite and digestion were fair; the bowels moved; she passed urine; she had no cough. Temperature was 99° F.; respiration, 28; pulse allorhythmic (counting in the first sixth of a minute 20, in the second sixth of a minute 14, and in the third sixth 12), averaging about 130 beats in a minute, otherwise of normal qualities. Physical examination was absolutely negative, excepting for the above-mentioned sensory disturbances. The family was told that all this might be but an aggravation of her original disease, although the slight elevation of the temperature, the peculiar behavior of the pulse, and the localized thoracic pain, and particularly the permanence of these symptoms, did not exactly fit into the picture, but were on the other hand so vague as not to permit of more definite interpretation. She was given some indifferent acid mixture, and assured that she would soon feel better, and she was encouraged to get out of bed soon. Thirty-six hours after that, it became necessary to see the patient at midnight, because she was reported to have become very much worse. She then stated that she did not have a minute's sleep during the preceding four days, and that she was suffering indescribable agony. Temperature was 103° F.; pulse, 120, of good qualities; respiration, 32. The tongue was slightly coated; the bowels were constipated. Urine was passed, and a specimen examined showed an excess of phosphates, but was otherwise negative. Percussion and auscultation of thoracic organs were negative; the heart, however, was pushed upward, and at the base a loud systolic murmur was heard. Astonished at this finding, considerable attention was paid to it, and its existence established beyond a doubt. It was thought that the cardiac murmur was in all probability due to the mechanical displacement of the heart by the distended stomach, but nevertheless the fever and the murmur seemed to call for salicylic acid; so this was prescribed. Further physical examination revealed considerable gaseous distention of the stomach.

Of the reflexes present, the patellar reflexes were somewhat weaker than on former examinations. Sensibility was as above. The patient evinced considerable weakness in standing or walking, but there was no actual motor paralysis.

To the family the findings of this evening were reported, and the view expressed that a definite diagnosis could not be made, and that all these symptoms occasionally occur in the course of a severe hysteria. The next morning the patient looked very much brighter and reported that, "After the first powder" (gr. x. of salicylate of sodium) "I slept all night." Thorough physical examination was absolutely negative. No trace of a heart murmur was audible; the bowels moved; the pains subsided. She was left in charge of the nurse and advised to continue taking her medicine. By the evening the clinical picture had undergone a most remarkable transformation. The patient was in a state of acute collapse. She was pale, covered with perspiration, the features were pinched, and in an aphonic voice she said, "I am very much better." The head was drawn to the left side; considerable tachypnœa, enormous tympanitic distention of the abdomen, and weakness of lower extremities were present. Temperature, 100° F.; pulse, 120. The nurse reported that the patient had voided involuntarily but small quantities of dark, badly smelling urine, and that she had vomited a few times some fluid intermixed with small black particles, not of fecal odor. The nurse was certain that considerable flatus had passed. A thorough examination could not be made, and the patient was given some cardiac stimulants. This remarkable change could not plausibly be explained to the family as being a continuation of the original disorder, as it was very difficult to familiarize them with the differential details between a genuine and a hysterical or dynamic ileus.

The necessity of getting surgical advice was considered, but before the final decision was reached the patient died.

Dr. Van Gieson, to whom I am indebted for the following notes of the post-mortem examination, was asked to perform the autopsy. I said to him that clinically the case presented the picture of a grave hysteria, and that the autopsy might reveal a severe organic lesion of the sympathetic chain, on account of the severity and fatality of the case.

Autopsy: Body of a woman, apparently thirty to thirty-three years old. About one-third of the hair over the frontal region had turned gray. The remainder of the black hair was only sparsely streaked with gray. External inspection of the body disclosed no abnormalities. The body was fairly well nourished, even plump. The diaphragm on the right side stands at the fifth rib, on the left side at the fourth intercostal space. The pleural cavities contain no fluid. The pericardial sac is normal. It contains about two ounces of clear limpid fluid. The heart is normal. The muscle is firm and the valves are normal. The left lung has on its posterior surface near the apex a thin pellicle of fresh fibrin about 3 cm. long and 1 to 1½ cm. wide. The substance of the lung is normal, excepting a slight degree of œdema and a moderate amount of emphysema. The right lung is in a similar condition. The pellicle of fresh fibrin on the posterior surface near the apex is a trifle less extensive. The bronchial glands and bronchi are normal, likewise the arch of the aorta, thoracic aorta, and œsophagus.

The four upper thoracic sympathetic ganglia of the left side and the intervening trunk are buried in a mass of purulent material from beneath the parietal pleura. The right inferior cervical ganglion is also surrounded by purulent material. The details of this involvement of the sympathetic are as follows: On the left side, the subpleural purulent mass is centred about the second intercostal space and its posterior terminus. From this point the purulent mass extends for a slight distance upward, for a greater distance downward, and also laterally along the second intercostal space (see diagram). In its lateral course the pus collection occupies about the posterior quarter of the second intercostal space, burrowing under the parietal pleura, and elevating it above the surface of the ribs, as a tense bulging, yellowish, opalescent membrane, of about the size of a pea. When the elevated pleura over the second space was cut, thick yellowish-white pus flowed out. The pus collection extends downward to the lower border of the fourth rib. It does not, however, in the downward extension, reach out under the pleura, along the ribs or intercostal spaces, but is confined to the left lateral surfaces of the vertebral bodies. The inferior tongue of the pus collection lies in the angle made by the junction of the ribs with the vertebral column, and partially fills up this space. The pus lies beneath the pleura and has stripped the membranes up from the bodies of the vertebræ to a point above one-quarter of the circumference of the bodies. The upper tongue of the pus collection occupies the same position with respect to the vertebral bodies and extends to the upper margin of the first rib. The depth of this abscess is on the average about ½ cm. There were no evidences of a recent reactive inflammation in the neighborhood. Thus it can be seen that a portion of the left thoracic sympathetic chain is buried in this flattened, linear, subpleural abscess. Indeed it seemed impossible to dissect out the sympathetic chain, as it passed through the abscess. Above the abscess, the inferior cervical and the first thoracic ganglion were free and distinct; below the pus mass, the fourth thoracic node, and the remainder of the chain down to the great splanchnic cord and semilunar ganglion, were free and normal; but the intervening segment was left hidden in the pus collection and thickened pleura, and hardened *en masse*. On the right side the thoracic chains and its nodes seemed from macroscopic inspection to be perfectly normal, yet when the inferior cervical was cut across a drop of pus oozed out from the region immediately surrounding the capsule. Apparently this thin layer of pus, enveloping the capsule of the right stellate ganglion, had ploughed its way downward, along the cervical cord, from some source in the neck, for the pus showed no track of communication with the abscess of the opposite side, and section of the cord above the inferior cervical ganglion still exuded scanty traces of pus. Unfortunately, just as we were about to trace out the cervical sympathetic, to determine the source and extension of this thin layer of pus enveloping the inferior cervical node, we were forbidden to continue the examination. The autopsy occurred at a private house, and the examination of the sympathetic was deferred until the organs could be studied first. The abdominal viscera are in general normal, and while attentively examined do not need individualized description for each organ. The general peritoneum is smooth, lustrous, and perfectly

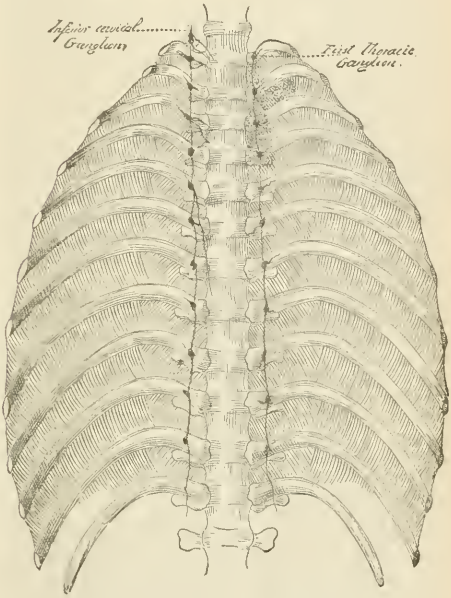

FIG. 1.—Interior of Thoracic Cavity, Showing Involvement of Sympathetic by Collections of Pus in Inferior Cervical and Upper Thoracic Ganglia.

normal. There are positively no naked-eye evidences of peritonitis, neither is there any collection of fluid in the pelvic or abdominal cavities.

The hollow viscera with smooth muscle walls, such as the stomach, intestine, and bladder, uniformly exhibit a long, flabby condition and are seemingly distended a moderate degree, as, for instance, especially the stomach and bladder. The liver, spleen, suprarenal capsules, pancreas, mesenteric lymph nodes, uterus, ovaries, and vagina seemed normal. The diaphragm has its natural arch, and the large abdominal vessels are normal. Volvulus was looked for but not found. The lumbar sympathetic cord was examined in detail on either side, and found normal. The left aortico-renal plexus was also partially dissected out on the right side, as well as a sympathetic trunk entering the left suprarenal capsule.

The semilunar ganglia are normal except that the one on the right side has attached to the middle of its upper surface a small, yellowish, cheesy nodule, about 2 mm. in diameter. Just above, and to the right of the right external iliac artery, apparently one of the deep inguinal lymph nodes is swollen and cheesy. Further examination was not permitted.

Anatomical diagnosis: Subpleural abscess involving the left second and third thoracic sympathetic ganglia and thin capsule of pus enveloping the left inferior cervical ganglion; localized apical acute fibrinous pleurisy; pulmonary œdema. The thin pellicle of fibrinous exudate under the apex of each lung seems plainly secondary to the contact of those surfaces to the pus collections on either side involving the sympathetic.

Microscopical examination: The right inferior cervical ganglion is surrounded by a zone of leucocytes about 1–2 mm. thick, which shows very plainly to the naked eye. Many of these leucocytes show various stages of degeneration and disintegration, and throughout the zone are great numbers of cocci of two kinds: one, the predominant form, apparently staphylococci, is grouped in clusters, while the other, seemingly streptococci, are arranged in chains or linear series. A number of bacilli are also present, resembling morphologically the colon bacillus. This zone of pus cells runs out in thin strings or stouter cords and gets into the fat tissues surrounding the ganglion. Bundles of nerve fibres, branches of the ganglion, are also surrounded by envelopes of pus cells, extending often some little distance from the ganglion itself. Thus the zone of pus cells extends out among the branches of the node, and along the main trunk of the cervical chain. The substance of the ganglia, however, is not infiltrated by the pus cells or bacteria, nor have they even penetrated into the outer layer of the capsule. The ganglion cells are not destroyed or diminished in number; on the other hand, they are normal as to arrangement and distribution. The internal structure of many of these cells, however, is abnormal. These cells, composing probably fifteen to twenty per cent. of the entire number, seem plainly degenerated; their central portions are bereft of granules, and remain clear after staining with Nissl's reagent, although the periphery still retains a number of plaques, one or two rows in thickness. The nucleus of such cells has an eccentric position, although its internal structure appears unchanged. The pigment contents of the cells do not seem abnormal in amount. The semilunar ganglia and second and third right lumbar nodes have also been examined, with the result of disclosing only a very few cells indeed of the degenerated variety mentioned above. Not over two or three can be found in a section.

We have, on the one hand, an array of symptoms which individually and collectively are often components of the clinical picture, hysteria. The general morale, the headache, the disturbed sleep, the vomiting, precordial pain, the hemianæsthesia, the contractures, the fugitive œdema, and finally the tympanites and pseudo-ileus, are known to be occasionally constituents of hysteria. The occurrence of hyperpyrexia and a fatal issue in pure and genuine hysteria is debatable. There are just as many authoritative voices in favor as against the first, and concerning the latter it may be stated that fatal hysteria is not altogether an unheard-of thing. It is true that I have been able to collect only about fourteen cases of fatal hysteria from the literature, and that none stood a thorough critical test. However, I have in my own experience seen two cases of death in hysterical patients under similar conditions to the above-described case. At any rate it seems to me that hysteria was the only possible clinical diagnosis that could be made of this case.

On the other hand, the anatomical findings are at first sight rather bewildering. Unfortunately, the anatomical examination could not be made so exhaustive and thorough as the importance of the case seems to have called for. But it is safe to assume that neither the brain nor the cord could very well be called upon to explain our clinical picture. To me at least it is unknown that a lesion of brain or cord could produce this kaleidoscopic symptomatology, except a severe injury to the cord. Still even so, the symptoms would naturally have been more stable, and finally in the given case such a supposition is entirely out of the question.

We have then practically a cold abscess of the rib, which accidentally involved the thoracic division of the left sympathetic, as an anatomical basis for the described symptoms, and have to answer, with these facts at hand, the following questions:

(1) Are the last scenes of the clinical picture necessarily a continuation of the first act, or mere expressions of the accidental localization of the given anatomical lesion, and in no connection with the original symptoms for which the patient sought relief?

(2) Supposing the above clinical picture to be a continuous one, is there any causal relationship between the clinical symptoms and the gross anatomical findings?

In the present state of our knowledge of the anatomy and pathogenesis of hysteria, and the anatomy and physiology of the sympathetic, it would seem very dangerous to attempt to answer these questions without thorough and extensive study, which, however, must be postponed for another occasion. For the present, it is best to accept the verdict of the Roman judges, "n. l.," *non liquet.*

Nephritis in Chickenpox.—Hans Haenel says that nephritis as a complication of varicella is not so very rare. Henoch was the first to observe these cases. The affection is usually of a mild character, very seldom fatal. It seems that the complication of varicella with nephritis depends greatly on the character of certain epidemics, as the author observed six cases of varicella, three of which were complicated with renal disease. One of the cases was of unusual character, and is therefore worth mentioning. A child one year old, recovering from an attack of pertussis and broncho-pneumonia, was affected with high fever, which lasted for eight days. The physical examination was negative. On the second day the examination of the urine showed quite an amount of albumin, hyalin and granular casts, and red blood corpuscles. On the tenth day there was a new rise of temperature, which was followed by a scanty but characteristic varicella eruption. The author is of the opinion that the primary nephritis was one of the prodromal symptoms and is inclined to think that the abortive eruption was due to the early elimination of the poison through the kidneys.—*Centralblatt für innere Medicin*, May 19, 1900.

Some Points in Connection with the Etiology and Treatment of Diabetes Mellitus.—Alexander W. Beck says that while nothing is as yet definitely known, it seems highly probable that in many cases diabetes is due to bacterial influence. This is based on: (1) The non-existence of uniform lesions after death; (2) the occurrence of the disease between certain ages; (3) the occurrence of the disease in more than one member of the family at the same time; (4) the occurrence of the disease in certain races, and its endemic form in certain countries. Nine cases are cited as treated upon the theory of bacterial origin. The bromide of gold and arsenic is well thought of, but the chloride of gold and sodium proved a pronounced failure.—*International Medical Magazine*, May, 1900.

Unusual Condition of the Skin and Kidneys following an Operation for Appendicitis.—W. G. Taylor reports a case in which the removal of the diseased appendix was followed by severe pain in the incision. Two subsequent operations by removing an adhesion attached to the under surface of the scar involving the omentum relieved the pain, but nutritional disturbances followed, and finally the kidneys, skin, and bowels showed evidence of disturbed function. The specific gravity of the urine went as high as 1.100; this the author considered due to glycogen. It is probable that as a result of shock to the organic nervous system the digestive tract suffered first, and no doubt primarily the liver. The stomach undertook to eliminate the imperfectly absorbed food stuffs, causing anorexia and irritability. Amenorrhœa and obstinate constipation were additional means of retention, but finally skin, kidneys, and bowels came to the rescue, and the patient recovered, although she is not in perfect health.—*Buffalo Medical Journal*, May, 1900.

Rupture of the Œsophagus Caused by Vomiting.—Bowles and G. R. Turner recently reported to the Royal Medical and Chirurgical Society the case of a woman aged sixty-two, who after purging herself with aloes and rhubarb became sick on taking some milk and then took a tumblerful of salt and water to "clear the stomach." The vomiting caused by the latter was followed by epigastric pain and collapse. There were retraction and some rigidity of the upper abdomen, vomiting having ceased on the occurrence of the collapse. She was partially quieted by morphine, but as she threw off the effects of the opiate her distress and pain returned and emphysema of the neck set in. Death came twenty-two hours after the attack. Autopsy showed, one and one-half inches above the diaphragm, a longitudinal rupture of the œsophagus five-eighths of an inch long, with thin edges and no peeling of the mucous membrane. The authors analyzed the literature of the subject, having been able to find on record the histories of some sixteen similar cases.—*Journal of Laryngology*, May, 1900.

Some Illustrations of the Clinical Significance and Importance of Decubitus.—J. O. Affleck describes the various postures characteristic of diseases of the respiratory, circulatory, alimentary, and nervous systems, a study of decubitus being most valuable to diagnosis. Even in fevers, he says, it is a good sign to find the patient lying on his side, particularly if that attitude is assumed spontaneously, testifying as it does to a fair measure of muscular strength; while on the contrary, when the patient lies on his back and tends to sink down low in the bed, it is regarded as an evidence of great debility, and often of evil omen. One serious accompaniment and result of this latter posture is the condition known as hypostatic congestion of the lungs. Taking the hint from this, it is often excellent practice in attending a case of long-lasting fever or debilitating disease, to have the patient occasionally moved round on one or the other side, so as to prevent blood stasis in the posterior parts of the lungs.—*The Scottish Medical and Surgical Journal*, March, 1900.

Comparative Anatomy of the Pharynx in Vertebrates.—C. Chauveau studies the development of the pharynx among branchial vertebrates, cyclostomes, elasmobranchiates, teleosteans, batrachians, reptiles, crocodiles, birds, and mammals. His study is of special interest as showing that the human embryo in its various stages of development successively presents practically all the varieties of pharynx enumerated as occurring in the various lower orders above mentioned.—*Annales des Maladies de l'Oreille, etc.*, April, 1900.

Case of a Peculiar Form of Dwarfed Growth.—John Thompson reports the case of a little girl aged four years, whose height was only twenty-eight and one-half inches, her weight twenty pounds and seven ounces. The body was well nourished and fairly normal, and the child was in good proportion. Intelligence was good. The administration of thyrocol caused slightly increased growth for ten months, after which it ceased to have effect. The child suffered from seizures the nature of which was obscure, but which finally proved fatal. At the autopsy the only abnormal conditions discoverable were great congestion of the brain, and the persistence of a greatly enlarged but otherwise healthy thymus gland.—*The Scottish Medical and Surgical Journal*, March, 1900.

Salol in the Treatment of Smallpox.—Charles Begg found that the administration of this drug kept the patient free from all sense of irritation without the slightest desire to scratch. This prevented exhaustion from sleepless nights and drain to the system from weeping vesicles and pustules torn by scratching, and avoided danger to the eyes from soiled fingers. Secondly, all the vesicles terminated as vesicles, and the stage of maturation was absent except in a few isolated vesicles. The author has not observed any evil effects from a daily dose of ʒ i. continued for long periods, and the slight mental depression sometimes caused at first quickly passes off with discontinuance of the drug.—*The Scottish Medical and Surgical Journal*, March, 1900.

Disturbances of the Sympathetic System in Lobar Pneumonia.—J. Eason, out of fifty-four cases of lobar pneumonia, found twenty-four patients with unequal pupils, the inequality being due to unusual dilatation of one pupil. Twenty-one of these had the large pupil on the side on which the signs of pneumonia were detected. The author suggests that the condition of the pupils may be explained by the irritation which the pneumonia causes to that part of the sympathetic system which is known to act as the dilator of the pupil. These fibres are said to pass from the first, second, and third dorsal nerves to the inferior cervical ganglion, and in their course must be intimately related to the lung at its uppermost part. This would explain why apical pneumonias appear specially liable to cause inequality of the pupils. There are other indications that the sympathetic in this region is irritated in pneumonia, as the flushing and pallor of the face, and in some cases a distinct though not very great protrusion of the eyeball.—*The Scottish Medical and Surgical Journal*, April, 1900.

MEDICAL RECORD:
A Weekly Journal of Medicine and Surgery.

THE ANTI-VIVISECTION BILL.

THE question as to the need or morality of that form of investigation known as vivisection has been the cause of more acrimonious discussion during the past twenty years in Great Britain, and within the past four or five years in this country, than of any other subject connected with experimental research. The men who experimented on animals and those who agreed with these methods of gaining knowledge have been characterized as inhuman, "without bowels of mercy," and maligned and slandered in every possible way. In Great Britain the anti-vivisectionists have been so far successful as to obtain the passing of an act restricting the practice of vivisection, which has, however, by no means had the effect of quenching the ardor of workers in this branch of medical science, although undoubtedly it has caused delay, annoyance, and loss of time.

In the United States during the past three years the opponents of vivisection have been busy, and have, as is well known, introduced into Congress, from the District of Columbia, a bill during that period under the sponsorship of Senator Gallinger, with the object of placing obstacles in the way of experimental animal research. However, scientific men in this country, judging that they had been supine in the matter long enough, and fearing from the favorable consideration accorded to the bill by the committee on the District of Columbia, that it might be allowed to slip through without the true bearings of the question being clearly understood, prevailed upon the committee to give to advocates and opponents of the "anti-vivisection" bill a public hearing.

At this meeting, which took place on February 21st, friends and enemies of the bill presented their views, and speaking without prejudice it may be asserted that the vivisectionists had distinctly the best of the argument. Of the statements made, those of Professor Welch, of Professor Bowditch, and of Dr. D. E. Salmon were perhaps the most instructive. Dr. Welch defined the situation and the attitude of the majority of scientific men in regard to it accurately when he said: "However much the advocates of the bill may assert that its enactment will not interfere with the proper uses of experimentation upon animals, and is designed only to check abuses, it is to be noted that the main part of their argument is an attack upon the practically unanimous opinion of well-informed scientific and medical men that experimentation upon animals is essential to the advancement of physiology and medicine, and has conferred inestimable benefits upon mankind. Nor is it surprising that anti-vivisectionists should cling tenaciously to this position, indefensible as it has become, for it is apparent that those who are convinced of the great value of experiments upon animals to science and humanity will hesitate long before approving any legislation likely to check the progress of scientific and practical medicine." And, again, he points out that there is no need for additional legislation restricting the practice of animal experimentation in the District of Columbia. The existing law permits only "properly conducted scientific experiments or investigations, which experiments shall be performed only under the authority of the faculty of some regularly incorporated medical college, university, or scientific society." The result of this discussion was that on March 9th an amended bill was printed for the committee, the only important changes in which are that cold-blooded animals are excluded, two classes of special certificates are omitted, and a freer hand is given in the selection of anæsthetics. Some of the restrictions are made more severe, and the most obnoxious features, in the eyes of its opponents, are unaltered.

President Eliot, of Harvard University, writes on the new bill and on the subject of the restriction of vivisection generally as follows: "This bill is a slight improvement on its predecessor, but is still very objectionable. I beg leave to state very briefly the objections to all such legislation: (1) To interfere with or retard the progress of medical discovery is an inhuman thing. Within fifteen years medical research has made rapid progress, almost exclusively through the use of the lower animals, and what such research has done for the diagnosis and treatment of diphtheria it can probably do in time for tuberculosis, erysipelas, cerebro-spinal meningitis, and cancer, to name only four horrible scourges of mankind which are known to be of germ origin. (2) The human race makes use of animals without the smallest compunction as articles of food and as laborers. It kills them, confines them, gelds them, and interferes in all manner of ways with their natural lives. The liberty we take with the animal creation in using utterly insignificant members of them for scientific researches is infinitesimal compared with the other liberties taken by us or the people who cry out against the infliction of any suffering on animals on behalf of mankind. It is of course possible to legislate against an improper use of vivisection. For instance, it should not be allowed in secondary schools or before college classes for purposes of demonstration only; but any attempt to interfere with the necessary processes of medical investigation is, in my judgment, in the highest degree inexpedient and is fundamentally inhuman." In respect to Senate Bill 34 its most serious defect is that it delegates to men who are ignorant of medicine and science authority to arbitrarily dictate concerning these matters. It places in the hands of two laymen who constitute the majority of the District commissioners the duty of deciding whether certain experiments upon animals shall be undertaken in the District of Columbia. There are other clauses of the bill which are unnecessary, but the one just referred to must strike any unprejudiced individual as absurd.

In regard to the stand now being made against vivisection, the fact should be remembered that all scientific progress has ever been obtained in the teeth of bitter and unreasoning opposition, and it could not be expected that a method which so powerfully appeals to the popular imagination and lends itself so easily to the creation of distorted views should escape the common fate. The public at large have in the nature of things no accurate knowledge of the manner in which experiments on animals are carried out, and consequently the imagination runs riot and pictures to itself the scientific laboratory as the scene of the most grewsome happenings. The belief is widespread—and this fallacy is unfortunately fostered and encouraged by many educated but prejudiced persons—that in in all, or at any rate the majority of instances in which animals are experimented upon torture is inflicted upon them. Any one who is intimately conversant with the subject knows well that such is not the case, and that while there is no doubt that vivisection has at times been abused, and perhaps on occasions is abused now, in the United States it is invariably conducted upon as humane lines as possible. Of course no scientific man would contend that even under existing conditions and as aided by anæsthetics pain is not sometimes inflicted upon animals undergoing operation for experimental purposes. But attention may be drawn to these facts: First, that no animal feels pain as man does—the higher the organization the greater the capacity for feeling pain; and secondly, that it is only pain given needlessly and uselessly that is cruel. Pain given for beneficent reasons cannot be termed cruelty. There is yet another point in the plea for vivisection which does not appear to be appreciated at its full worth by the opponents of the method; that is, the benefits which have accrued to the human race from experimental animal research. It would not be too much to say that almost every discovery of permanent value in medicine and surgery had its origin in experimental investigation. Charles Darwin some years ago made use of these words: "I am fully convinced that physiology can progress only by the aid of experiments on living animals. I cannot think of any one step which has been made in physiology without that aid." There has been no proof that vivisection has been abused in this country, and therefore it would seem that more restrictive vivisection regulations than at present exist would be both unnecessary and tiresome. Sir Michael Foster, in a letter written to Professor Hodge, of Clark University, in 1890, expresses himself as follows: "I have always said, and always shall say, that the necessity of a restrictive law has never been shown. The English commission failed to demonstrate any abuse such as could justify the measures adopted, and from what I know of America and Americans I am confident that no such laws are needed with you. Indeed my objections to the act as a politician are quite as strong as my objections as a physiologist; the act is stamped with that mark of bad statesmanship, meddlesomeness." This will probably be the opinion of the majority of medical and scientific men.

OUR REPORT OF THE AMERICAN MEDICAL ASSOCIATION.

We take a commendable pride in referring our readers to our exhaustive report of the meeting of the American Medical Association. Although we reported the proceedings in full up to the date of going to press, there was not an hour's delay in the delivery of the journal. Aside from the accuracy of the report, the time of its presentation is a matter for gratification.

Without attempting to make any invidious comparisons, we feel warranted in stating that the Medical Record stands alone in this respect, so far as the timely publication of the proceedings is concerned. We regret to notice that several of our contemporaries that pride themselves on being rivals in this method of journalism have been quite behindhand in this respect. One, from which we might naturally expect the most, as being the official organ of the association, has no report at all for the last week, save that of the president's address, which, of course, was furnished in advance. Another journal, in order to make a fuller report, delayed its edition, which, of course, is not prompt journalism as understood in this age. Still another journal had no mention at all. We say this much only in plea for modern, progressive journalism based on fair business principles, which consists in giving the most news up to the latest date of going to press, and not delaying the publication for mere convenience of what is mistakenly called generous rivalry in journalistic enterprise.

NEW THEORIES OF PLAGUE PROPAGATION.

The apparently mysterious manner in which the bubonic plague spreads itself to distant and widely separated localities gives becoming interest to any new theories explaining such methods of propagation.

When it is considered that much of what is now known concerning the character of the scourge has been learned since 1894, when the specific bacillus was discovered by Kitasato, the profession can congratulate itself that very much has been accomplished in solving many of the apparent problems which attached themselves to propagating qualities of this direful scourge. The isolation of the plague microbe was the first step in this direction. Then followed the various experiments by numerous observers, in connection with inoculation tests and the more minute and careful examination of autopsical lesions as bearing upon their relations with symptoms and the way in which the disease spreads in accordance with the modern views of pathology.

So far it may be definitely stated that the plague bacillus is the specific cause of the disease. This has been abundantly proved by the usual bacteriological methods of isolation of the micro-organism, its cultivation, its inoculation into animals, the transmission of the bacillus through their bodies, and its final recovery from the dead victims. The latest theories of the propagation of the disease are quite exhaustively presented in the work of Dr. José Verdes Montenegro,[1] of Madrid, who in connection with other important studies of the disease has summarized his experience with the Oporto epidemic.

The rat is acknowledged to be a chief factor in the dissemination of the disease, as this animal is peculiarly liable to infection through the intestinal canal and is notoriously migratory in his habits. Montenegro asserts that the plague is simply a disease of rats which infects man. According to the observations of Simon, the epidemic among rats follows a course analogous to that in man. After a period during which the cases are not very frequent the plague becomes suddenly very severe with a consequently increased mortality. Thus it happens that before the disease attacks man large numbers of dead rodents are found in the houses and streets of a threatened district. This was the case in Mandvi, where the street arabs amused themselves by using the dead animals as missiles in play.

Curiously enough Simon has discovered that preceding the rat in initiative causative influences comes the rat flea, which appears to have the real credit of starting the humble bacillus in its ambitious tendencies for better company. Simon says that a healthy rat has very few fleas on it, but the sick animal becomes very soon covered with them. The insects become gorged with bacilli and transfer the disease not only from one rat to another, but also to man.

While this very ingenious theory might explain quite satisfactorily why some sporadic cases appear in widely separated localities, it does not seem capable of accounting for the actual explosion of an epidemic which is evidently due to the varied conditions of human infection. It must be admitted with all our recent knowledge on the subject of propagation of the disease gained by those who have had large experience with the plague, that we have not yet arrived at safe or definite conclusions upon the subject. Whether or not the disease is contagious or infectious, whether or not it depends upon soil or house contamination, we certainly know one thing—that an epidemic when once started burns like a devouring fire madly reaching for available fuel. The epidemic influence, whatever it may be, gives the virulence of the disease a new force and a new purpose. If we rule out the latter condition and confine ourselves to the study of isolated cases, the conclusion seems almost irresistible that the real danger of directly communicating the disease from person to person is very much exaggerated.

It does not appear to be distinctly contagious in the sense in which that term is now used. There is great probability, however, that it is markedly infectious under certain circumstances of careless contact. This is most frequently manifest in cases of autopsy in which the operator becomes infected through accidental wounds coming in contact with the blood and secretions of the corpse. Two of Kitasato's assistants acquired plague that way. The experiences in the Vienna laboratory, still fresh in the minds of medical men, were on parallel lines. It is quite assuring to know, however, that physicians, nurses, and undertakers who come most in contact with plague cases are seldom stricken when proper aseptic precautions are taken. The danger appears more in the direction of actual contact, actual and direct transmission of virus, than by any other means. But a most ready means of transmission of the disease is by house infection, which by many high authorities is considered to be the underlying and controlling factor in all widespreading epidemics.

Regarding human infection the same laws govern as in similar communicable diseases. With plague the most direct avenue of infection appears to be by inoculation or by the transference of the germ to the nasopharyngeal mucus. Next in order come wound infection, contact with articles of soiled clothing, utensils of sick-room, sputum or dejections generally, and, last and perhaps least of all, constantly breathing the air of the sick-chamber. It is by no means proven that the intestine can be infected as in typhoid, as numerous experiments on animals have proved the negative side of this question.

News of the Week.

Sir John William Moore.—Among the recipients of knighthood conferred in honor of Queen Victoria's birthday is Dr. John William Moore, president of the Royal College of Physicians of Ireland, and editor of the *Dublin Journal of Medical Science.* Her Majesty's advisers might have searched the United Kingdom over without finding among the members of the medical profession one more worthy of this honor.

Dr. Pilcher a Doctor of Laws.—Among the June honors from the colleges may be especially noted the degree of LL.D. conferred by Dickinson College upon Dr. Lewis Stephen Pilcher, of New York, the editor of the *Annals of Surgery.* Such an honor to a distinguished American surgeon is particularly appropriate upon the part of an institution of which Benjamin Rush was one of the founders and for many years an active trustee.

Thirteenth International Medical Congress.—Dr. Henry Barton Jacobs, secretary of the American National Committee, writes that, according to instructions from Dr. A. Chauffard, secretary-general of the Thirteenth International Medical Congress, no subscriptions to the congress will be received after the 15th of July, and the name of no subscriber will appear in the official programme whose subscription is not received before the 15th of June. The publications of the Congress will consist of seventeen volumes, one of which will be sent gratuitously to each subscriber; that is, the volume containing the papers of the section under which he has inscribed himself. The other sixteen volumes may be purchased at a price of 4 francs per volume, or 45 francs for the series.

---

[1] "Bubonic Plague: Its Course, Symptoms and Means of Prevention and Treatment," by Dr. José Verdes Montenegro, Ex-interne Central University of Medicine and Professor at Municipal Micrographical Laboratory, Madrid. Translated by W. Munro, M.D., Medical Officer St. Kitts, W. I. New York: William Wood and Company. 1900.

Dr. John V. Shoemaker, surgeon-general of the Pennsylvania National Guard, and acting president of the trustees of the Medico-Chirurgical College of Philadelphia, has been appointed a director in the Department of Charities and Correction of Philadelphia.

The Lucien Moss Home for Incurables of the Jewish Hospital, at Philadelphia, was formally dedicated on June 10th. The building, which cost $50,000, is an exceedingly fine fire-proof structure. It is forty-eight by one hundred and thirty-four feet in size, and constructed of stone, brick, and terra-cotta, with a roof of slate.

University of Pennsylvania, Medical Department.—Dr. J. William White has been elected Rhea Barton professor of surgery and Dr. Edward Martin and Charles H. Frazier clinical professors of surgery. Dr. Richard M. Pearce has been elected demonstrator of pathology, and Drs. William F. Hendrickson and Frederick H. Howard assistant demonstrators of pathology.

Tuberculosis Declared Infectious.—The board of health of Trenton, N. J., has placed pulmonary tuberculosis on the list of infectious diseases which must be reported by the physician in charge. The latter is allowed thirty days in which to make this report, failing in which he is liable to fine or imprisonment. When reporting existing or suspected cases the physician must forward sputum in receptacles which are to be furnished by the board of health, in order that in case there is any doubt cultures can be made. Hospitals are not exempted from the general provisions. After the death of a tuberculous patient the bedding, clothing, and other articles which may have become infected must, if possible, be destroyed by fire.

The International Congress of Obstetrics and Gynæcology is unfortunate. The third congress, held last summer in Amsterdam, was boycotted by German gynæcologists who had taken umbrage at some action of the estimable Dutch gentleman who presided over the deliberations of the assembly. The fourth congress, it has been announced, will be held in London in 1902, under the presidency of Professor Simpson, of Edinburgh, and now we learn from *The Hospital* that the past and present teachers of gynæcology and obstetrics in the metropolitan medical schools now practising in London have decided with quite an interesting unanimity to boycott this congress. "This they do in sorrow, as a protest, not against the distinguished professor, but against the manner and source of the invitation. . . . That an international congress should be held in London and should be 'bossed' by the non-elect was too much to be borne." In view of the present disjointed condition of the medical profession, our contemporary remarks, "it is somewhat instructive to note the sort of thing which is capable of producing an absolutely unanimous action in any group among its members, an action so unanimous in this case that the letter in which the boycott was announced was, we believe, signed by every member of the set."

A Study of Alcoholism in Germany.—The Prussian minister of education, Dr. Studt, has recently ordered the government bureau of statistics to collect material regarding the effects upon the nation of the abuse of alcoholic beverages.

Smallpox is reported from several places in Massachusetts, near Westport and New Bedford. The board of health of the latter has ordered all the local mill managers to exercise caution in giving employment to help from Fall River and Westport.

A Temperance Congress.—The World's Temperance Congress has been in session in London this week under the presidency of the Archbishop of Canterbury. The archbishop delivered an address at the opening of the congress on Monday, and on Thursday entertained the members of the Congress at a garden party at Lambeth Palace. The lord mayor, A. J. Newton, gave a reception to the delegates on Friday. A leading feature of the programme was a grand cosmopolitan temperance meeting, over which the Earl of Carlisle presided. Many Americans took part in the deliberations and discussions of the congress.

The Philippine Association of Acting Assistant Surgeons, U.S.A.—The first annual meeting and banquet of this association was held at the Paris Café, Manila, on May 1st. The toastmaster was Dr. Harry Morell. This association was formed on April 28th on board the United States steamer *Grant*, on which seventeen of the members of the society came over to the Philippines to administer relief to the sick and wounded soldiers. The following were elected officers of the association: *President*, Dr. H. W. Beal; *Vice-President*, Dr. H. Morell; *Corresponding Secretary*, Dr. R. M. Inglish; *Recorder*, Dr. H. M. Stromberger. *Members*—Drs. F. M. Baker, L. P. Bell, H. P. Belt, C. R. Byars, J. A. Collie, C. L. Hodgkins, L. P. Howell, G. L. Marcion, J. N. Merreck, J. L. Norris, C. R. Ohliger, J. J. Reilly, E. R. Rockhill, W. H. Spiller, S. A. Springwater, R. M. Thornburgh, E. M. Trook, and C. E. Ward. It is the intention of the association to enroll as members all the acting assistant surgeons in the Philippine Islands and hold a meeting and banquet on Dewey Day every year in the future.

An Incident of the Tuberculosis Congress.—The following amusing tale regarding the congress for the study of tuberculosis, held recently in Naples, is related in *The Practitioner*. The members of the congress "were expected to wear a badge, besides carrying a little token showing them to be entitled to all the privileges of membership. Both the badge and the token were described as works of art which members would be proud to display. But nothing seems to have been said as to any official costume. The dress-coat is recognized in Italy as a kind of ceremonial vestment which must be worn on solemn occasions. It may easily be imagined, therefore, that when a considerable number of foreign members presented themselves without having on the regulation garment, the native mind suffered a serious shock. The 'undressed' strangers were refused admission, and when they attempted to assert what they considered their rights, they were promptly ejected by the arm of the civil power in the form of policemen. So hot was the fray that the police called firemen as auxiliaries! Thereupon the excluded ones retired to a neighboring hostelry bearing the suggestive name of Gambrinus; here, under the inspiration of the beery *genus loci*, they drew up a formal protest against the injustice and indignity to which they had been subjected."

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending June 9, 1900. June 2d.—Passed Assistant Surgeon A. M. D. McCormick detached from the *Montgomery* and ordered to the *Chicago*. Assistant Surgeon J. R. Whiting detached from the *Chicago* and ordered to the *Montgomery*. June 6th.—Passed Assistant Surgeon W. C. Braisted ordered to the *Massachusetts* immediately. Passed Assistant Surgeon L. L. von Wedekind detached from the *Richmond* and ordered to the *Indiana* immediately. Pharmacist S. W. Douglass ordered to additional duty on the *Massasoit*.

The American Electro-Therapeutic Association.—The tenth annual meeting of this society will be held at the Academy of Medicine in this city on September 25, 26, and 27, 1900, under the presidency of Dr. Walter H. White, of Boston. The chairman of the committee of arrangements is Dr. Robert Newman, 148 West Seventy-third Street, New York. The secretary of the association is Dr. George E. Bill, 255 North Street, Harrisburg, Pa. The subjects announced for set discussion are "Electricity in Gynæcology and the Present Reluctance of Gynæcologists to Use Electricity," and "Electricity in Tuberculosis and the Present Modes of Treatment."

The Late Dr. Landon Carter Gray.—"The members of the New York Neurological Society wish to record their profound sorrow at the untimely death of Dr. Landon Carter Gray. As one of the earliest members of the society, he was ever zealous in its behalf, and during many years of his activity added much to the interests of its meetings. His work was characterized by care and thoroughness in preparation; his thoughts were soberly presented in the light of a large clinical experience, and his conclusions were those of a sound thinker. In every line he wrote, and in every word he spoke, there was evidence of broad culture and refinement. He was a kind friend to many, disposed to help those who sought his counsel, and was always ready to allow for honest differences of opinion.

"*Whereas*, The members of this society have sustained a severe loss in the death of their honored friend and colleague; be it

"*Resolved*, That this acknowledgment of Dr. Gray's estimable qualities be recorded in the minutes of the society, and that a copy of these resolutions be sent to the New York MEDICAL RECORD, the New York *Medical Journal*, and the *Medical News*."

B. SACHS, M.D., C. L. DANA, M.D., FREDERICK PETERSON, M.D.

Dr. Edmund C. Wendt, of this city, recently gave a reception at the Hotel Cap, Paris, in honor of the United States commissioners to the Exposition.

Turkish Medical Students in Trouble.—The students in the military medical school of Stamboul recently rebelled against the system of supervision to which they are subject. Ninety of them have been arrested, and will be brought before court-martial.

Dr. John Wyllie, who was recently appointed to the chair of medicine at the University of Edinburgh, left vacant by the death of Sir Thomas Grainger Stewart, is said to have been the only one of the numerous candidates who did not back up his application with a stack of testimonials.

Another Testimonial to Dr. Jacobi.—The dinner of the Section on Diseases of Children of the American Medical Association, which was held at the Hotel St. Charles, Atlantic City, on Tuesday evening, June 5th, was made the occasion for the presentation to Dr. A. Jacobi of a handsome loving-cup and engrossed testimonial from the section.

Obituary Notes.—DR. JAMES T. WHITTAKER, of Cincinnati, died at his home in that city on June 5th of cancer of the intestine. He was graduated in medicine from the University of Pennsylvania in 1866, and from the Medical College of Ohio in 1867. During the civil war he served for a time as a private in the army, and later as acting assistant surgeon in the navy. After graduation he studied for a time in Berlin and then began the practice of medicine in Cincinnati. He was professor of theory and practice of medicine in the Ohio Medical College, and was attending physician to the Good Samaritan Hospital and to the Cincinnati Hospital. Dr. Whittaker's contributions to the literature of medicine were numerous and important.

DR. MELANCTHON STORRS, of Hartford, Conn., died in that city on June 9th, from a septicæmia contracted during an operation. He was a graduate of the Yale Medical School in 1853. During the Civil War he served as brigade surgeon on the staff of Gen. Edward Harland, and at the close of the war took up practice in Hartford. He was a member of many local, State, and national medical societies.

DR. PAUL GIBIER, of this city, was killed in a runaway accident near the medical institute of which he was the head, at Suffern, N. Y., on June 9th. He was born in France on October 9, 1851, and was graduated in medicine from the University of Paris in 1884. He was for several years an assistant at the

Pasteur Institute. His first public work was the study of cholera and of Ferran's preventive inoculations in Spain, and in 1888 he was sent by the French government to Havana to make a study of yellow fever. On his way home he spent some time in this city, and a year later returned here to reside permanently, opening a small hospital for the preventive treatment of rabies. Later he built a large sanatorium in the upper part of the city, but a few years ago moved the institution to Suffern. He was a chevalier of the Legion of Honor.

Dr. Robert Locke, of Chicago, committed suicide in the Occidental Hotel, San Francisco, on June 9th. He was a graduate of the Rush Medical College. Some time ago he was sent to the Philippines as a government press censor, but ill health forced him to return, and it was shortly after his arrival that he shot himself.

Dr. G. R. Chambers, a dentist in Vineland, N. J., died on June 4th, of apoplexy. He was sixty years old.

Dr. Valerius Idelson died recently at Bern, Switzerland. Dr. Idelson was an expatriated Russian, and was for many years a contributor to American and European journals of reviews of Russian medical publications.

Progress of Medical Science.

New York Medical Journal, June 9, 1900.

The Treatment of the Opium Habit by the Bromide Method.—A. Church says that the purpose of this plan of treatment is to stupefy the patient utterly for a number of days, during which time the opium is rapidly withdrawn and the physical disturbance secondary to its withdrawal is recovered from. The drug should be given only in the daytime, gr. cxx. of sodium bromide in half a tumbler of water every two hours, until an ounce is given in the first day. The second day a smaller amount is given in the same way, and this may be sufficient, or it may be necessary to continue the doses in the same way on the third day. Three deaths occurring in twelve cases, although in each instance attributable only remotely to the bromide, and occurring when the bromide had been used in extraordinary doses, doses that can no longer be advised, show that the plan of treatment is very far from being simple and without danger.

Æstivo-Autumnal Fever in New Orleans, Summer and Autumn, 1899.—H. A. Veazie concludes a series of articles, the object of which has been to prove that the fever outbreak in question was malarial in nature and had nothing at all to do with yellow fever. The articles are of interest chiefly from their bearing on various sanitary questions concerning the locality in which the fever occurred.

Ethylic Bromide as an Anæsthetic for Short Operations.—This agent is commended by P. F. Sondern, who gives a brief description of its effects and of the proper method of administration. Nothing new is presented.

Abstract of President's Address Delivered at the Fifty-first Annual Meeting of the American Medical Association, Held at Atlantic City, June 5-8, 1900.—By W. W. Keen.

The Collection, Preservation, and Transportation of Clinical Material for Laboratory Examination.—By S. Hart.

Some New Traction Apparatus for Hip Disease, Pott's Disease, etc.—By R. T. Taylor.

Journal of the American Medical Ass'n, June 9, 1900.

Neurasthenia and the Rest Cure.—Frederick A. McGrew distinguishes three varieties of neurasthenia—developmental, overstimulation, and developmental plus overstimulation neurasthenia. In some individuals asthenia is a prevailing factor from the cradle to the grave. The developmental neurasthenic is usually a woman of healthy appearance who complains of chronic fatigue. This patient needs exercise, not rest. In the class of overstimulation neurasthenia belong individuals, mostly men in middle life, whose baneful habits end in exhaustion of their inherited nervous vitality. The rest cure is here the treatment *par excellence*, combined with massage, etc. The developmental and overstimulation elements may be combined, either predominating. The degree of nerve strain necessary to precipitate an attack is in inverse ratio to the degree of developmental weakness. In those cases in which loss of weight, dyspepsia, headache, neuralgia, and other symptoms indicating a failure of nutrition accompany a history of recent nervous overstrain, the rest cure is the best thing, preliminary to subsequent treatment, to develop nerve vitality as indicated above under the first class. On the other hand, with patients who have succumbed to a slight overtaxation of the nervous system, the overstimulation element may be disregarded altogether, and treatment for the development of nerve force instituted at once; it is with this class that a sea-voyage or a sojourn among the mountains proves most beneficial.

Improved Methods and Details in the Care of Patients during Surgical Operations.—T. B. Turck gives methods of preventing infection from the skin with hands, instruments, sponges, etc.; of preventing the skin from becoming contaminated, by the use of an improved laparotomy sheet made from thin rubber dam fitted close to the body. A similar arrangement for shutting off the peritoneal cavity is figured. A thin rubber cylinder is employed to protect against leakage around a drainage tube inserted within it. Another device is a thin rubber hot-water bag placed within a gauze pad to apply heat to the viscera; a temperature of 48° C. is that found most useful. Hot rubber sponge pads are figured, and hot-water-coil slippers for application to the foot-soles especially in preventing shock.

Intralaryngeal Insufflation.—Rudolph Matas gives details of a procedure for the relief of acute surgical pneumothorax. He concludes his article with a history of pulmonary insufflation as applied to the surgery of the chest, presenting drawings of bellows, insufflating-tubes, etc. The features of the apparatus presented by the writer are that the original O'Dwyer cannula is modified so as to be used as a respirator, tampon cannula, anæsthetizer, tractor of the larynx and tongue, insufflator, and as an aspirator. In total extirpation of the tongue, etc., the value of an apparatus which will permit of easy respiration while the larynx is securely plugged, can be readily appreciated.

Address of Chairman, Section on Practice, American Medical Association.—By George Dock.

President's Address, American Medical Association.—By W. W. Keen.

Typhoid Fever among American Soldiers in 1898.—By V. C. Vaughan.

Philadelphia Medical Journal, June 9, 1900.

Criticism in Medicine.—George Dock finds a discouraging fact in the waning influence which medicine has over the layman. While the science is becoming more candid and more accurate, the grossest delusions flourish and the ridiculous claims of half-crazed brains find believers by thousands. This is an age of little respect for authority. Healthy scepticism can do no harm, and it is well to remember that with all our great advances there are still about us some relics of mediævalism. It is often impossible to distinguish the wares of the professor of chemistry or pharmacology from those of the modern seekers after the philosopher's stone. Commercialism is largely responsible. He fears that false prophets will last long into the twentieth century.

Conclusions Reached after a Study of Typhoid Fever among the American Soldiers in 1898.—By Victor C. Vaughan.

Gastric Ulcer: Non-Perforating Hemorrhage.—By William L. Rodman.

The Endowment of Medical Colleges.—By W. W. Keen.

Gastric Hemorrhage.—By W. L. Rodman.

The Boston Medical and Surgical Journal, June 7, 1900.

A New Intra-Abdominal Method for Retroverted Uteri.—George W. Kaan says that in all cases of retroverted uteri the round ligaments, with the peritoneal covering, are elongated, and his method consists simply in puckering them upon a gathering string, and so shortening them that the uterus is brought into normal position. He picks up the round ligament and peritoneum together with a double hook, about midway between the cornu of the uterus and the internal abdominal ring, then passes a suture of silk subperitoneally from the uterus as far outward along the round ligament as seems necessary. The tissue is puckered along this suture, the two ends of which are then tied together with moderate traction. To avoid its cutting through, the silk used is of medium size, and is passed into the tissue of the fundus at its point of entrance, and through ligamentous tissue at its exit. The strain on this stitch, however, is not nearly so great as upon the stitches of a ventral suspension, which drags the uterus out of position.

Report of Cases in which the Bacillus Aerogenes Capsulatus was Found.—Joseph H. Pratt and Frank T. Fulton report five cases and draw the following conclusions: Only one of the cases was a pure infection with the gas bacillus, but this case shows what marked pyogenic properties the gas bacillus may possess. In these cases the organism appeared to gain entry into the tissues from the gastro-intestinal tract. In two, infection was probably referable to dirt containing the gas bacillus which gained access into the body through wounds of the skin. The bacillus is shown to be easily destroyed by cold. The lesions produced by it on a muscle tissue are remarkable. This was shown in two cases of emphysematous gangrene reported by Dr. Thorndike. In some places the muscle fibres were broken into small pieces—the appearance being that of débris thrown about by an explosion. In other places degeneration and digestion of the muscle fibres appeared to have taken place.

New Nasal Scissors for the Removal of the Lower Turbinate.—Carolus M. Cobb describes scissors which are more convenient to use than the turbinate saw, and leave a cleaner cut. The fault with most nasal scissors is that the blades are not firm enough to cut through the body of the turbinate; the blades either slip by each other, or one is not able to put force enough on the handles to make the points cut anything more than the mucous membrane. The blades of this instrument are short, and the whole so strong that the blades will cut through any part of the lower turbinate. The shape of the instrument allows the operator to reach any part of the lower turbinate that can be reached by the saw or by any other instrument except the cold wire snare.

Clinical Report of Cases of Infection due to the Bacillus Aerogenes Capsulatus of Welch.—Paul Thorndike describes four cases which were, clinically speaking, cases of malignant œdema; in two of these the bacillus present was not the Koch bacillus, although similar to it. Dr. Post considers that the symptoms of malignant œdema may be caused by other spore-bearing, gas-producing organisms equally well as by the bacillus known as that of malignant œdema. The lesson deduced by the author from the cases reported is to operate as early as possible, but operate even after the time when the whole of the diseased tissue could have been removed by earlier operation.

Chairman's Address before the Section on Practice of Medicine.—By George Dock.

Gastric Hemorrhage.—By W. L. Rodman.

The Lancet, June 2, 1900.

Preventive Inoculation against Typhoid Fever.—A. G. R. Foulerton describes the different steps which have led up to the introduction of inoculative measures, and gives some figures indicative of results thus far obtained. In regard to the length of the protective period he says that if we accept the persistence of the agglutinative power as an indication of the persistence of immunity, the protective effect lasts for two years. The immediate effects of inoculation are often unpleasant, but they are only temporary. The symptoms following the inoculation have been as follows. Toward the evening more or less severe constitutional symptoms may set in; thus there have been severe frontal headache, slight shivering, and in one case actual rigors and nausea, accompanied sometimes by vomiting. A tendency to syncope is sometimes present; it occurs within between four and six hours after the inoculation and very soon passes off, but is quite sufficient to render it necessary that the recumbent position for some hours should in every case be insisted on. All these constitutional symptoms, except perhaps a little headache, have invariably disappeared by the next morning—that is to say, within about eighteen hours of the inoculation. The patient feels fairly well except for the local reaction which now begins to make itself felt at the site of inoculation. The local reaction results in a firm and painful œdema of the subcutaneous tissue with redness of the skin over it extending for about two inches round the puncture made by the syringe; there may also be redness of the skin extending for some little distance along the line of the lymphatics. Shooting pains may be present which radiate from the puncture in the flank principally upward toward the pectoral region. The inguinal glands are enlarged and tender. By the following morning all the signs of local inflammation will have disappeared in nearly every case, and the completeness of the disappearance of what is sometimes a very intense local reaction in the short space of time is very striking. The only remaining effects of the inoculation felt by the patient are a general feeling of tiredness and a sensation of bruising and stiffness about the site of inoculation, although no trace of redness or œdema is now perceptible nor is there any tenderness on pressure.

Removal of a Foreign Body from the Ear.—J. G. Macaskie's patient was a school-boy who had pushed into the ear the india-rubber attached to a pencil. Owing to its flat surface and the depth to which it had gone, it was impossible to remove it by either forceps or syringing. Macaskie therefore teased out a small piece of twine, and giving it a good coating of some adhesive material, packed it against the rubber, surrounding the whole with cotton wool. It was allowed to dry for twenty-four hours. Then gentle traction on the string easily removed the whole mass.

Intestinal Obstruction due to Persistent Meckel's Diverticulum; Successful Laparotomy.—By F. Fawcett and R. F. Jowers. The patient was a girl aged eleven years, with evidences of intestinal obstruction referred to intussusception. Abdominal section showed several coils of small gut tightly nipped by a thin cord which came from the extremity of a Meckel's diverticulum, which was again attached to the bowel, forming a ring through which the strangulated coils had slipped. Recovery was uneventful.

A Contribution to the Statistics of Rheumatic Fever and its Complications.—W. C. Bosenquet analyzes four hundred and fifty cases of rheumatic fever treated in the course of eight years at the Charing Cross Hospital. Statistics are given as to age, sex, heredity, occupations, season, onset, duration, location, complications, causes of death, and treatment.

On Operations for Cancer in the Aged.—E. H. Freeland records the case of a spinster aged eighty-two years, who underwent an operation for cancer of the mamma. Immediate surgical results were successful, and the patient lived about eighteen months, dying of sudden heart failure. The growth had not recurred.

Note on the Passage of a Calculus of Exceptional Size through the Right Ureter and the Urethra of a Man of about Fifty Years of Age.—By J. A. Cunningham.

The Use of Massage in Recent Fractures and Common Injuries.—A clinical lecture by W. H. Bennett.

A Case of Two Aneurisms of the Transverse Arch of the Aorta.—By G. J. Arnold.

Primary Syphilitic Chancres.—A clinical lecture by Jonathan Hutchinson.

British Medical Journal, May 26 and June 2, 1900.

The Treatment of Puerperal Eclampsia by Diuretic Infusions.—Robert Jardine treats these cases on the principle of toxic elimination; he believes that the renal activity should be stimulated immediately during the actual attack, and considers saline infusions of sodium chloride and potassium bicarbonate or sodium acetate the best means of producing early diuresis. The fits should be controlled by chloroform, chloral, or the bromides, or if the pulse be quick and tense ten or fifteen minims of tincture of veratrum viride should be given hypodermically. Free catharsis is produced by administering four to six tablespoonfuls of magnesium sulphate in water, using a tube if necessary. The skin should be kept active by steam or hot pack. The most important part of the treatment is the subcutaneous infusion under the breasts, into the abdominal wall or axilla of a hot (104° F.) saline solution containing half a drachm each of sodium chloride and of potassium bicarbonate to the pint of water. Of twenty-two cases treated, in twelve this solution was employed, while in the last ten cases he used a drachm each of sodium chloride and sodium acetate to the pint. One to three pints were infused at a time, repeated as indicated. Seventeen patients recovered; one of the five died from perforating duodenal ulcer. In all cases the urine was increased in quantity, and the percentage of urea and uric acid rose. Of the twenty-three children, ten were alive and thirteen dead. Of the ten full-time children all were saved except two on whom craniotomy was performed. In two cases in which urine was obtained from the new-born it contained albumin in considerable quantity.

The Treatment of Smallpox by Salol.—J. Biernacki and P. N. Jones discuss the suggestion made by Charles Begg that salol will arrest the development of the rash in the vesicular stage. A score of cases were subjected to this treatment. All but eight had been vaccinated, so that modification of the process aside from salol was to be looked for. Their conclusions based upon the eight cases are that salol may practically avert general pustulation, and even have a partial abortive effect when given after maturation has commenced. The influence of the treatment on maturation is, however, not constant in degree, and in one case was almost *nil*. Short of an abortive effect, it almost invariably hinders pustulation, so that the pustules form tardily, the process being imperfect in a much higher proportion than usual. The cutaneous inflammation is slight, and irritation commonly absent even in confluent cases. There is generally an entire absence of unpleasant odor. Scarring is inconsiderable and often absent, the scabs scaling off with great rapidity. The most remarkable effect of the treatment is its effect on the secondary fever, which, if not absent altogether, is as a rule of little importance. These results appear to resemble, but exceed, those obtained by the red-light treatment. On the whole, the statement is justified that salol affords a means of treating smallpox superior to the methods in vogue.

A Case of Puerperal Septicæmia; Treatment by Antistreptoccus Serum; Recovery.—Harcourt Gervis reports the case of a woman suffering from puerperal sepsis, seen by him on the sixth day after delivery. There were a slight offensive discharge, some tymphanites, and diarrhœa. Injections of 10 c.c. of antistreptococcic serum were made morning and evening for six days, until the temperature of 105.5° F. and pulse of 144 fell to 99° F. and pulse 88 respectively. The uterus, at first irrigated with 1 : 4,000 bichloride solution, was subsequently washed out with a 1 : 2,000 solution of chinosol. An apparent relapse or reinfection occurred a week later with high temperature, and serum was again injected and the uterus scraped; but a subsequent parametritis explained the symptoms. Gervis believes that septic absorption was stopped after the sixth day, and that the further injections were unnecessary, and that curetting should not have been performed. He injected in all 170 c.c. of serum, and concludes that antitoxin is harmless; that no one should be satisfied, when treating a case of puerperal fever, unless, in addition to the ordinary methods of treatment, he also employs antistreptococcic serum.

Chronic Brass Poisoning.—William Murray gives the clinical picture of an affection seen in metal manufacturing centres which is apt to puzzle a stranger. Symptoms may come on only after years of brass polishing. The first indication is usually anæmia. A green line on the teeth may be seen very early. Later on subcutaneous fat gradually diminishes and progressive emaciation supervenes. Dyspepsia, gastralgia, catarrh, itching skin eruptions, etc., are among the symptoms. Excessive debility and nervousness are among the features of the early stages. Whether it is the copper or the zinc of the alloy which poisons has not been definitely ascertained. Phosphorus has been found to act beneficially. Milk diet and change of occupation are advised.

Remarks on the Pathology of Acute Yellow Atrophy of the Liver.—J. W. Findlay gives with pathological illustrations clinical notes of a case of acute yellow atrophy in a girl aged fifteen years. Distinct evidences of proliferation and division of the hepatic cells were noted in the peripheral parts of the lobule, and such proliferation is considered a forerunner, not of degeneration but of regeneration of the proper hepatic tissue. Fatty degeneration of the hepatic cell is considered the primary lesion and connective tissue increase secondary. Some of the writer's pathological conclusions differ from those of other observers quoted.

Infectiousness of Acute Rheumatism.—By C. W. Lanson.

Berliner klinische Wochenschrift, No. 21, May 21, 1900.

Treatment with Hetol.—C. A. Ewald gives his experience with this remedy, which is the commercial name of cinnamate of sodium. Twenty-five cases of pulmonary tuberculosis were placed upon a course of treatment therewith. Of these, eleven patients were during the whole period free from fever, ten had long afebrile intervals, while in only four did the fever persist. None of the cases had cavities when the administration was begun, though all but two showed bacilli in the sputa. The remainder of the article goes into the details of the cases and cannot be analyzed here. Ewald believes that the remedy is deserving of a further trial, but he is unwilling to accept, on the basis of results thus far attained, the sweeping claims of Landerer and others who have been its advocates.

Are Special Divisions for Tuberculous Patients Necessary in General Hospitals?—This question is answered in the affirmative by E. Aron, though he does not take the extreme views of some of the latter-day sanitarians.

Hæmolysine.—By P. Ehrlich and J. Morgenroth.

French Journals.

The So-Called Pernicious Dysenteric Fever.—S. Kanellis and J. Cardamatis, having observed many cases, conclude (1) that pernicious dysenteric fever is not an especial or essential morbid entity. (2) A similar form does not result primarily from paludal miasm, that is to say, this element cannot produce essential dysenteroid catarrh. (3) In case of complication of dysenteric paludal miasm the products of one of the causes cannot influence those of the other excepting by the debility of the organism which both bring about. Each one of the nosological entities evolute in the same organism independently of the effects of the other, each progressing in the nosological camp on its own account. (4) These two nosological entities do not oppose each other nor join forces, and when they follow out their evolution in the same organism the one does not the less predispose the soil for the establishment or for the renaissance of the other disease after the debility of the organism which it produces. (5) Dysenteric fever, called pernicious, should be erased from the list of malarial fevers, since it does not exist with the nosological properties which are attributed to it. It should be referred to as paludism, complicated with dysenteric catarrh.—*Le Progrès Médical*, May 19, 1900.

Hypertrophic Alcoholic Cirrhosis with Diabetes.—A. Gilbert and P. Lereboullet report two observations which seem to belong to the class of indurated and indolent hypertrophy of the liver in alcoholics affected with diabetes. In one case intemperate habits were persisted in; little treatment was carried out, and the cirrhosis ended in death with hypothermic coma without the disappearance of sugar from the urine. In the second case treatment was directed toward the cirrhosis, and the glycosuria disappeared coincidently with marked improvement in the hepatic symptoms. It is thought that in both cases the evolution showed the dependence of the diabetes upon the hypertrophic cirrhosis, and the liver disease seemed to govern the evolution of the diabetes instead of causing the sugar to disappear as is the case in atrophic cirrhosis.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, May 20, 1900.

Traumatic Bilateral Cowperitis in a Bicyclist.—E. Ozenne records an instance of this affection due to falling forward upon the point of the saddle. There was burning in the canal on urinating and perineal discomfort for the rest of the day. The following day there was painful tumefaction on either side of the canal. The Cowper glands could be made out behind the bulb in the membranous portion, especially on combined rectal and perineal touch, or rather ano-perineal touch with the thumb and index of one hand. The swelling was firm and oblong along the canal. Simple treatment and rest brought about prompt relief. The glands were still to be felt at the end of six weeks.—*Journal de Médecine de Paris*, May 27, 1900.

Syphilis of the Liver.—P. Hutinel in his course on internal pathology states that hepatic lesions are among the most frequent and the most severe manifestations of visceral syphilis, both hereditary and acquired. The lesions are diffuse or gummous with small infiltrations. Small nodules are generally associated with diffuse infiltrations. Diffuse lesions are found in infancy, while in the adult sclerous lesions are found about the vessels, especially the hepatic artery. Recent lesions disappear under treatment, but it is difficult to bring back normal vitality to a liver which has been the seat of old fibrous lesions.—*La Tribune Médicale*, May 23, 1900.

The Plague in Australia and South America.—Netter reviews the history of the plague in these countries. He finds that the first cases usually escape recognition. The period between their occurrence and the official recognition of the presence of the plague varies from one to several months. At times the exact time of first invasion cannot be determined. Early bacteriological researches are insisted upon. Even when prophylactic measures have not been taken epidemics have remained limited in extent. An extensive development can occur only in insalubrious localities or quarters.—*La Presse Médicale*, May 26, 1900.

Repose and Exercise in Cardiac Disease.—H. Vaquez cautions against a too exclusive drug medication in heart disease. He does not pretend to claim that exercise can be set up as a systematic treatment for all cardiac affections, but applied to particular forms and individual cases it may render great service, and this is in some instances so considerable that physicians cannot longer afford to ignore it as one of the curative measures. The theory and technique are discussed.—*La Presse Médicale*, May 23, 1900.

Ulcero-Membranous Anginas.—Bonnus and Deguy give a number of observations upon an angina showing fusiform bacilli and spirals. The first may exist alone, the spirals being merely associate forms. These cases must be recognized so that rational therapy can be established. Antiseptic applications, tincture of iodine, phenosalyl, and chlorate of potassium are recommended with frequent gargling, and oxygenated water renders good service.—*Journal des Praticiens*, May 19, 1900.

Psoriasis Treated by Full Baths Containing Oil of Cade.—Balzer and Mousseaux offer a new method of applying oil of cade. A soap emulsion is made with one part of green soap and two parts of water. To 100 gm. of oil of cade is added enough of this emulsion to make 250 c.c. to be added to each bath. The results have been about the same as after other forms of active treatment, but it is considered more agreeable for the patient, who continues at his occupation.—*Journal des Praticiens*, May 26, 1900.

Acute Blennorrhagic Aortitis and Endocarditis.—Bodier and Laroche call attention to an attenuated form of endocarditis in gonorrhœa, giving the history of a case with aortitis. Modifications in the volume of the aorta may at times be quite rapid. Salicylates and revulsives are recommended. These cases should be recognized early by daily examinations of the heart in the course of gonorrhœa.—*Gazette des Hôpitaux*, May 22, 1900.

Treatment in Strangulated Hernia.—Pauchet says that taxis should not be attempted; most deaths after operation are to be attributed to preceding attempts at reduction. Directions for operating are given, and the steps to be taken when gangrene is present. Radical cure in various forms of hernia is described. Opium must never be given after abdominal operations.—*Journal de Médecine de Paris*, May 20, 1900.

Acute Spinal Perimeningitis.—A. Deléarde discusses the inflammation of the cellulo-adipose tissues which envelop the dura mater of the cord and separate it from the vertebræ. Historical considerations, etiology, pathology, and treatment are discussed, and a case is reported. The abscess should be opened by incision of the vertebral laminæ.—*Gazette Hebdomadaire de Médecine*, May 27, 1900.

Digitalis in Heart Disease.—Professor Potain considers the indications and contraindications of this drug, which is a very useful and powerful remedy without possessing any succedaneum. It should be employed with great caution, since in too strong or too long-continued dose it may prove injurious.—*Le Bulletin Médical*, May 26, 1900.

American Journal of the Medical Sciences, June, 1900.

A Contribution to the Pathology of Chronic Hyperplastic Tuberculosis of the Cæcum, Based upon the Study of Two Cases, in One of which Carcinoma of the Cæcum Coexisted.—T. R. Crowder contributes an elaborate article in which the subject of cæcal tuberculosis is carefully studied. He says that a review of the clinical histories and the post-mortem findings proves that with active, destructive, and disseminated tuberculosis of the intestine there is usually found in the lungs a similarly active process, while in cases of localized chronic cæcum tuberculosis there is quite as frequently found a latent healed or healing pulmonary involvement. In primary tuberculosis of the cæcum the general conditions would be much the same as in that contracted from a healing pulmonary lesion. The clinical history seems often to point to such a primary infection, but even when the physical examination fails to show any involvement of the lung there is found post mortem an old lesion. On account of this slight involvement, or the inability to demonstrate clinically any at all when the tumor is first noticed, many authors have concluded that the pulmonary affection is secondary. Opposed to this view are two facts: the extreme rarity of localized cæcum tuberculosis with no lung findings, and the extreme frequency of slight ancient pulmonary involvement. Even when a patient with a tuberculous cæcal tumor has died of a later pulmonary tuberculosis there has been found evidence of an old latent or healed preceding process which may have given rise to the cæcal trouble.

Permanent Non-Progressive Ataxia, with a Clinical Report of Three Cases.—Sanger Brown presented these cases, which showed the common features of a more or less severe, acute, and probably infectious illness of varying duration and character, resulting in profound general muscular ataxia showing itself conspicuously in the muscles concerned in articulate speech. In none was there any lasting impairment of special sense or of general sensation. The ataxia in all was essentially stationary. Experiments on the lower animals, studies in embryology, clinical and post-mortem observations on the human subject, have abundantly demonstrated definite relations between the neurons of the cerebellum and those of other parts of the nervous system, both sensory and motor. Assuming that the cerebellum exercises a predominating influence upon the co-ordination of voluntary muscular movements, then it would not be unreasonable to assume in the cases cited that one effect of the primary disease had been to injure permanently those parts of the organ subserving this function, or, what would amount to the same thing, a considerable number of the neuron processes connecting it with other parts of the nervous system.

A Fifth Case of Family Periodic Paralysis.—L. M. Crafts reports the case of a man aged thirty-five years, under observation for a period of seven years. He regards this rare neurosis as due to same form of auto-intoxication, though the poison has never been isolated. The poison, whatever it may be, seems to be developed only at intervals and not constantly. It seems to result from over-exertion and gastro-intestinal disturbances, but it is unknown why these causes evolve the poison in certain individuals. All of the cases have presented a massive muscular supply. In the present case, a muscular snip from the inner portion of the right gastrocnemius shows a distinct increase in the fibrous tissue and moderate hypertrophy and vacuolation of the fibres.

On the Spinal-Cord Changes in Paralysis Agitans.—By Max Nonne.

The Medical Chronicle, May, 1900.

Widely Conducted Cardiac Murmurs.—E. M. Brockbank reports twenty-four cases of heart disease in which the murmurs were heard in unusual situations. The only explanation which suggests itself to him is that the sound was carried along the aorta and large vessels, and transmitted to the surface over the liver, spleen, and kidneys by the intervening tissues, and over the upper part of the chest by the resonant qualities of the thorax. There was no pulmonary consolidation. The author has never met with these widely conducted murmurs in health, in anæmia, or in any case without a cardiac lesion. As a means of cardiac diagnosis their value is doubtful, but it is possible that they may indicate an abnormal condition of the aortic or anterior cusp of the mitral valve, which is thrown into vibration during ventricular systole and the passage of a column of blood—with which it is in contact—into the aorta. Their occurrence must be remembered in examining cases of supposed aneurism, or obstruction of the thoracic or abdominal aorta.

Immunity to Diphtheritic Infection, and Reinfection after the Use of Antitoxin.—R. W. Marsden reports several cases which seem to demonstrate that immunity after an attack of diphtheria may have quite ceased to exist at the expiration of three weeks, when that attack has been terminated by the injection of antitoxin. It is interesting to note that in each instance the second attack was practically a recapitulation of the first, *i.e.*, was of an exactly similar type. The author does not incline to believe that the period of immunity is proportionate to the dose of antitoxin administered, or at least, he holds that a consideration of the doses administered warrants the conclusion that the connection cannot be a very close one. For his own guidance, he has decided that during convalescence from an attack of diphtheria, the reinjection of antitoxin must be immediately performed upon the supervention of "croupiness" or signs of early laryngeal stridor.

Two Cases of Intestinal Obstruction due to Peritoneal Bands.—J. E. Platt describes two cases, and remarks that the most frequent causes of peritoneal bands are appendicular trouble and pelvic peritonitis. Obstruction from compression of the gut under the band, as in the first case, is the most common way in which the lumen of the bowel is interfered with in these cases. Less frequently the obstruction is due to traction of the band upon a loop of bowel, as in the second case. The course of the disease is usually rapid, the average duration of life in cases not subjected to operation being five days, according to Treves. Treatment must be conducted on the lines for acute intestinal obstruction generally, for in only a few cases will it be possible to diagnose the exact cause of obstruction.

A Case of Pneumothorax Complicating Whooping-Cough.—Francis Villy reports a case in a child aged three years, who had just previously suffered from faucial diphtheria, whooping-cough, measles, and otitis media. There were no pressure signs in the chest, but a slight difference was perceptible in the percussion noted at the two bases of the lungs behind, and the child's general condition was so serious that aspiration was performed. A considerable quantity of gas was evacuated, but no pus was found. The immediate relief did not appear to be very great, but the child steadily improved, and finally recovered.

The Enucleation of Interstitial Fibro-Myomata by Cervico-Vaginal Hysterotomy.—By Louis Dartigues.

Medicine, June, 1900.

Ether Anæsthesia from a Medical Standpoint.—Louis Faugères Bishop thinks that as a rule more ether is given than is necessary. If a patient be put thoroughly under in the early part of an operation, very little additional ether is required to keep him under for a considerable length of time. There is great danger of doing insidious damage to a patient by having him at some stage during an operation too profoundly anæsthetized. Such an occurrence upon the nervous system is like what might be produced by a blow upon the abdomen or a condition of shock. Many of the ultimate bad results of ether might be accounted for by such an interference with innervation of different parts of the body, such as the kidneys. The management of the tongue is often a source of much worry. So long as the air enters and leaves the chest with freedom the tongue can be let alone. If it gives trouble, lifting the angles of the jaw in the usual way is sufficient in most cases. Nausea may be to a large extent avoided by regulating the anæsthesia so that it is never too deep.

Maternal Impressions.—James G. Kiernan gives an account of the early beliefs and superstitions in regard to maternal impressions, and illustrates his article with photographs of monstrosities supposed to have been due to mental shock, but really due to arrested development. Profound shock, destitution, and want of food act on the mother and may influence the fœtus deleteriously. Hence the significance of the fact that of ninety-two children born in Paris during the siege of 1870–71, sixty-four had slight physical or mental anomalies; the remaining twenty-eight were all weakly. Not only do poverty and want produce anæmia and malnutrition of the fœtus, but profound shock disturbs the whole bodily metabolism. The nutrition of the mother may thereby be so disturbed as to result in a partial toxæmia, which would tend to check or disturb the healthy development of the fœtus in utero. In this way a nexus of cause and effect can be traced, but facts which can be thus explained give no support to the view of maternal impressions popularly entertained.

Rumination and Periodic and Habitual Vomiting.—Fenton B. Turck says that rumination is characterized by return of food without nausea or effort through the œsophagus into the mouth, to be rechewed and reswallowed. This occurs not only without distress, but is accompanied often by a peculiar enjoyment. Peripheral irritation of the vagus nerve should be looked for in every case, and should be corrected by both local and general treatment. Periodic vomiting is a symptomatic disorder characterized by regular recurring cycles of vomiting, or the more or less constant rejection of food. Nervous vomiting may be divided, for description, into three classes: (1) cerebral, spinal, or central vomiting; (2) hysterical or neurasthenic; (3) that caused by irritations of various parts of the body.

The Repair of Old Traumatic Nasal Deformities.—By J. Homer Coulter.

Talmudic and Jewish Medicine.—By Lawrence Irwell.

Archivio per le Scienze Mediche, vol. xxiv., No. 1, 1900.

The Pathogenesis of Periodic Hæmoglobinuria.—Ettore Chiaruttini says that there are three stages in the production of hæmoglobinuria: (1) Alteration of the blood (preexisting); (2) alteration of circulation (paroxysmal); (3) kidney lesion (usually only functional). The blood changes may affect the corpuscles or the plasma. The globules become in part disintegrated, and the hæmoglobin escapes. The alteration in the plasma consists of a power to cause dissociation of the hæmoglobin from the corpuscles. The circulatory changes are produced by vasomotor disturbances and induce paroxysms by causing hæmoglobinæmia. The kidney lesion consists of a temporary loss of the property possessed by the epithelium of the convoluted tubules of decomposing the hæmoglobin and separating the iron. This kidney lesion is essential to the appearance of hæmoglobin in the urine.

The Alterations Caused by Rachitis in the Metabolic Processes of the Epiphyseal Cartilages.—V. Grandis and C. Mainini, from experimentation, deduce the theory that the growth of bones is caused by a fixation of the circulating lime by means of the phosphorus accumulated in the cartilage cells. In rachitis the cells do not prepare and do not elaborate the phosphorated products. This gives a scientific basis to the well-known clinical fact of the good effects of phosphorus in the treatment of rickets. In a case studied carefully by the authors, the rachitis was without doubt due to a quantitative and qualitative alteration in the distribution of the phosphorus in the cartilage, the amount of lime salts being certainly equal to that of normal conditions.

The Physiology of the Spleen.—By Angelo Pugliese and Tullio Luzzati.

Correspondence.

THE MEDICAL ASPECT OF THE SOUTH AFRICAN WAR.

(From our Special Correspondent.)

Since I last wrote the war has come almost certainly to a close, while winter has definitely set in. Lord Roberts is virtually in possession of all the Orange Free State (which he has formally annexed to the British Crown), and of the two chief cities of the Transvaal. The change of temperature has exerted a marked influence upon the soldiers. The sick rate has gone up, and there is a considerable increase in the number suffering from pneumonia and dysentery. On the other hand, the tremendous activity shown by Lord Roberts in the field has not tired his troops in the least, those who have had to march hardest showing the cleanest bills of health. In fact, throughout the war it has been noted that inactivity has been followed by disease.

The Plight of Mafeking.—On May 18th, as all the world knows, Mafeking was relieved. The little town, so near the Boer capital and so far from the British base, seemed doomed, but some admirable marching on the part of combined forces from the north and the south drove the investing troops away just in time. There is no need for me to expatiate upon the heroic nature of Baden-Powell's defence of Mafeking. Everything possible to be said has been said twice over, but the total casualties incurred by the garrison prove the nature of the struggle they endured. Among the combatants 22 officers were killed, wounded, or missing out of a total of 44, and 190 men out of a total of 970. The total casualties among the non-combatants, black and white, brought the list of injured up to 924, a figure which sufficiently indicates the persistent nature of the shelling and "sniping" to which the inhabitants of Mafeking were subjected during their seven months' siege. There were 60 deaths among adults of disease, and a great many native children perished, but on the whole, the health of Mafeking, when it was relieved, was found to be better than had been anticipated. The investment of the place was never so close as that of Ladysmith, so that there was not the same trouble about water supply, and enteric fever was not so rife, while the natives were occasionally able to drive cattle into the town through the Boer lines and thus replenish the stock pots a little. Still Mafeking was on starvation rations when Captain Mahon entered it, and even on that scale of diet could not have held out more than another three weeks or so.

Inoculation against Typhoid Fever is on its trial in this war, and when the figures are published (as in the interests of science they should be) medical opinion ought to be able to declare itself for or against the process. Inoculation was practised on the outgoing British transports to the considerable discomfort of the men, and it is admitted that in a striking proportion of cases it has proved an entire failure as a measure of protection under the circumstances of camp life. All the fever that has prostrated the British soldiers during the South African campaign is not typhoid fever, malaria and typho-malaria having accounted for long sick lists, but there is no doubt that a good many who were presumably protected by inoculation have succumbed to genuine enteric fever. Full notes have been kept of all deaths in the hospitals, so that interesting statistics may be looked for.

The British War Office has approved of pay at the rate of £1 per day being given to civilian medical practitioners in temporary military employ who are not receiving either fixed or capitation rates of pay from the army fund.

The Princess Christian Hospital, which has been presented to the Natal government by Mr. Alfred Mosely, is now open. The building is situated at Pinetown Bridge, a healthy spot fifteen miles from Durban amidst fine scenery, and contains two hundred beds together with the most complete fittings necessary for a military hospital. The beds are all occupied already, and Mr. Mosely has undertaken to bear at his own expense for four months the whole cost of the establishment, which cost is estimated at £25,000. This is truly practical patriotism

The Death Rate in Bloemfontein, especially among the sick in the hospitals, is ominously high. This is a great disappointment to medical authorities, for the pretty town was regarded as a model place to have the sick during the great march northward. But Bloemfontein is forty-six hundred feet above the sea-level, and this altitude causes a diurnal variation of temperature that tells heavily upon sick men. For the future the sick will be sent farther south, as all lines of communication are now quite safe as far as the British are concerned.

Dr. William Davies, son of Dr. Ebenezer Davies, the medical officer of health of Swansea, who was imprisoned owing to his supposed connection with the Jameson raid, was in charge of the medical stores with the Mafeking relief column.

By the request of the principal medical officer at Bloemfontein the Langman Hospital, which, as your readers may remember, consisted originally of one hundred beds, has been converted into one of one hundred and fifty beds, the necessary additional equipment having been provided by Mr. Langman.

Nearing the End.—The war is believed to be practically over. I shall send you information concerning the sanitary condition of Johannesburg and Pretoria when Lord Roberts enters those towns, as well as a note upon the plight of the three thousand prisoners whose stay in the latter city has been so prolonged and by many accounts so uncomfortable. These will be the last medical aspects of the war, accurately speaking, though the submission of the Boers in their capital will not preclude the possibility of prolonged guerilla warfare.

LETTER FROM NEW ZEALAND.

(From our Special Correspondent.)

A PLAGUE SCARE—THE PLAGUE IN SYDNEY—SURGERY IN AUCKLAND.

AUCKLAND, May 12, 1900.

DURING the last month we have been suffering from a plague scare. Your readers may possibly have learned that the plague has been in Sydney, New South Wales, for more than two months. Now the whole of New Zealand is in constant connection with Sydney, which is only eleven or twelve hundred miles distant. The mail steamers from San Francisco go on to Sydney from Auckland, and having delivered the mails for Australia, and received those for New Zealand, America, and Europe, return to Auckland and there receive the outward mails. Besides these, there is, or rather was, a regular weekly service of steamers. All this in addition to sailing-vessels. When the plague appeared in New Caledonia and Sydney, the usual precaution of subjecting all vessels arriving from those parts to quarantine until they received pratique was adopted. Later on, seeing that the whole of Australia was liable to be infected by travellers overland from Sydney, the whole continent was declared infected. In Auckland the municipal authorities were at last stirred up from their usual lethargic condition, and sanitary measures were taken which had been neglected for years. The harbor board offered a reward of sixpence a head for rats caught about the wharves. The city council offered a penny a head (two cents) for rats caught on shore; poison was distributed gratis, and so carelessly that the wonder is that human beings were not poisoned. His excellency the governor, the Earl of Ranfurly, went about the slums in Auckland, and very usefully employed himself in poling up the mayor and council. We don't think quite so much of earls as you do in the States, because we are more used to them; but still an earl who is also governor has a good deal of influence.

Then came the news that some man on the Queen's wharf had caught a rat, and that this rat, or the fleas that infested him, had the plague bacillus. Then the harbor board went mad, shut up the man and two of his mates in one of the landing-sheds, barricaded the wharf, and would not allow any one to visit the men or that part of the wharf where they were confined. Meanwhile the premier, Mr. Seddon, a most energetic individual, came up post-haste from Wellington, and he went off his head too. He even went so far as to inform the city council that if they did overstep the law in their zeal to suppress nuisances, he would introduce an indemnity act in the next session of Parliament to protect them from the consequences! You ought to bless your stars that your ancestors instituted a supreme court that can protect you against the vagaries of ministers with a majority in both houses of the legislature. We have no such protection.

Last of all, a boy was bitten by a rat. He grew feverish and the wound did not heal kindly. The medical man who was attending thought it a case of blood poisoning, and advised that he should be sent to the Auckland Hospital. There he was put in the smallpox ward (which has never had a smallpox case in it), and he was isolated—after the New Zealand fashion. A young lady who has just taken her degrees in the New Zealand University, and of course never saw a case of plague nor probably of typhus in her life, volunteered to attend him. Cultures were taken from his blood; the plague bacillus was found; it was wired all over the world that a case of plague, but a mild one, had appeared in Auckland. A number of people were inoculated with Haffkine's serum, and the scare became intense. One lady whose children were all at boarding-schools in Auckland took the first boat from the town she resided in, rushed up to the schools with cabs, had the children's luggage bundled in anyhow, and started off for the country forthwith. Trade was seriously interfered with. A boot and shoe manufacturer, who had nearly completed a large order for the South, received a telegram peremptorily telling him to send nothing until further orders. Even loads of timber were countermanded, as they would have to be fumigated at a cost of nearly two dollars a ton.

Some days elapsed; the boy did not die, but seemed getting better. Fortunately, just at this point a physician arrived on a visit who had seen plague on a large scale in India. In conjunction with the staff of the hospital he examined the patient, and unhesitatingly affirmed that it was not a case of plague at all! Then there were rage and fury on the part of the trading classes, and indeed of all classes. Who was responsible for pronouncing the case plague? Well, the medical superintendent of the hospital, who had also been just made by the premier a sanitary commissioner with extraordinary powers, had undoubtedly wired up to the colonial secretary that it was a case of plague. He had to resign his hospital appointment, instead of getting the six months' leave he had applied for in order to fulfil his duties as a sanitary commissioner. As an illustration of the despotic powers assumed by Mr. Seddon, I may just remark that there is no such person as a sanitary commissioner known to our law; he is entirely the creation of Mr. Seddon.

I asked in an article published in the principal daily paper for particulars as to the culture experiments adopted, whether there were any control cultures, how many, and of what kind. To these impertinent inquiries I of course got no answer.

However, as the plague still continues in Sydney, no precautions are omitted. We have a Maori population of about forty thousand, and if the plague once got among them it would carry off thousands. They live in the most unsanitary conditions possible; they are accustomed to eat dried shark's flesh and other fish dried in such a way that they are most offensive to the smell of Europeans; they delight in maize soaked in water until it becomes putrid, absolutely putrid; and they crowd together in huts at night, sleeping on the floor, men and women and children all together, in an atmosphere that would suffocate a European. For their sakes we must keep out the plague if possible. Then we have four thousand of the lowest class of Chinese, living as Chinese always do.

It seems probable that we shall have the plague sooner or later, as it shows no signs of abating in Sydney, although winter has commenced. With proper care, however, it may be kept sporadic, as it has been in Sydney. There, in nine weeks there were only one hundred and fifty-three cases and forty-nine deaths, which in a city of about four hundred and fifty thousand inhabitants can hardly be called an epidemic. Sydney is the oldest town in Australia, having been founded in 1780 (or thereabouts) as a convict settlement. The older streets are very narrow, and there are some horrible slums in those parts of the city near the wharves. The government is resuming the control of the wharves, and has shut up several of them. It is estimated that this step, which is quite unnecessary, and merely the result of the scare, will cost the colony of New South Wales between two and three millions sterling.

There is nothing new here except the plague scare. I paid a couple of visits to the Auckland Hospital lately, and saw some very pretty operations by Mr. Hope Lewis, who is one of the honorary visiting surgeons—a tenotomy, an Alexander, an amputation of the hip joint, a hysterectomy, and an ovariotomy. The hip-joint case was the first amputation of the kind I have seen done since I served in the Crimea. We had five cases there and all ended fatally. The ovariotomy was really a funny case. It was a dermoid cyst, and when the incision was made to admit the trocar, out shot hundreds of little white spherical bodies, exactly the size and shape of sugar-coated pills; out they came with every movement of the cyst, and ran out on the floor and rolled about in a really ludicrous way. There were a number of masses of hair as well. Mr. Hope Lewis is an excellent operator and making a name for himself by his laparotomies and other operations. His style reminds one of the late Sir William Ferguson, of King's College, London.

OUR LONDON LETTER.

(From Our Special Correspondent.)

QUEEN'S BIRTHDAY HONORS—MEETING OF MEDICAL COUNCIL—THE MEDICO-CHI. ON WOUNDS IN THE WAR—THE ORATION AT THE MEDICAL SOCIETY—EXCISION OF THE GASSERIAN GANGLION—FIRST SOUND OF THE HEART—PATHOLOGICAL SOCIETY'S LABORATORY MEETING—DEATHS.

LONDON, May 25, 1900.

WE have been celebrating the Queen's birthday yesterday (24th) with more than usual enthusiasm, making the occasion a demonstration of patriotism as well as loyalty. The list of honors conferred on this occasion is long enough, but the medical profession scarcely gets its share. No baronetcy is given us, but there are four knighthoods, viz., Dr. Hector Cameron, President of the Glasgow Faculty, Dr. J. W. Moore, P.R.C.P.I., Dr. W. B. Berry, Speaker of the late House of Assembly, and Dr. D. P. Ross, surgeon-general of British Guiana. There are also three medals for services in India.

The General Medical Council met for its sixty-ninth session on Tuesday, and is still sitting with much work yet to do. With its oppressive cost and its inability to find time for all its work, why should the president persist in giving a lengthy address? There is no need to tell the members what they have to do. A good programme would suffice. Details of what has been done and told in all the journals are equally unnecessary, and laudation of outgoing councillors would be best omitted.

Two new members put in an appearance, viz., Sir H. Beevor, *vice* Mr. Brudenell Carter, for the Society of Apothecaries, and Mr. W. R. Power for the Crown in succession to the late lamented Sir R. Thorne. Dr. Leech is absent from illness, and Sir W. Thomson is in South Africa. Reports of committees and formal business occupied most of the first day. In the evening the president of the Royal College of Physicians and Mrs. Church gave a reception as they also did on the following evening.

On Wednesday the midwives bill monopolized the major part of the time. The report of the committee was discussed with some animation, but other points managed to force their way into the speeches. The committee accepted the suggestion of the lord president of the council that the central board could frame a rule requiring the midwife to send for a registered practitioner in case of abnormality, but Mr. Horsley, who was on the committee, had dissented from this point in the report and divided the council upon it. The report, however, was adopted, and so far as the council is concerned the midwife will do as she pleases.

The question of personation of registered practitioners came on. It seems the public prosecutor does not consider such personation criminal in the sense that he is bound to prosecute. Counsel's opinion is to be obtained, and the question will then be considered, perhaps to-morrow. The proposed conjoint board for London, the appointment of a solicitor, and resolutions forwarded about the mode of appointing councillors received the usual attention. Yesterday renal cases occupied the council. The Medico-Chi. gave another evening (Tuesday, the 22d) to the subject of the wounded in the present war.

Mr. C. T. Dent, of St. George's Hospital, told of his experience in this campaign. He thought tent hospitals better than wood or iron in a climate like that of South Africa, for they permitted of practically open-air treatment. If chilling was avoided, only good resulted. Churches and schools were very ill adapted for hospitals. He entered into various particulars as to different wounds, but, of course, admitted that there is much more to be learned before positive conclusions can be formulated on many points.

Sir William MacCormac also gave some details of his experience, though he admitted he had said all he wished to say in his letters to *The Lancet*. He exhibited a one-hundred-pound shell presented to him by the officers of the Royal Artillery, and a smaller one was also shown, said to be the first fired into the English lines at the battle of Colenso.

Major W. Dick, of Netley, made some remarks on the wounds after the men returned. There had been many injuries of the musculo-spiral nerve. He thought small-bore bullets more often deflected than supposed and gave instances. He thought, too, the successful issue of abdominal wounds was favored by their having been inflicted on men when starving.

You will naturally take it for granted that there was an unusually large assembly to hear the returned surgeons and welcome them back. In fact, with such a subject as the war and exhibits of bullets, shells, etc., with lantern slides and other attractions this session, the Medico-Chi. bids fair to become quite popular—a change which will be welcomed by many.

On Monday evening the Medical Society gave its annual conversazione. There was a full assembly of fellows and their friends, and everything passed off successfully. The oration was delivered by Dr. Kingston Fowler, who took for his subject "Science and Medicine in the Eighteenth Century." Sir W. Gairdner was present and proposed the vote of thanks (cordially carried), contrasting in a few words Cullen and Brown, and remarking that the eighteenth century was one of revolution, the nineteenth one of evolution.

At the last ordinary meeting for the session held on the preceding Monday evening, Mr. Hutchinson, Jr., read a paper on excision of the Gasserian ganglion for epileptiform neuralgia of the fifth nerve, in which he detailed the cases in which he had performed this operation. He thought the Hartley-Krause method the only practicable one of exposing the ganglion. In all his cases the neuralgia had lasted five years, but he thought it would be justifiable to operate after two or three years or before the patient was worn out by pain and treatment. If the pain was confined to one branch, a full removal of that branch would suffice; but when it affected two divisions and had an epileptiform character, excision of the ganglion would be necessary and, if the patient were running down, might be undertaken after one year.

Dr. A. Morison read a paper on "The First Sound of the Heart, Considered from a Clinical Point of View." His study led him to attribute the largest share in producing the sound to "vibrations in the blood itself, to produce which at a normal rate valvular support of the vibrating blood columns is necessary." Thus he would seem to take a view between that of Quain on the one hand and Leared on the other. Of course this was objected to. Indeed, the first sound seems to be a perennial source of controversy. Dr. Sansom insisted on tension and could not believe the blood had much to do with the sounds; while Dr. Robert Maguire held by Quain's view. He said the first sound was produced by one column of blood against another, or one bubbling through another, and asked if murmurs might not be due to the same thing modified. I pass the question on to physicists and physiologists instead of following this debate further.

Lord Lister presided at the laboratory meeting of the Pathological Society on the 15th, which was held at King's College. Professor Crookshank said he had lately found in healthy field rats the flagellate protozoa which he described fourteen years ago in sewer rats, and which were then thought to indicate disease. A similar protozoon is found in equines and camels.

Dr. Dean described an apparatus for the cultivation of the tetanus bacillus; Messrs. Hewlett and Rowland their plan of measuring a volume of serum for diagnostic purposes.

Dr. MacFadyen described experiments on the virus of African horse sickness, which point to the possibility of bacilli being so minute as to pass through Chamberland's filters. At any rate, the fluid which so passed killed the horses experimented on. It has been asserted that the bacillus of bovine pleuropneumonia will pass through such filters.

Drs. Bullock and Hunter made a preliminary communication on a hæmolytic poison in pyocyanic toxin and an antihæmolytic body in the serum of immune animals.

Dr. G. Newman had tested the inoculability of twenty-nine species of animals with tubercle. Guinea-pigs could always be inoculated with the tubercle of mammals, never with that of birds. In fishes and reptiles he had not found a bacillus which answered the tests for tubercle. In birds, tubercle attacks the abdominal viscera, rarely the lungs. In cattle, the serous membranes are the most frequently attacked.

Dr. Hewlett demonstrated the indol-like reaction given by cultures of the diphtheria and of the pseudo-diphtheria bacillus.

Dr. Drysdale gave an account of research on the bacillus capsulatus aërogenes to which post-mortem emphysema is attributed.

Mr. Pryce Jones exhibited three varieties of streptothrix from rum, horse dung, and drinking-water.

The late Dr. George Bird, who died on the fourth inst. at the advanced age of eighty-three years, was a very noteworthy man, the friend and adviser of a considerable number of "men of light and leading." Sir R. Burton dedicated to him a volume of his "Arabian Nights," and many other marks of the appreciation of his worth by great thinkers fell to his lot. It is said that Ringer's "Therapeutics" owes any literary grace it possesses to his revision. He was always attached to athletics and even took up the bicycle in his old age.

Capt. W. F. Hopkins, M.D., who went from Australia with the contingent and performed prodigies of valor at Rensburg, where the officer in charge declared if any one deserved the V. C. he did, has died of typhoid.

Captain Dowse, R.A.M.C., has also died at Bloemfontein. He had the medal for service in the Chitral expedition.

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

Second Day—Wednesday, June 6th.

Parturition as a Factor in Gynæcic Practice.—Dr. John M. Duff, of Pittsburg, read this paper. He said that to convince gynæcologists that parturition was the principal factor in producing morbidity calling for their interference, no other argument was needed than the statistics of their own practice. He felt justified in saying that considerably over fifty per cent. of all gynæcological cases could be charged to parturition. He believed that a rigid enforcement of the rules of obstetric practice as laid down by the best teachers of to-day would eliminate more than fifty per cent. of the gynæcic cases resulting from parturition, if we except those resulting from abortion. In proof of this he referred to records of cases in maternity hospitals. The author declared that the day of antiseptic midwifery was past. To-day its principles were not only directly harmful, but a neglect of asepsis, with a dependence upon antiseptics to right wrongs, was not only unscientific but cruel and murderous. The true antiseptics were stated to be the normal and healthy secretions of the body, and especially that greatest of all germicides, the blood. Hence the necessity of due attention to the secretions and to the condition of the blood previous to the onset of labor. In instituting aseptic precautions before labor the douching of the vagina with antiseptics was declared to be harmful in a healthy woman: and in an unhealthy vagina with pernicious secretions it was not effective. When necessary to cleanse the vagina, it should be prepared as carefully as for vaginal hysterectomy. The vulva should undergo the most careful cleansing possible. One cause of infection through putrefaction was a failure to remove all placental tissue and membranes, and in this connection he emphatically called attention to placenta succenturiata and placenta spuria, which he believed to be frequently the direct cause of sepsis which could not be accounted for. On five occasions he had found spurious placentæ. The author still believed his previously published opinion, that "the routine practice of administering ergot after the third stage of labor" was pernicious and frequently the cause of the woman coming into the gynæcologist's hands. The too early resumption of household cares after labor he considered accountable for many malpositions with their concomitant disorders.

In conclusion it was stated that by a rational midwifery such as suggested, with careful asepsis and proper and timely repair of lacerations, salpingitis, ovarian abscess, and endometritis would be less frequent, and prolapsus uteri, vesicocele, and rectocele, with all their accompanying phenomena, would be comparatively rare.

Dr. Mordecai Price, of Philadelphia, opened the discussion of Dr. Duff's paper by heartily indorsing the author's views upon the antiseptic treatment of puerperal conditions. The cases thrown into his hands, of puerperal fever, or fever following the puerperal state, in nine cases out of ten had been caused wholly and entirely by the unnecessary and dangerous use of antiseptics. He thought that the profession had been so imbued with the old idea of antisepsis that such papers as this were required to correct the past teaching.

Dr. L. H. Dunning, of Indianapolis, indorsed the paper of Dr. Duff most heartily. He thought that Dr. Price had perhaps stated the matter a little too strongly, though he had seen some of the results indicated, from intra-uterine douches. He considered of great importance the matter of displacement due to subinvolution, which could readily be corrected if the obstetrician would follow the cases after delivery. He agreed that every case of laceration should be attended to at once unless there were strong contraindications. He did not believe in the immediate repair of laceration of the cervix, but did believe that when there was reason to suspect such laceration the case ought to be examined in six weeks and repaired if the necessity was present. Otherwise there was the possibility of subinvolution of the uterus and of the ligaments, resulting in displacement, endometritis, chronic congestion of the pelvic organs, and chronic invalidism. He emphasized the point that the care of the woman delivered should not end until the cervix had been attended to and involution completed.

Dr. Joseph Price, of Philadelphia, said the practice of midwifery in private and public cases differed greatly, and that there was not the enthusiasm in obstetrics that there was a few years ago. With Parvin died the last obstetrician in America. He deplored the general use of the family syringe in private practice. The indiscriminate use of the curette in many cases was simply guesswork: often the finger would bring away that which had not been detected by the curette. He believed that nothing was more important than the fact that at the present time we have no enthusiastic specialists in obstetrics. Too often an obstetrician sought the position of teaching obstetrics, but practised gynæcology.

Dr. Ritter, of Kansas City, said that Dr. Duff's paper had the genuine ring, and, as Dr. Price had said, enthusiasm in obstetrics was on the wane. He also thought that there was too great a tendency to use the syringe. He believed that if more attention was paid to the alimentary canal the patients would be in a better condition. He also agreed with the essayist that too often strong germicidal remedies were used. Of more importance was thorough cleanliness in the practice of obstetrics.

Dr. Miller, of Syracuse, thought that in treating puerperal fever the source of infection should first be ascertained. This infection was sometimes carried by the physician, who might at the same time be in attendance upon a pus case which was due to the more virulent infection, and if the field was sufficiently large there would be great development of the septic poison with serious danger to the patient. If due to sapræmia the curette and irrigation would do good by washing away the products. The specific treatment was indicated by a recognition of the source of infection.

Dr. Tuttle believed that if the cases of disease due to parturition were ruled out, there would be few women complaining of abdominal trouble. He thought the matter must be regarded from a preventive standpoint, and that it resolved itself into two stages: (1) the preparation of the patient before delivery, which should be as careful as that for abdominal section or vaginal hysterectomy; (2) that which was perhaps more important than the first—careful investigation of the parts immediately at the close of labor.

Dr. Zinke, of Cincinnati, did not doubt that the majority present knew how to prevent sepsis during and after labor; when and when not to curette, and when and when not to use a dull or sharp curette. The trouble he believed lay elsewhere: the obstetrician of the present day did not hold the position he should because it did not pay to be a specialist of obstetrics, and the cause of this was in the fact that when graduating a man thought he knew all about obstetrics. He appreciated the remark of Dr. Price because he held the chair of obstetrics, and was bound to practise gynæcology to make it possible for him to pay his debts. In his opinion the chair of obstetrics ought to be endowed. He thought obstetrics could be thoroughly taught even if the obstetrician found time to do gynæcological work. The attempt to establish maternities for teaching-purposes had been frustrated, and to teach obstetrics thoroughly and to practise this department as it should be practised, due consideration must be given to all these things. Dr. Zinke thought an obstetrician should not be blamed for not limiting himself to the position which he occupied and for practising something else which he understood just as well, simply because it did not seem right to some. For himself he would like to practise obstetrics and nothing else, but he would have to starve if he depended upon the practice of obstetrics alone.

Dr. Duff, in closing the discussion, said the subject of obstetrics had not been a popular one; that he made his living out of gynæcology, and taught obstetrics incidentally. That obstetrics did not pay financially he believed to be the fault of the profession. With reference to sepsis he thought we were coming to the day when consideration would be given, not to septic infection, but rather to the prevention of sepsis in obstetrics. He expressed the hope that the spirit engendered by this discussion might aid in the obstetric physician becoming popular.

The Causal Relation Intra-Abdominal Diseases Bear to Nervous Disturbances Recognized by Gynæcologists, Ignored by Neurologists.—Dr. Henry O. Marcy, of Boston, in this paper considered the importance of the physiological function of reflex action of nervous centres in health, the normal relationship of afferent fibres, nerve centre, and efferent fibres. Motor impulses were spoken of; also inhibitory nerve centres, and automatic action. The deep reflexes were believed to be of little value. Certain groups of symptoms were shown to be indicative of local lesions. These were considered in relation to their bearing on the reproductive organs of woman in health and in disease. A careful knowledge of the pathological reflexes of the first were stated to be important in proper differentiation of organic lesions of pelvic structures.

The Principal Obstetrical Advance during the Last Half-Century.—Dr. A. H. Halberstadt, of Pottsville, Pa., in this paper declared the standstill in obstetrics to be due to so much attention being given to gynæcology through the fascination of abdominal surgery. He said that little advance had been made in obstetrics since the death of Hodge and Meigs. Asepsis and anæsthesia he considered to be the only advances made during the last half-century, and these he stated did not apply to obstetrics more than to medicine and surgery. Symphyseotomy he considered as fleeting, and gave a brief report of two cases.

Neuroses due to Auto-Intoxication from Faulty Menstruation.—Dr. Arthur Johnstone, of Cincinnati, read this paper. He spoke of the repair or the cure of an inflammation of the pelvis as doing much to regulate menstruation; and stated that with this regulation came the relief of headaches, migraines, neuralgias, and all the other nervous symptoms to which we were so thoroughly accustomed. This relief he believed to be sometimes caused by the removal of the scar tissue; but this scar tissue could not by any means cause the general systemic disturbance present in most of these cases. Relief came gradually, and each successive menstruation was better; still, perfect relief did not come for six months or a year, which proved that the relief was due to the drainage of accumulated poisons from the system by a perfect menstruation. The majority of nervous symptoms in gynæcological subjects he believed to be due to retained excretions which defective menstruation had failed to eliminate. Another great cause of neuroses was the intestinal infection accompanying nearly all these cases. The main thing to remember was that the bad cases belonged to gouty families, and for their relief reference was made to Haig and Rachford on the leucomain poisons. Elimination was the keynote of their work. Exercise was stated to be only another form of elimination.

Traumatisms and Malformation of the Female Generative Apparatus as the Cause of Insanity.—Dr. George H. Noble, of Atlanta, Ga., based this paper upon his personal observation, and many replies received from alienists and gynæcologists of the United States relative to the subject. He stated: (1) that traumatisms and malformations of the female genital apparatus were indirect or exciting causes of insanity; (2) that heredity did not necessarily play a part as a cause, but was found in a large percentage of cases; (3) that many operations had been done with satisfaction and uniformly good results; (4) that no special form of insanity followed the above conditions. Some institutions made a practice of examining women inmates for the above-mentioned conditions, and were giving much attention to the gynæcological side of the question with much satisfaction.

The Third Element in the Equation between Pelvic and Abdominal Disease in Women and Disturbance in the Nervous System.—Dr. H. A. Tomlinson, superintendent of St. Peter State Hospital, St. Peter, Minn., read a paper on this subject. He said that menstrual disorder and pelvic diseases were quite commonly associated with the different neuroses and psychoses, but in his experience they bore no apparent causal relation to the nervous disturbance, nor was the intensity of the nervous disturbance in proportion to the gravity of the physical disease; but, on the contrary, the most grave pelvic disease, even among the neurotic and insane, existed without disturbance in the nervous system and frequently without physical symptoms. In cases in which the insanity or chronic nervous disease had existed for more than a year, or the patient had a defective nervous organization, it was stated that treatment of the disease of the generative organs was practically without effect upon the insanity or neurosis, and in such cases operative interference resulting in the establishment of an artificial menopause almost invariably hastened the onset of the dementia. Operative interference the author believed was called for in the treatment of pelvic disease among the insane for the same reasons that would determine the necessity for such treatment among the sane: *i.e.*, the reasons were purely surgical. In order to know the probable curative effect on insanity of treatment of diseased generative organs, it was considered important to know the family and personal history of the patient with regard to the presence or absence of evidence of unstable or defective nervous organization, the length of time the condition had existed, and to what extent the general health of the woman was affected by the pelvic disease independently of the insanity or nervous disease.

Pelvic Disease as a Factor in the Insanity of Females, and Surgery as a Factor of Cure.—Dr. E. C. Carpenter, of Columbus, O., read this paper. He said that from the data at hand we seemed to be justified in the conclusion that pelvic disease was a factor in the cause, and that surgery was a factor in the cure, of the insane condition. The question confronting us now was, what estimate may be placed upon them as factors. As such he believed both had their limitations. The established law of multiplicity and complexity of cause admitted few exceptions in singleness of cause. He thought it important to take the broadest view in the consideration of the etiology in insanity. The specialist, the speaker said, was too prone to infer that the organ of his specialty must be the source of all other pathological conditions, when the lesions, the remote symptoms, might be but consequential to general conditions. In the consideration of cause in the insanity of women he stated that heredity, predisposition, puberty, the puerperal and the climateric periods were especially to be borne in mind. In the general physical examination pelvic disease should always be sought for, and when found to exist it should be eradicated. No physician, in his opinion, should consent to the commitment of a woman for insanity until the existing pelvic disease was removed; except under absolute necessity from the mental condition. He further believed that upon entrance into our asylums every female should be examined by a conscientious specialist, and if she was found diseased operation should be urged. In the absence of pelvic disease operative procedure should be approached with our best judgment. He thought it questionable whether medical knowledge and experience would justify operating on the defective classes, women at puberty, idiopathic epileptics, those in the preclimacteric years, and those whose insanity was not over two years in duration. All our asylums, it was stated, had representatives in them from these classes, who had not only not been benefited but made worse by operation. This list he believed it would be at least instructive to place in parallel with those benefited, in passing judgment on any case to be operated. Reference was made to a class which might be regarded as non-diseased but operable—the hysterical, those especially disturbed at the catamenia, and those in the post-climacteric years. From the first two the author considered that some of our most brilliant recoveries have come by the employment of surgery alone. Operation in the post-climacteric period, he believed, might hasten senility, but was not likely to do much absolute harm.

Interrelation of Gynæcology and Neurology in Practice.—Dr. C. H. Hughes, of St. Louis, Mo., read this paper. He stated that advances made in bio-neurological discovery gave us just warrant for the statement that, with a proper understanding of this subject, there ought to be one opinion respecting the interrelation of neurology and gynæcology in practice; there should be but one method of therapeutic procedure among both gynæcologists and neurologists, *i.e.*, to treat the whole organism and every damaged part for the best results. The omnipresence of the nervous system throughout the organism, with its afferent and efferent communications, as could be witnessed, for instance, in the interrelations of the vagus nerve and the brain and the abdominal and thoracic viscera; the relations of hysteria, a cortex lesion, to its varying subcortical and peripheral abnormalities of functions; the proven interrelations of pelvic and cerebral states as shown in the various phases of erotic life and evolution; the neurophysiological and neuropathological changes, both central and peripheral, of the catamenial stages, and the menopause in women—were dealt with. It was shown that these alterations beginning in the governing nervous system, and affecting active and reactive influences, revealed to us in a clinical symptomatology largely nervous, but also in grave pathological changes of uterine structure, admonished us that we have a patient to treat as well as a part, a case in which the knowledge of more than one specialist is often demanded in treatment. Woman, the author said, had both a gynæcic and a neurocerebral function and sphere of physiological and pathological influence, and often deserved when ill both neurological and gynæcological attention at the same time. The gynæcologist, if he treated her all over as she deserved, should be much of a neurologist, and the neurologist should be much of a gynæcologist.

Tubo-Ovarian Adhesions: their Reflexes.—Dr. A. L. Beahan, of Canandaigua, N. Y., called attention to the simulation of hysteria by conditions resulting from simple inflammatory forms of adhesions between tubes and ovaries. Differential diagnosis of this border-line disease was shown to be paralleled by insanity caused from structural changes in the appendages; the former consigning the patient to chronic invalidism, misnamed neurasthenia or hysteria, the latter excluding from society if not ostracizing from home. The author emphasized the fact that tubo-ovarian adhesions occurring in the early years of a woman's life might, by reflex as well as by direct effects, give in insidious ways obscure nervous symptoms, and a great error would be made if from a lack of a discriminating diagnosis this disturbance was characterized as one in which systemic forces alone were at fault instead of local ones. It was claimed that a clean removal of both appendages cured the patient, and a nervous wreck became a healthy, happy, useful being.

Gall Stones and Diseases of the Gall Bladder, and Nervous Symptoms Resulting Therefrom.—Dr. Edwin Ricketts, of Cincinnati, read this paper. He said that clinically speaking there were recognized by operators marked nervous manifestations of a most detrimental kind, but that just how these were caused had so far not been satisfactorily explained. The contents of the gall bladder, with or without gall stones, might become infected by the bacillus coli communis or a pyogenic streptococcus entering the biliary passages from the duodenum or through the blood of the portal vein. He advocated the removal of gall stones as soon as diagnosed. Distended gall bladders that failed to empty themselves by well-selected internal medication and with massage through the abdominal wall, he believed should be drained by means of cholecystotomy. The views of the author were based upon an experience of forty-six cases.

The foregoing papers were discussed together.

Dr. Porter, of New York, in opening the discussion said that to him the most interesting fact demonstrated by the papers was that physicians must not attempt as gynæcologists to deal with this most important subject alone, but must combine with the neurologist, which unfortunately was too infrequently done. In his opinion, by operation the patient was sometimes put into a worse condition than before. He believed that in connection with the asylums for the insane there should be consulting gynæcologists.

Dr. G. E. Shoemaker, of Philadelphia, thought that Dr. Hughes struck the point at issue when he stated that the gynæcologist and the neurologist should have the same view-point. He stated that there was one central standpoint of truth, and if all could get the same training and look at the problem from the same point the problems would be solved. Reference was made to a friend who was at the head of a great institution for the insane, who was strongly opposed to gynæcological work for the insane, and he stated that large numbers came into the institution who showed depraved nutrition. They were fed to the highest point. Many were helped and not a few cured. It was shown that the gynæcologist treated cases showing definite disease and profound nervous disease in the same way.

Dr. Eastman, of Indianapolis, referred to the remarkable increase of cancer and insanity as the two important subjects confronting the medical profession to-day. From the discussion he thought it appeared as if the old practitioner, who looked through the whole system, was again to come to the front; but "to plough deep, means in no sense to turn a wide furrow." Two specialists working along these lines would, in his opinion, secure the best results.

DR. I. S. STONE, of Washington, said he was reminded of a discussion along these lines some years ago, when several papers were read before the American Medical Association on insanity due to pelvic disease, which resulted in inquiries being made of every insane asylum in the United States as to examinations. He claimed credit for the gynæcologists in starting this inquiry.

DR. BENJAMIN, of Camden, referred to his success in the treatment of patients in whom there was no clear indication of lesion, with those medicines which were used in neurological cases, and through this means there had been a reduction of ovariotomy.

DR. ZINKE, of Cincinnati, said he was reminded by the discussion of to-day of that held in Denver at a previous meeting of the American Medical Association, and a comparison showed the wonderful progress that had been made: peace prevailed to-day where then all was war. He wished to contribute his share of compliments due Dr. Hughes. He cited two cases, one in which he had removed two pus tubes and in which the wound healed perfectly and the woman left the hospital sane, but within a short time symptoms of insanity developed and she was placed in an insane asylum for eighteen months. The doctor was condemned. The other case he saw within two months thereafter, in which also there were pus tubes, and in this case he urged operation, notwithstanding the result in the first. Comparisons were made by the family and operation refused. In exactly two weeks afterward this patient was insane without operation. She was not right to-day, while the other had recovered perfectly. He regretted that he could not agree with Dr. Ricketts in everything he said. He had seen patients who had been the victims of gall stones for years, recover without operative interference and he did not believe it was right to operate as soon as the diagnosis of gall stones was made.

DR. CARSTENS believed that if it was simply considered that healthy ovaries and healthy tubes would not produce insanity, and that the same organs diseased would produce all kinds of disturbances in the alimentary canal and interfere with the process of digestion, the function of the kidney, and the elimination of effete material—which effete material would lower the nutrition of the nerves—it would be easily seen that there was a tendency to the increase of insanity from this source. If it was considered, too, that the pathological condition at the nerve periphery produced a process of irritation and, if the process of irritation continued for a long time, we might remove the nerves but the pathological condition became permanent, the wisdom of early removal of the reflex cause would be apparent. He believed great precaution should be used not to promise the patient too much from operation. He defended Dr. Ricketts by saying that if pus tubes ought to be removed, also gall stones when diagnosed should be removed.

DR. BALDY, of Philadelphia, thought the whole subject resolved itself into the two questions: Will pelvic or gynæcological troubles cause insanity; and, if so, will operation cure? After due consideration he was convinced that gynæcological troubles did not cause insanity. So convinced of that was he, that the suggestion that every insane woman should undergo a physical examination, and operation be done if a lesion was found, appeared to him a preposterous one and entirely indefensible. Many healthy married women had lesions which in no way caused symptoms, and the only argument in favor of operation was for the removal of symptoms.

DR. PALMER DUDLEY, of New York, said that he did not discuss the subject from the standpoint of the neurologist, but from his experience he believed that if neurologists would look over the statistics of cases in women they would find, aside from heredity when they could trace a direct line of insanity, that the majority of cases under their care were puerperal, *i.e.*, having puerperal fever as a starting-point. Therefore he agreed with the neurologists that insanity was directly produced by pelvic trouble.

DR. HUGHES, in closing the discussion of his paper, referred to the matter of promising too much from operation, and stated that he was very guarded in his prognosis.

DR. CARPENTER, in closing, said his position, in giving to the insane the same advantages as to the sane woman, was unchanged, because the minutest part of the disease was so serious a question even when only a probable element that he thought the patient should undergo operation for the removal of the cause.

DR. MARCY, in closing, referred to a consultation between the distinguished Brodie and Watson, the result of which was the opinion that it was good medical practice to remove the cause of irritation if possible, and then trust that the irritation itself would cease; and it would appear from the discussion that in this century we were not very much wiser than those celebrated men of the earlier time. Gynæcologists and the neurologists were one in removing the cause of irritation and in trusting to God for a better result.

SECTION ON PEDIATRICS.

Second Day—Wednesday, June 6th.

Demonstration of Home Milk Modifier.—DR. A. L. SHERMAN, of New York City, exhibited this apparatus, which consisted of a glass jar showing seven panels, with lip, capable of holding sixteen ounces. One of the panels presented an ounce graduation, while the other six had different formulæ for modifying cow's milk. He said that the physician should decide what formula was to be used, and ignore the others. The food should be compounded for the period of twenty-four hours. The apparatus is called "the materna."

Causation and Relative Frequency of Typhlitis, Perityphilitis, and Appendicitis in Infancy and Childhood.—DR. JOSEPH N. BYRNE, of New York, presented this paper. He said that typhlitis was generally due to primary conditions, while perityphlitis was always secondary. The advancement in bacteriology and pathology during the past twenty years forced us to abandon our former theories. He spoke of the relative position of the appendix, it often being directed toward the spleen, but it might be, and often was, directed downward.

Milk Supply and Control at the Kaiserin Friedrich Hospital.—This interesting paper, by DRS. ADOLF BAGINSKY and PAUL SOMMERFIELD, of Berlin, was read by Dr. Louis Fischer, of New York. The control of the milk supply in general necessarily began with the care and the arrangement of the cow stables. They were built of brick, iron, and cement, and were two stories in height, and the walls were finished with glazed brick. The building was 30 metres long, 11 metres wide, and 4 metres high. The lower story was divided into two compartments, while the second story was one open room. The ground floor was raised at one end slightly in order that it could be flushed easily. The cows stood in stalls that were called "feeding-tables," which were made of cement. The mangers were of glazed bricks. Each animal had a separate stand, and it was raised 2.7 cm. with a sloping floor. The water supply was automatic. Sawdust was used in the stalls. The cows were of Holland breed. All of them were injected with tuberculin and were under the constant care of a veterinary surgeon. The animals were fed in two ways, viz., dry feeding and wet feeding. Those that were dry-fed produced the milk used for infant feeding. Swill was entirely forbidden. It had been noted that cows fed on the products of distillation of potatoes and corn soon suffered from diarrhœa, and the milk had a certain toxic effect upon the child. The principal dry food-stuffs used were clover, residue of breweries, wheat, and the bran of rye. When it was necessary to stimulate the appetite, small quantities of dry cut bagasse, or sugar-cane stalks, were given. The wet or moist feedings used were turnips, rye, bran, and hay. The stables were cleaned before each milking, and the men were obliged to wash their hands as well as the udders. This did away with milking-machines. The milk was removed immediately. Milking was done three times a day. By the immediate removal of the milk to the dairy, where it was filtered, sterilized, and cooled, the danger of infection was reduced to a very small point. It was found that the bacilli of potatoes and hay were the most difficult to destroy, and the warm milk easily absorbing fumes would become infected. Thus the milk would be affected by the perspiration from the cow, and so would have a repulsive taste. In filtering the milk, linen cloths were used. These were readily boiled and cleaned, which was a simple and inexpensive method. The milk for house use was cooked in copper vessels and packed in ice-boxes. Milk for children was mixed with oatmeal gruel, and after sterilization was bottled and cooled to 10° C. The milk was transported in galvanized tin cans. Sterilization was performed by the Soxhlet method in what is called a Henneberg sterilizer. This held two hundred and sixty-four bottles. The paper closed by mentioning some of the different modified milks.

Infant Feeding.—DR. ALEXANDER MCALLISTER, of Camden, N. J., read this paper. He said that the generations yet unborn were more or less influenced by the methods of infant feeding. The mother's milk would go farther to solve this question than any chemical combination. The infant's food was strictly an animal food and not a vegetable one. We could not improve upon nature's method. He then spoke of young married society women, who for social or other reasons would not nurse their young. Dr. McAllister mentioned, in passing, the well-known pictures of "fat babies" seen in certain advertisements of "infant foods." Babies fed naturally were in a better condition to resist disease, while the artificially fed infants were exposed to constant dangers. The milk from the time of milking to the place of feeding was in constant danger of being infected. Pasteurization and sterilization were used, but not in every home. He spoke of the importance of partial breast-feeding, and thought that even one breast-feeding in twenty-four hours would be very beneficial. Young mothers, who had little milk, should be treated for it, and everything possible should be done to increase the flow. Food for the mother was very important, such as cow's milk and other fats. He referred to galactagogues, with diet, and thought in this way many lives might be saved. In considering the different modified milks, he said that there should be an excess of proteids in water, but one had to keep in mind the needs of the individual case.

Infant Feeding; Accidents and Incidents.—DR. WILLIAM P. NORTHRUP, of New York, read this paper. He spoke of the responsibility of the physician in such cases. In regard to modified cow's milk he said there was a greater responsibility upon those who persisted in using a fixed formula. He cited a case of a female child that had a fair start in life. When she was three days old, modified milk was given. At the age of nine months she had bleeding of the gums. One eye was seen to be black and blue, and then swelling of the ankles and knees was noticed together with paresis of the lower extremities. Later she had blood in the urine. The patient was put on orange juice and other anti-scorbutic treatment, but the child did not improve as much as she should have done. When she was two years old she had typical rachitis. Dr. Northrup advised, in closing, to begin with a formula and increase the amounts rapidly. Sick children could not stand as much proteid as could well children.

DR. H. D. CHAPIN, of New York, said that in sterilizing milk a chemical change took place. When modified milk first came into use it was thought that the question of the percentage of fats and proteids was solved. It was not solved. The less manipulation of the milk the better. When an emulsion such as milk was once broken up it could never be restored in as perfect a form. Dr. Chapin said that the milk should be bottled at the farm and then sent on its journey. He said that when milk was bottled in cylindrical vessels and cooled to a temperature of 50° F., nine-tenths of the butter fat rises to the top of the bottle. He said that there was nothing so variable as cream, the percentage of fat varying with the layers. Dr. Chapin exhibited a small dipper which held one ounce, to be used to take the cream off of the top instead of using a siphon drawing from the bottom. He showed a chart relating to what was called the "deep-setting process of milk," and its relation to fats. Mother's milk varies from day to day. Dr. Chapin spoke of the importance of watching the stools, and said that gruels were of service because of their dextrinizing power. When a gruel was thoroughly dextrinized, the solution would separate into two layers.

DR. VICTOR C. VAUGHAN was the next speaker. He agreed with Dr. Chapin as to the value of sterilization of milk. Sterilization changed the proteid into a nucleo-albumin at high temperature. There was no change at the temperature of 158° F., but when heated two degrees higher nucleo-albumin was formed. He spoke of the bacillus coli communis in milk, and said that while we were able to kill the bacilli we had no control over their toxins. Dr. Vaughan mentioned a case of a child who was poisoned by the parents' allowing the milk to stand for three hours at summer heat.

DR. W. L. STOWELL, of New York, said that modified feeding was ideal, but did not work practically. He mentioned some cases of scorbutus, and said that children would digest an amount of casein. He thought the main difficulty in artificial feeding was that the milk was not modified rapidly enough for the growing child.

DR. A. JACOBI said that if any person present thought he could lay out any routine feeding, that person had found by the papers read that he was mistaken. He had taught for years that milk should be diluted with cereals. He said milk once separated could never be made milk again. Nine to ten per cent. of breast-fed children had fat in their stools. He said that nature was more generous than doctors.

DR. J. P. CROZER GRIFFITH, of Philadelphia, said that he believed in sterilized milk.

DR. KOPLIK, of New York, said that the whole problem was still unsettled. He believed the day would never come when a clean milk could be procured.

DR. NORTHRUP said that he had learned of a new mixture, that of "milk and brains," and this he thought was the secret of Dr. Jacobi's success.

Demonstration of Specimen of a Fatal Fœtal Ichthyosis, with Complete Pathological and Bacteriological Examinations.—Dr. A. S. Daniel, of New York, exhibited this specimen. The maternal history was negative with the exception of severe grief over the loss of her previous child. She was delivered by a midwife, the head presenting. The paternal history was also negative as far as syphilis was concerned. The child passed urine and meconium at birth. During its life the child's body was rigid and cold. After death the temperature was 103° F. Necropsy showed an absence of the panniculus adiposus, and the heart was normal. There were a few small areas of emphysema in the lungs. The liver was congested and showed granular degeneration of the liver cells. A meningeal hemorrhage was also present. Dr. Daniel then reviewed the histories of these cases, and found that only forty-two cases had been reported.

Gastro-Intestinal Hemorrhage in the New-Born.—Dr. Edward H. Small, of Pittsburg, Pa., read this paper. He had had a case of a female child, born at full term, who began to vomit blood about the third day. A little later she had a tarry movement, and then she passed clots of blood. She died on the eighteenth day, treatment being of no avail. Dr. Small said that the following causes had been ascribed to this accident: sepsis, syphilis, respiratory disturbances, malformation of the heart, conditions of the blood, hæmophilia, worms, ulcerations in the gastro-intestinal tract, and delayed labor. These cases were more common in hospitals. This fact, he said, suggested that this disease was of the character of an infection. Diplococci resembling that of pneumonia and streptococci had been described.

Clinical Significance of Stools in Diarrhœa of Infants.—Dr. William E. Darnall, of Atlantic City, N. J., read this very interesting paper. He spoke of the importance of examining the stool and napkins of the child and not depending upon the mother's statement. The usual history of these cases was as follows: The child became cross and irritable, which was soon followed by an attack of acute indigestion and colic. The mother would feed the child every time it cried, thus increasing the symptom. Green stools were the rule, the so-called spinage-green stool; sometimes they were pea-green in color; others were brown and muddy in character. These he thought were due to bile. Some stools were loose and watery. He spoke of the stools with more or less mucus, due to some colitis or proctitis present. In these cases the rectum was often relaxed. The "constipated stool," so-called, he thought was due to a deficiency of fat in the child's diet. The serous discharges were often important. The treatment of these cases consisted of elimination, disinfection, and feeding. All food was to be withdrawn for twenty-four hours, and only cold water given that had been boiled, or barley water. He prescribed ʒ ss. of aromatic syrup of rhubarb, or salol gr. ¼ t.i.d. Dover's power in grain doses was also of great benefit in cases with an excessive number of stools. Hot applications over the abdomen were often of service. In cases of mucous stools, high rectal irrigations of warm water or saline solution were very serviceable as well as soothing and comforting to the patient.

Shall Children be Kept from Measles and Exanthemata Usually Incident to Children?—Dr. C. F. Wahrer, of Fort Madison, Iowa, read this paper. He said that one of the axioms in medicine was "If a child did not have a disease, it could not die from that disease." He thought that preventive medicine was better than a cure. We had quarantine regulations for consumption and cerebro-spinal meningitis. Scarlatina was the most dreaded of these diseases, for there was no way of foretelling its complications, which sometimes disfigured the patient for life. The same was true of diphtheria. The mortality of measles in some epidemics was very great, more especially among adults. There were mild epidemics of measles, and why should not all children be exposed to the disease?

Rötheln: a Distinct Affection Apart from Measles and Scarlatina, and its Differentiation from these Exanthemata.—Dr. Henry Koplik, of New York, presented this paper. He said that some observers doubted that rötheln was a distinct disease. It was most often mistaken for measles. He said that rötheln was not a disease of the mucous membrane. He had never seen coryza and cough in this disease, as it occurred in measles. The slight cough present was due to an infection of the mucous membrane and tonsils as in la grippe. Children rarely complained of sore throats, but adults did. The temperature was practically normal. He said a typical case might run its course without fever. He had seen one case of rötheln with desquamation. He paid especial attention to the recent enlargement of lymphatic nodules in the groin and axillæ.

Clinical and Pathological Study of the Rash of Scarlet Fever.—Dr. Jay F. Schaumberg, of Philadelphia, read this paper. He said that the eruption in scarlatina was an infectious dermatitis, and that it varied with the patient. The different colors produced were known as redness, raspberry, and boiled-lobster appearance. In some cases there was a bluish color, due to venous congestion. The punctate spots were due to inflammation around the hair follicles, and sometimes they were so enlarged as to produce roughness, which was spoken of as "nutmeg feel." Sudamina were due to droplets of sweat. He exhibited a photograph showing marked sudamina over the mons veneris. Vesicles were often present, but not much larger than pin-points, and oftentimes they were microscopical. He said that the vesicles were directly proportional to the intensity of the disease. The skin was infiltrated with eosinophiles, and these seemed to stimulate the cells in the corium to multiply. Several karyokinetic figures were shown in microphotographs.

Dr. Wahrer said that what was wanted was a clinical study of the disease.

Dr. Griffith said that he would not be willing to expose his children to measles. The mortality was as large as that of scarlatina and diphtheria together. He said that desquamation in rötheln did occur. Ten years ago his attention had been called to a case of measles with enlarged cervical glands and no disease of the scalp.

Dr. Louis Fischer spoke of the complications of measles. Last winter he had cases with otitis media and emphysema, and one case of vaginitis following measles and lasting for several months.

Fœtal and Infantile Typhoid.—This paper was read by Dr. John Lovett Morse, of Boston. He said he would not consider the cases reported before the typhoid bacillus was discovered. By experiments on animals he found that the bacilli could pass from the mother to the child; also that they were found in the amniotic fluid. He referred to fœtal typhoid, which had entrance through the blood, and called it a septicæmia; he also spoke of infantile typhoid and the serum reaction.

SECTION ON MATERIA MEDICA AND THERAPEUTICS.

Second Day, Wednesday, June 6th.

Discussion on Diabetes.—Dr. O. T. Osborne, of New Haven, differentiated between true diabetes and glycosuria. In all cases some malfunction of the pancreas was at the bottom of it.

Dr. J. M. Allen said that in seven personal cases of diabetes in which an autopsy was made he found a chronic inflammatory process in the duodenum in each of them. The value of opium consisted in its quieting effect on the bowel. Intestinal antiseptics were to be used in all cases.

Dr. Brower, of Chicago, related the history of a case that was due to colon infection, with recovery.

Dr. Bartley, of Brooklyn, pointed out that the copper test was useless for determining small quantities of sugar in the urine. When albumin was not present, the bismuth test was the best that we possessed.

Dr. Solomon believed that we might educate patients to consume large amounts of fats. A certain percentage of alcohol was often beneficial. The discussion was continued by Drs. Lyons, of Detroit, and Zwisohn, of New York.

Dr. Stern stated that for the past ten years in New York City there were eighteen hundred and seventy-six deaths from this cause; fifty per cent. of these cases were in women. In some patients an absolute milk diet afforded the best results. In most cases of diabetic coma oxybutyric acid was present. The most frequent cause of oxybutyric acid was fat meat. The color tests for sugar in the urine were unreliable.

Gastro-Intestinal Remedies in Typhoid Fever.—Dr. I. M. Anders, of Philadelphia, presented this paper. The importance of careful feeding and cool baths in the prevention of complications could not be said to be overestimated. From two to three quarts of water should be administered daily. This was best given between the feedings. If hydrochloric acid was given after the feeding, there was less likelihood of indigestion. The stools should always be examined both microscopically and macroscopically whenever any complication arose. Errors in diet and digestion were generally the cause of fresh symptoms. Intestinal antiseptics controlled meteorism, diarrhœa, etc. They had no effect on the bacillus typhosus. Calomel should be given for the first few days, or even as late as the second week if necessary. Salol gr. iii. every three hours was his favorite drug. In tympanites due to ulceration of the colon turpentine in small doses was often useful. The so-called specific or Woodbridge treatment was entirely useless in the control of the disease. Intestinal irrigation was often beneficial for the diarrhœa that occurred late in the disease. In many cases of delayed convalescence a saline would cause rapid and permanent reduction of the temperature.

Dr. Favill, of Chicago, said that the type of the disease had changed in the last ten years. Much of our success was due to hydrotherapy. He employed saline enemas of one pint several times daily with much success. Guaiacol was given internally.

Dr. T. F. Reilly, of New York, called attention to the value of fair-sized doses of strychnine in the management of the constipation during the decline of the fever.

Dr. W. B. Hill, of Milwaukee, believed that we feed too often. Flushing of the colon with cold saline solution lowered the temperature better than the external application of cold water.

Dr. F. Woodbury, of Philadelphia, pointed out that all water that was given to the patient should be sterilized.

Dr. Anders in closing said that the urine should be watched if large doses of salol were administered. The salol prevented complications, but had no effect on relapses. The intestinal antiseptics prevented the multiplication of other germs and rendered the stools less offensive. An absolute milk diet was best in most cases.

Brief Note on Ointments and Some of their Medicinal Applications; the Iatraliptic Method of Treatment.—Dr. Frank Woodbury, of Philadelphia, read this paper. He described the various classes of ointments. If warmed, many of them could be used in a nebulizer and sprayed over the cavities of the body. The value of inunctions of cacao butter and cod-liver oil in overcoming the denutrition of typhoid fever and of diabetes was pointed out. Poisons might be transmitted by the skin as well as medicines. Most of the ointment bases in present use contained various toxic agents, as a result of the micro-organisms contained in them. Lard was generally septic. In order to overcome this ointments should be dispensed in collapsible tubes similar to those containing artists' colors. This would also prevent the carrying of infection, and was an economical way of using an ointment.

Idiosyncrasy against Mercury; a Case of Erythema Mercuriale.—Dr. A. Bernheim, of Philadelphia, presented this history of a case of erythema mercuriale, due to the ingestion of a small amount of mercury. There was a history of four such attacks in the same patient, following at each time the use of the drug.

The Unbroken Skin as an Absorbing Medium.—This paper was read by Dr. Thomas F. Reilly, of New York. He said that a medicinal agent to be absorbed by the unbroken skin either must become volatile during its application, or be incorporated in a fatty base and applied with friction. Occlusion was an absolute requirement in the case of volatile substances. Most of the absorption occurred in the crypts of the sebaceous glands. The effect was much slower, about one-fourth as intense, and continued longer than when the same agent was administered by the mouth. A large number of medicinal agents, which when given by mouth were intolerable to many patients, could be administered in this way with scarcely any unpleasant effects. The literature mentioned the following medicinal agents as having been successfully employed for their constitutional effects when applied in this manner: Mercury, iodine and iodides, salicylic acid and some salicylates, guaiacol, creosote, iodoform, turpentine, carbolic acid, pilocarpine, croton and cod-liver oils, metallic silver, quinine, digitalis, and belladonna.

Dr. Remington, of Philadelphia, said that cacao butter was one of the best bases that we possessed. It was practically sterile and could be softened if mixed with a small quantity of any fixed oil. For inunction purposes he placed oleic acid at the head of the list. The great advantage of cacao butter was that it was solid at 94° F., and fluid at 98° F.

Dr. Solomon called attention to the fact that some drugs were readily absorbed no matter what the ointment base might be. Ichthyol was cited as an example of this class.

The paper was further discussed by Drs. Rotter of Harrisburg, Lyon of Detroit, Wheatly, Reamy, and E. Boardman-Reed of Philadelphia.

The Metric System.—Dr. F. G. Wheatley, of North Abington, Mass., in this paper set forth the many advantages that would arise from the general use of this system.

Dr. Bartley, of Brooklyn, said that if the prescriptions were written only in terms of grams and milligrams much confusion would be avoided.

Report of Cases Illustrating the Value of Rectal Injections of Salt Solution in Hemorrhage.—Dr. T. B. Greenley, of Meadow Lawn, Ky., presented this report. The histories of several such cases were reported in which the procedure was a life-saving measure. From one to two quarts of decinormal salt solution was employed.

Preventive Treatment of Migraine.—Dr. E. W. Mitchell, of Cincinnati, Ohio, discussed in this paper the various theories that had been advanced to explain the cause of this affection. The theory of auto-intoxication had the most adherents. The paraxanthin theory had not been verified. He believed in an absolute withdrawal of all red meats. These attacks could generally be prevented by the use of the following mixture, to be taken each morning before breakfast: Sodii sulph. and sodii phosph., of each ʒ ii.; sodii salicylas, gr. x.; tr. nux vom., ♏ iii; water, ℥ iv. This was best administered in seltzer or Vichy.

Dr. A. L. Benedict, of Buffalo, said that as a general rule the amount of hydrochloric acid was very much diminished in the gastric secretions of these patients. He advised that it should be administered as a routine treatment.

Dr. I. N. Upshur, of Richmond, thought that the disease was in almost every case due to nerve strain. It was caused by dietetic disturbances in only a very small percentage of the cases. In many of these cases during an attack the fæces were clay-colored, and this was due to disturbances in the liver. Full doses of sodium phosphate in hot water on an empty stomach for several days had given him the best results.

Dr. J. M. Allen stated that in many of these cases in which he had performed autopsies there was a chronic ulceration of the common bile duct, which, when inflamed, penned up the secretions in the gall bladder, and then they were diffused throughout the system.

Dr. Bartley pointed out that Haig, in his work on this subject, confused xanthin with uric acid, and that many of his conclusions were faulty.

The paper was further discussed by Drs. Yasnall, of Washington, and H. Stern, of New York.

Dr. Mitchell, in closing, said that the white meats were less likely to cause fermentation than the red meats, and therefore were to be preferred.

The Rôle of Drugs in the Management of Consumption.—Dr. S. Solis-Cohen, of Philadelphia, presented a paper with this title. He said that tuberculosis was a curable disease. Drugs played a secondary part in its management. In the pretuberculous stage nitroglycerin was a valuable agent, causing the blood to penetrate to the utmost recesses of the lungs and thus to favor nutrition. All the tonics and good hygiene were to be employed during this stage. The building up of nutrition was the broad principle of cure, and should be pursued throughout the whole course of the disease. Digitalis was very valuable in cases in childhood and also in the florid or galloping variety, and in the bronchopneumonias occurring in chronic tuberculosis. Iodine and iodoform were the most useful drugs to influence the local condition. He began with doses of iodoform gr. ss. three times a day in pill form. This was gradually increased until in three months the patient was taking gr. v. t.i.d. As an inhalation both the iodide of ethyl and myrtol had given very satisfactory results. Myrtol if given internally was one of the best agents for the control of the bronchial inflammatory conditions accompanying the disease. Formaldehyde by inhalation acted well in the laryngeal form. Calcium chloride given in dose of gr. xv. every two hours continuously for three or four days would stop persistent hæmoptysis. It should not be continued for more than five days. Hydrastine hydrochlorate was also useful. Ergot was useless for this purpose. Camphoric acid and atropine usually would control the night sweats.

Importance of Early Recognition of Tuberculosis.—This paper was read by Dr. A. M. Holmes, of Denver, Col. He divided the disease into three stages: (1) The pretuberculous stage, in which there was no lesion but a susceptibility; (2) early incipiency—a lesion or tuberculous infection being established, but bacilli not being present in secretions or excreta; (3) when a well-established lesion was present and bacilli appeared in the sputa. Among the early suspicious symptoms might be mentioned a rapid and variable pulse. Pleuritic friction sounds were generally of tuberculous origin. The cog-wheel respiration was a very suspicious sign. This was heard most plainly toward the end of inspiration, and was accentuated if a strong heart action was present. Subnormal temperature in the morning was another early sign.

Dr. William H. Thomson, of New York, said that tuberculosis was either simple or complicated. In the lungs it was always of the latter sort. The disease would have no antitoxin because it was unlike the other infections in that nature did not tend to limit its growth. Birch-Hirschfeld was quoted as having found it present in seventy-eight per cent. of four thousand autopsies. In the lungs the constant movement in respiration was a great hindrance to its cure. The specific effect of the tubercle bacillus was emaciation. By this was meant a loss of fat in every tissue except the nervous system. The facial expression and contour of the consumptive was the result of this emaciation. As therapeutic agents iodoform and arsenic ranked foremost. He administered creosotal in doses of gr. xx. every two or three hours. There was no drug that would act so well in the septic cases as fresh air. Cod-liver oil was generally ordered when the stomach tolerated it.

Dr. I. N. Upshur said that the stomach was to be preserved at all hazards. Hygiene was to be relied on, and few drugs should be given.

Dr. Cohen, in closing, emphasized the point that the patient's vital resistance was the key to the whole situation, and everything possible should be devoted to the increasing of this resistance.

Heart Tonics.—Dr. I. N. Upshur, of Richmond, Va., discussed this subject. He said that digitalis was an unsatisfactory and uncertain remedy because its action could not be controlled. The same was true to a less degree of convallaria. Sparteine was of great service in weak and flabby hearts. Strophanthus was very much superior to digitalis. It was more prompt in its action and more permanent in its effects. When combined with strychnine it was a most valuable agent in fevers and weak states of the system. Atropine was of especial value in cases of cardiac insufficiency accompanied by bronchorrhœa. Caffeine was of considerable service when the kidneys were affected. Strychnine was our most valuable and reliable heart tonic. If given before chloroform anæsthesia it prevented cardiac failure. It was invaluable in the case of a weak heart from any cause. Nitroglycerin was not a heart tonic. It was contraindicated in weak states of the system, and especially in surgical shock. It was a motor depressant, and its too free use was fruitful of harm. In the late stages of typhoid, opium seemed to have a true tonic effect on the heart. Cactus grandiflorus was useful in cases of rapid heart due to tobacco poisoning.

Dr. Garlock, of Little Falls, N. Y., said that most of our therapy in heart diseases should be directed to the condition of the blood rather than to the heart itself.

Dr. Melvin, of Saguache, Colo., said he had employed cactus grandiflorus either alone or with strophanthus in various forms of cardiac disease, and was well pleased with its action. He gave the fluid ex tract every four hours in doses of ♏ ix.

Dr. Heinrich Stern said that adonidin was one of the safest and surest of cardiac tonics that we possessed. It was of especial value when nephritis was present.

Classification of Medicines Based on the Time Required to Produce their Effects.—Dr. William

H. Thomson, of New York, read this paper. He said that the vagueness of terms used to designate medicinal agents was the cause of much of the therapeutic scepticism of the present day. The classification should be founded on fundamental distinctions. He distinguished two general classes: (1) Functional or symptom medicines; these had no effect on structure. (2) Nutritive medicines; these should not produce symptoms no matter how long they were employed, and they affected structure solely. He outlined how the classification could be carried out in the case of the commoner drugs, and spoke of the different actions of large and small doses of the same drug.

GENERAL SESSIONS.

Third Day—Thursday, June 7th.

Oration on Medicine.—Dr. John A. Witherspoon, of Nashville, Tenn., delivered this oration. He first paid his respects, in a witty and pointed manner, to the manufacturing chemists and their commercial allies, who were so fond of deluging the profession with their products, and, at the same time, giving "instruction" to the doctor concerning the use of these products, and incidentally as to the best way for him to practise the healing-art. A strong plea was made for the establishment of a national department of health, and the advantages which would accrue to the whole nation from such an arrangement were clearly pointed out. The speaker then went on to sound a note of warning against the present tendency of physicians to give indiscriminately the preparations of opium. Too often, he said, the degeneracy produced by this insidious drug was transmitted to the offspring of the unfortunate victims. The "hypodermic shot" was too often given for a stomach-ache when a dose of oil was what was needed, or it was given month after month to relieve painful menstruation, until the brilliant eye of the young and healthy woman gave way to the dull expressionless eye and the muddy skin of the morphine habitué. The same was true of cocaine, and its careless and indiscriminate use in minor surgery and elsewhere. In approaching the subject of the useless multiplication of books and authors, the speaker declared that he did so with trepidation, and that he felt like taking off his shoes, for he knew he was standing on "holy ground." Many books and papers were written merely to satisfy the personal ambition of their authors. There was a prevailing tendency, amounting almost to a mania, among young men to rush into print and appear as "authorities." He did not mean that young men should stay in the rear, but he did contend that they should print their views, not in books, but in the medical journals—those great educators of our busy profession. In conclusion, the speaker averred that when the regal robes of ethical medicine should have been made aseptic, and should have been cleansed from their present pollution, we might be justified in exclaiming:

> "Sound the loud timbrels o'er Egypt's dark sea.
> Jehovah has triumphed; the people are free."

Military Education and Sanitary Knowledge.—On motion of Dr. Tuckerman, of Ohio, the following resolution was adopted:

"*Resolved*, That the national legislative committee, in conjunction with the special committee on reorganization of the army and navy medical corps, cause to be drafted a bill providing for adequate instruction in hygiene and sanitation in the national military and naval academies, such bill to be perfected at the next meeting of the joint national legislative committee of the American Medical Association and affiliated societies, and to be pushed through Congress as speedily as possible."

A Grant for Scientific Research.—In accordance with the suggestion in the president's address, the trustees were requested to set aside the sum of $500 annually for the encouragement of scientific research, this sum to be increased in the future if the finances of the association warranted such a course. The manner of expending this sum was left to the committee on scientific research, and it was directed that the money be distributed in sums not to exceed $50 or $100 to any one individual.

Fourth Day—Friday, June 8th.

This was only a short session for the transaction of routine business.

After the usual votes of thanks, the association adjourned at 11:30 A.M., to meet in St. Paul, Minn., on the first Tuesday in June, 1901.

The total number registered at this meeting of the association was 2,030.

SECTION ON PRACTICE OF MEDICINE.

Third Day—Thursday, June 7th.

Malaria and Mosquitos.—In discussing the paper upon malaria Dr. Thayer said the commonest mosquito was not capable of transmitting malaria. Those of one genus only did so, and these only when they were themselves infected. They could take in the poison from a case of relapse and transmit it in regions previously free from malaria. As to transmission by the gastro-intestinal tract, there was little evidence in favor of it.

Dr. Edwards, of Philadelphia, said that getting rid of ground-water and using rain-water or that from deep wells had seemed to do away with malaria in certain regions of North Carolina.

Dr. Howard said the Anopheles had been found at an elevation of one thousand feet, but it was usually found lower.

Dr. Woldert said that the mosquito remained infective for two to three weeks after biting a subject of malaria. Hæmoglobinuria was due to the malaria as a rule and not to the quinine administered.

Dr. Burns, of Arkansas, reported on sixteen cases of malaria showing hæmoglobinuria, more than half of the patients having died without quinine having been given. He gave quinine in one case, and although hæmoglobinuria came on the man recovered, and since then he had used quinine freely. He thought that quinine might often save life in these cases. He objected to the term post-malarial hæmoglobinuria.

Prolonged Fevers of Obscure Origin.—Dr. Robert B. Preble, of Chicago, in this paper confined his remarks to cryptogenic sepsis, leaving aside a great number of obscure fevers due to a wide range of causes, and these were termed "obscure" only because of their occurrence in unusual locations or because of being obscured in their symptomatology and course. The reactions recently introduced (Widal, diazo, etc.), more careful examinations of the blood, exclusion of the malarial parasites, etc., had done much to aid in the proper recognition of such confusing conditions. A wide range of diseases were included in this sepsis, such as malignant heart disease, purpura, etc. In treatment the strength must be supported, and antistreptococcic serum, salt solution, etc., used.

Dr. Bishop, of New York, said there was a class of cases usually referred to as blood-poisoning. He thought some of the cases were really typhoid, as another speaker had suggested. The blood should always be examined to exclude the latter.

Dr. Davis, of Chicago, thought the explanation made a certain class of cases much clearer. In obscure fever of septic origin we must watch for endocarditis just as in rheumatism.

Dr. Preble said he did not exclude a diagnosis because of the absence of the Widal reaction. He did not suggest doing away with terms of convenience, but students should be instructed that these conditions were but different manifestations of similar processes.

Pathology of Rheumatism.—This paper was read by Dr. David Riesman, of Philadelphia.

Some Thoughts on Rheumatism and Prevention of Heart Complications.—Dr. James J. Walsh, of New York, read this paper. He said that rheumatism was regarded as an infectious disease, probably a mild pyæmia, and was self-limited. Dampness was a secondary cause. The contagiousness seemed established. That rheumatism was not a simple disease was shown by the multiplicity of organisms giving a series of similar affections closely associated. The simple form was due to a diplococcus, in rapidly fatal cases to an anaerobic bacillus in all probability. The uric-acid theory has been practically abandoned. More than half the endocarditis was due to rheumatism. There was no specific, and no drug treatment lessened the liability to the involvement of other joints or of the heart. The salicylates alleviated symptoms better than any drugs previously recommended, and were less objectionable. For heart complications nothing equalled rest in bed. These were not complications, but integral parts of the general infectious process.

The Relation of Chorea and Rheumatism.—Dr. C. W. Burr, of Philadelphia, read this paper. He said there was frequently a history of rheumatic fever or less frequently of "growing pains" preceding Saint Vitus' dance. Chorea less often occurred during an actual outbreak of rheumatism. Valvular heart disease was frequent.

The speaker did not think the coincidence of rheumatism and chorea was of sufficiently frequent occurrence to show that the one had more than a predisposing influence over the other.

The Heart in Rheumatism.—This paper was read by Dr. De Lancey Rochester, of Buffalo. He looked upon rheumatism as an infectious disease involving the heart in a large percentage of cases. The younger the patient the greater the liability to endocardial involvement. Pericarditis because of its variety was to be looked upon as a complication, more severe in effects as a rule than was endocarditis. The myocardium became involved in the presence of both inflammatory processes, but was more pronounced in pericarditis. The occurrence of endocarditis or of pericarditis did not contraindicate treatment by the salicylates.

Pathogenesis and Clinical Features of Arthritis Deformans.—Dr. A. O. J. Kelly, of Philadelphia, read this paper. He thought that of all the names suggested, the one here employed was to be preferred. The pathogenesis excluded gout and rheumatism, though these might precede or complicate. Only two theories were worthy of present serious consideration, *i.e.*, the neural or nervous and the infectious or bacterial. The arguments advanced in support of each were reviewed. He believed the disease to be an infectious tropho-neurosis, and not a disease of spinal origin or the result of peripheral neuritis. It occurred after known infectious processes.

Dr. J. M. Anders, of Philadelphia, said he had observed a heart murmur disappear in chorea following rheumatism, and did not think such murmurs always indicative of endocarditis. Acute articular rheumatism as a primary affection was rare. It was common after infectious diseases and in convalescence from scarlatina. Osteomyelitis must not be confounded with acute articular rheumatism, or the results would be disastrous. The bones here became enlarged, and side-to-side pressure directly over or above or below the joint elicited tenderness and pain in the early stages. It was often monarticular, but might involve more than one joint. In septic ostitis the symptoms were more severe, but sweats were less profuse. Salicylates did not relieve the pain. Alkalies combined with salicylates tended to obviate heart complications.

Dr. C. G. Stockton, of Buffalo, said that we had not reached a point where we could say that rheumatism depended upon one single infection, as was the case in scarlatina. Arthritis deformans was an entity. By neuro-trophic infection was undoubtedly meant that neuro-trophic changes predisposed certain tissues to infection. This was a tenable belief. So-called diatheses might likewise predispose to infection at certain points. There were climatic influences which surely had an effect. Little could be at present positively affirmed.

Dr. L. F. Bishop, of New York, said he felt more clear in his mind than some speakers as to classification. There were disorders of the chemistry of the body and of nutrition which had an influence outside of infection on which acute articular rheumatism depended. Gout was a disorder of the chemistry of the body. Trophic disturbances accounted for some affections. Arthritis deformans might come on after shock, grief, etc. He did not look upon chorea and rheumatism as the same disease.

Dr. H. B. Favill, of Chicago, believed with Dr. Bishop that there was a chemical foundation. He thought, however, that we must wipe off the slate and begin the study of rheumatism anew. On one side there was a toxic relation, on the other infection, but he could not define his views more closely. Chorea did not result from rheumatism, but occurred in those in whom rheumatism was prone to develop.

Dr. McCaskey said that the use of the term rheumatism should be strictly limited to the clinical picture we all recognized, and the designation rheumatic dropped in speaking of other affections. In arthritis deformans cataphoresis with a solution of iodide of potassium had given him satisfactory relief of symptoms. Antiseptics could be used in the same way.

Dr. Solis-Cohen said arthritis deformans must be still further separated into several classes. He thought "toxic" tropho-neurosis was more appropriate than the term "infectious." Then all would agree. He referred to the tincture of the chloride of iron in treating acute rheumatism, especially combined with salicylates and alkalies, as means of preventing heart complications.

Dr. Riesman said that we had agreed that rheumatism was "several diseases." Polyarthritis would be found to be due to one organism, and one alone.

Dr. Walsh said that endocarditis always occurred in the left heart. The blood flowing here came direct from the lungs. If the organism was aerobic, this location might be accounted for. Choreic children had usually had rheumatism previously, and that is why they had it subsequently.

Dr. Rochester said that rest in bed for six to eight weeks, often between blankets, was necessary in every case of acute articular rheumatism. He advised milk diet, occasional doses of Rochelle salts, and salicylates in large doses at intervals of two or three hours day and night. It did not affect the heart. He had given 2 gm. of salicylate of sodium every three hours for several days. Oil of wintergreen disturbed the stomach more. Iron was of the utmost importance, especially the pyrophosphate ½ gm. to 1 gm., or ♏ xx.–xxx. of tincture of the chloride.

Dr. Kelly referred to different forms of arthritis deformans. Superheated air or steam over long periods of time had been of much benefit. The salicylate of strontium had given good results.

In What Relation does Occupation Stand to Tuberculosis?—In this paper, read by Dr. W. Freudenthal, of New York, the predisposition of tailors, sewing-women, printers, and others to tuberculosis was pointed out. The speaker gave the statistics of others and the results obtained in analyzing fifteen hundred cases. He found that in many instances the primary lesion of tuberculosis was not to be looked for in the lungs, but in the upper respiratory tract, especially the retropharynx.

Diagnosis and Treatment of the Prebacillary Stage of Tuberculosis.—Dr. J. M. Anders, of Philadelphia, read this paper. He thought there was reasonable certainty about accurate diagnosis before bacilli showed themselves in the sputum. He employed with this aim *x*-rays and the tuberculin test, and carefully studies the anamnesis, looking out for symptoms and physical signs in cases presenting unusual onset. It was possible for the bacilli to remain encapsulated until inroads had been made by the disease. He advocated early pre-bacillary treatment, and recognized the superiority of hygienic and climatic conditions in these early stages.

Rest in Pulmonary Tuberculosis.—Dr. Carroll E. Edson, of Denver, in this paper showed the importance of securing proper rest, many advising exercise in the early stages, especially to the disadvantage of the patient. There were indications in the pathology of the disease for rest, and while physicians followed them as they applied to articular and laryngeal tuberculosis, they ignored them when the lungs were in question. There were also physiological reasons why phthisical patients should do well under this plan of management. This was especially true as applied to those who sought high altitudes such as those of Colorado, and there was abundance of clinical proof to substantiate the claim.

Pulmonary Tuberculosis.—Dr. C. P. Ambler, of Asheville, N. C., read a paper showing the present condition of one hundred and six patients treated in 1898, upon whose cases he had reported to the section at the last meeting. Of the cases then reported apparently cured under serum therapy reports had been received showing that they continued for the most part in the same highly satisfactory condition. Tabulated data arranged for comparison with the previous report were presented. Serum therapy was highly praised.

Tuberculosis of the Lungs.—Dr. A. F. Lemke, of Chicago, read a report upon special cases treated by the Murphy method, with nitrogen compression, giving the rationale of the method, considering the pathology, and presenting the results of his experiments on dogs. The average quantity of nitrogen which could be introduced into the pleural cavity without injurious effects was 120 cubic inches. Healthy lung tissue could be compressed for a year, and retained its capacity to expand. He found intra-pleural injections curative, and there was no evidence that fresh tubercle could develop in a compressed lung.

Silver-Injection Treatment of Pulmonary Consumption.—Dr. Thomas Mays, of Philadelphia, who read this paper, said he believed that primary changes in pulmonary tuberculosis did not reside in the lungs, but in the nervous system. Basing his treatment upon this view the reader had employed nitrate of silver injections to cause irritation over the tract of the vagi in the region of the neck. The counter-irritation stimulated to vital resistance the vagi throughout their ramifications, modifying lung conditions. In a period of a year and a half in which he had employed the method the results had been good, and more than half the patients so treated were now, at the end of eighteen months, practically well.

Dr. Vaughan, of Ann Arbor, thought that out-of-door treatment was not sufficiently utilized, in the East especially.

Dr. Rochester spoke of dissemination of phthisis by sewing-women having the disease, who worked in close quarters and had a habit of wetting the thread in the mouth. The naso-pharynx as well as the mouth was a good culture-ground for the bacilli. It was important to watch the temperature. It was probable that in health there was a normal curve of variation. Hence temperature observations must be made carefully. The sanatorium treatment was the very best, with rest out-of-doors. The individual should be treated.

Dr. Solis-Cohen said that there was a disease present before the tubercle bacillus gained entrance to the tissues. Treatment must vary with the stage. The first point was nutrition, but in all cases we must individualize. The temperature of the atmosphere had more influence upon the patient's temperature in phthisis than in almost any other disease.

Dr. Knopf, of New York, had found that laundresses who sorted dirty linen, and rag sorters were more prone to consumption than others. Prolonged rest on the back produced hypostatic congestion, so we must alternate it with exercise in well-regulated stages. He gave as little creosote as possible. Counter-irritants were of value. The tenements of the poor must first of all be improved before sanatoria are established to counteract their evil effects. The State should contribute to the care of the consumptive poor close to their homes. Climate was not a specific. Consumption was a social disease.

Dr. Newton, of New Jersey, related a case in which there was an evening temperature in anæmia, tuberculosis being suspected.

Fourth Day—Friday, June 8th.

The Relative Importance of Valvular and Muscular Lesions in Diseases of the Heart.—This paper was read by Dr. S. Solis-Cohen, of Philadelphia. He said that in the great majority of cases of chronic disease of the heart, the exact site and nature of the valvular lesion. while always to be taken into consideration in treatment, were of less importance therapeutically and prognostically than the state of the cardiac muscle. The most important exception to this general rule was in the case of mitral stenosis with great narrowing. Aconite was often in use in this condition to reduce the excessive muscular effort, not only in the absence of hypertrophy in cases of compensation, but even when compensatory hypertrophy had not become sufficient. In many cases in which no evidence of valvular lesion could be detected during life, and in some of which slight valvular alterations, in others normal valves were demonstrable after death, there existed rational signs of cardiac incompetence which were due to diseases of the cardiac muscle. In the absence of valvular lesions, intermittence or irregularities of the pulse, disturbance of rate or rhythm by slight causes. and recurrent pain referred to the precordium, in non-hysterical and non-neurasthenic subjects, were the principal local symptoms. There was usually impurity or weakness of the first sound of the heart, with approximation of the two sounds in quality or relative accentuation of the second sound; later embryocardia and gallop rhythm might develop. Gout, syphilis, alcohol and tobacco, tea and coffee, sexual excesses, mental strain, and physical overwork were among the chief provocatives of disease of the myocardium. Among the acute infections, influenza was a frequent cause of cardiac-muscle disease.

Diagnosis.—Other than the general diagnosis of disease of the myocardium, there was not yet sufficient knowledge of clinical signs to permit accurate recognition of the lesion. The differentiation between neurasthenia of the heart and disease of the myocardium might be difficult. The chief importance of the subject lay in the avoidance of error—(1) in the prognosis and treatment of valvular disease, which might be over-treated or under-treated through failure to estimate properly the condition of the muscle; (2) in the recognition of serious lesions of the muscular structure of the heart in cases that had been supposed to be normal because of the absence of valvular murmurs; (3) in the distinction between organic and muscular lesions and functional disturbances, and in the realization of the fact that the latter might lead to the former.

Treatment.—In treatment, judicious regulation of diet, rest and exercise, avoidance of exciting causes and excesses of any kind, the good functional condition of the skin and eliminative organs were of the first importance. Warm, saline, carbonated baths and, in some cases, gentle massage and resistance exercises carefully adapted to the individual case, were of great benefit. Nitroglycerin was the most useful single agent of the materia medica. Strychnine, digitalis, adonis, cactus, strophanthus, and sparteine had usefulness in individual cases. Venesection should be made promptly in cardiac failure.

Clinical Study of Myocarditis.—Dr. Louis F. Bishop, of New York, said he believed the importance of recognizing myocardial lesions to be very great, as it had a decided bearing on prognosis in many affections. The myocardium was as important as the peri- and endocardium. The symptoms here gave us more aid than did the physical signs, but in many instances we must carefully differentiate from "nervous heart." A study of a series of cases which he referred to showed the relation of irregularity of rhythm to disease of the muscle.

Plea for More Rational Prognosis in Cardiac Affections.—This paper was read by Dr. J. J. Morrissey, of New York, and was based upon the study of two hundred and fifty-five cases. He said that accurate prognosis necessitated a complete diagnosis. This should not be based solely upon the physical signs present, which were frequently deceptive and limited in character, but upon a consideration of the cardiac efficiency, of the presence of hypertrophy, and of the condition of organs far removed from the thoracic cavity. We should obtain as accurate a history of causation and duration as possible. A gloomy prognosis should not be given upon the simple fact of murmur alone; the condition of the cardiac walls should be considered, the probable duration, the presence of dilatation or hypertrophy, and the occupation and temperament of the patient. There was no means of recognizing the strength of the individual heart except by its power of resistance to the effects of alcohol, tobacco, disease, occupation, and exposure. As Allbutt says: "Give your prognosis on the best suppositions, treat your patient on the worst." Prognosis based on the presence of a murmur was unjust and demonstrated incapacity upon the part of the physician. We wished to be just to the applicant, and at the same time to do our duty toward the insurance company. The fact that a man had a murmur at the apex, of which he was entirely unconscious, whose heart was doing its work thoroughly despite the existence of the lesion, whose occupation was not of an adversely laborious character, who had passed that period of life when acute rheumatic infection was liable to stimulate into fresh and renewed activity the latent inflammatory products of an endocarditis, should be factors in recommending a policy commensurate with the degree of cardiac inefficiency. A presystolic murmur did not always indicate mitral stenosis. From the standpoint of longevity aortic stenosis was a favorable lesion. The speaker differed from authors who stated that it appeared for the most part after middle life. He found it between the ages of thirty and fifty as part of general atheromatous changes, but it was more frequently present without such pathological manifestations than had been suspected. A young man between the ages of eighteen and twenty-five should not be informed that he had heart disease because some hypertrophy had been discovered, with no complication, the result in most instances of active exercise. The patient should return for further examination, as the condition might then have entirely changed.

Diagnosis of Diabetes.—Dr. J. B. Herrick, of Chicago, read this paper. He said that the detection of sugar was always the final test, but there were rarer manifestations which, if taken in time, would not only lead to proper diagnosis, but would permit of early proper treatment. Among such symptoms were neuralgias, neuritis, dry mouth, skin affections, impotence, psychical disturbances, angina, dyspnœa, somnolence, and irritability. The failure to detect or confirm diabetes was due to error in examination; to the fact that the urine was not examined or sugar was not present at the time of examination. Insurance companies should change their rule which required examination for sugar only when the specific gravity was above 1.015, since sugar was not infrequently found below 1.010. The variety of diabetes present should be studied.

Mortality from Diabetes Mellitus in the City of New York during the Decade 1889–99.—Dr. Heinrich Stern, of New York, read this paper, in which he drew deductions from statistics furnished by the city's bureau. In 1867, 931 deaths from diabetes occurred in females, a much larger proportion than that given in previous records. Tables by years were presented. For the eleven years the deaths by months scarcely varied; the limits being 190 and 134, showing that temperature, sunshine, etc., had but little influence on mortality. The increase in October was because the city was then most fully populated. The mortality in negroes was low.

Cutaneous Diseases Accompanying Diabetes.—Dr. M. B. Hartzell, of Philadelphia, read this paper. He said the importance of recognition of the relationship between skin manifestations and general conditions applied to many other affections besides diabetes. This was from both a diagnostic and therapeutic standpoint. In diabetes the skin was dry, the hair lustreless, the nails were brittle. Papular lesions might occur upon the arms. Eczema, beginning as a pruritus, especially about the genitals and anus, was one of the commonest forms. The prepuce might become thickened and fissured. Acne cachecticorum was often due to glycosuria, just as was furunculosis. Papillomatosis diabeticorum occurred as an inflamed patch upon the back of the hand. Gangrene might be moist or dry. Bronzing of the skin and xanthoma were characteristic features. Some affections might be prevented by proper bathing to remove all deposited sugar from the surface.

Dr. Solis-Cohen said that every case of glycosuria was not diabetes, although most cases were. It frequently followed influenza. Bilateral sciatica should make one suspect true diabetes.

Dr. Walsh said that tuberculous and nephritic subjects often died of unrecognized diabetes.

Dr. Morrissey said the same factors acting to produce the sugar produced the lessened sexual function. In examining a series of one hundred tuberculous subjects, he found sugar present in thirty per cent. In another series of fifty patients ten per cent. showed sugar.

Dr. Wahral, of Iowa, made a plea for the patient. Molecular changes in the nervous system should receive attention. Strict dieting was vigorously denounced as torturing the patient without good results.

Dr. Russell, of Philadelphia, thought fixed diet rules should not be laid down.

Dr. Osborne, of Connecticut, said that fifty per cent. of cases showed pancreatic disease. The other fifty per cent. occurred in a variety of affections, thyroid disease, etc. If we took away carbohydrates, we should slowly substitute fats.

Dr. Herrick spoke of obesity in regard to its predisposing to diabetes. He had never seen bilateral sciatica in diabetes, though he had been on the lookout for it for years. Too vigorous enforcement of diet was not advisable. All authors mentioned its dangers.

Dr. Stern said his statistics showed a large proportion of diabetes in the poor. The name diabetes mellitus was inappropriate. There were a pre-diabetic and a post-diabetic stage. Anti-diabetic diet was utilized only experimentally to determine the proper diet for each subject.

Exophthalmic Goitre.—Dr. O. T. Osborne, of New Haven, in this paper said that the name was a misnomer. He suggested that of Graves' thyroid disease. The cause of its frequency in women was the increased activity of the gland called forth by the normal sexual function, and the consequent susceptibility to permanent irritation. The relationship of the gland to the symptoms of the disease was discussed in relation to hypersecretion. Thyroid feeding, when it increased the symptoms in obscure cases, pointed to impending Graves' disease. Eighty per cent. of cases occurred in women. In treatment, those things which tended to diminish secretion and quiet the circulation did good, *i.e.*, strophanthus, with mental and physical rest. In an active case thyroid feeding would tend to do harm. Thymus-gland treatment at times did good. A portion of the gland should be removed if there were pressure symptoms. Ordinarily it was not justifiable to operate.

Dr. Herrick said that many patients suffered long before they presented marked symptoms, often giving signs of neurasthenia, or even of incipient tuberculosis.

Dr. Solis-Cohen thought experience showed mental and physical rest to be the most important factor. There was weight in favor of thymus feeding. The symptoms might spontaneously recede or disappear. Digitalis was to be used only when the particular heart showed its employment to be indicated. Hydrobromate of hyoscine, gr. $\frac{1}{200}$, for a maximum dose, and picrotoxin up to gr. $\frac{1}{20}$ every three or four hours, did good.

Dr. Osborne said it was a functional disturbance and not a disease at all. We must look to the emotional or psychic side of the individual for a cause of the hypersecretion.

Lesions of the Cauda Equina and Conus Medullaris.—Dr. Bertram W. Sippy, of Chicago, designated by the term conus medullaris that portion of the spinal cord at the lower end of the lumbar enlargement. He found that lesions here situated were characterized by well-marked disturbances, both sensory and motor. By means of diagrams he illustrated impairment of sensation in symmetrical distribution involving the perineum and the anal and scrotal regions. There might be loss of sexual power. That which chiefly characterized caudal disease was pain. The absence of pain indicated the conus affection.

Movable Kidney from the Standpoint of the General Practitioner.—Dr. A. Marcy, Jr., of Riverton, N. J., read this paper. He said that the disease was very frequent. All women who complained of reflex nervous symptoms, digestive disorders, hysteria, etc., and especially those of light weight, should be examined for movable kidney. Thin patients could be examined in the erect posture, the examiner standing behind and using one hand for either kidney. In stout subjects both hands should be used, the physician being seated at the patient's side. If necessary an anæsthetic could be given. A distended gall bladder or other organ must not be mistaken. Suitable cases should come to operation.

Dr. Cleveland, of Cincinnati, said that movable kidney was a general abdominal condition associated with enteroptosis and gastroptosis. He doubted the advantages of operation. There might be no painful symptoms.

Dr. Am Ende said that the first thing to do was to put away the corset.

Dr. Marcy replied that some patients were comfortable only when the corset was worn.

Antiseptic Treatment of Diphtheria.—This paper was read by Dr. D. Benjamin, of Camden, N. J. He said that statistics should be collected by an expert paid by the association. He had tabulated forty thousand cases of diphtheria. The success of germicidal treatment depended upon the thoroughness of application. For twenty years he had used local antiseptic treatment, chiefly tincture of iron chloride, and had not lost one per cent. by death. He gave tincture of iron coincidently in frequent doses.

Observations on Direct Antiseptic Treatment of Infectious Diseases.—Dr. C. Am Ende read this paper. He found that direct antisepsis gave gratifying results in diphtheria, as well as in a number of other infectious diseases. A pre-membranous stage could be detected, and medication could be applied early and prophylaxis thus be extended to others. Antiseptics modified the bacilli so that the microscope showed them changed. He used quinine with an excess of muriatic acid.

The Climatology of Arizona.—This was described in a paper by Dr. William Duffield, of Phœnix, Ariz.

The Clinical Examination of the Blood.—This paper was read by Dr. R. L. Watkins, of New York.

Certain Clinical Features of Influenza Recently Epidemic.—Dr. H. S. Anders, of Philadelphia, read a paper based on personal observations alone. Special features, as conjunctivitis, otitis media, laryngitis, purulent bronchitis, influence of previous affections on special features, complications, bradycardia during convalescence, antecedent and associated meteorological conditions and their bearing on symptomatology, were all discussed.

The section then adjourned.

SECTION ON SURGERY AND ANATOMY

Third Day—Thursday, June 7th.

Treatment of Hernia in Children.—Dr. A. J. Ochsner, of Chicago, read this paper. In considering the predisposing causes he laid particular stress on the descent of the testicle, and of congenital weakness of the abdominal walls. Long mesenteries he considered a questionable etiological factor. Among the exciting causes he mentioned: (1) Abnormal intra-abdominal pressure; (2) constipation; (3) phimosis; (4) coughing. These factors were, directly or indirectly, remote results of bad nourishment and evil hygiene. Hernia was, in support of this statement, by far more frequent among the children of the poor than among those of wealthy parentage. Another very interesting etiological factor was the nationality of the child, the lesion being particularly prevalent among the Jews. He suggested that here close intermarriage might be the cause, and believed that this subject would reward careful investigation. Herniæ in the young tended to spontaneous cure. At birth, one child out of every twenty-one was ruptured; at thirteen years of age there was but one in every seventy-seven. This spoke for itself. He felt that because of this, less than five per cent. of herniæ in adult life were congenital. He by no means insisted on early operation in childhood hernia; on the contrary, only acute conditions should lead to it. Intelligent medical treatment, however, was of the utmost importance, and in this connection he detailed some of the most important points. Posture was considered among the first. He recommended that the patient should be kept in a bed the foot of which had been elevated. The constipation, the coughing, the malnutrition were each to receive the most careful attention. A truss should be worn at night as well as by day, unless the recumbency kept the hernia reduced. Special attention should be given to the prevention of gaseous intra-abdominal pressure by the most careful feeding. In conclusion, he said that operation was indicated only under the following conditions: (1) Strangulation, (2) irreducibility, (3) abdominal hyperdistention, (4) irreducible hydrocele.

Treatment of Ventral Hernia.—Dr. M. M. Johnson, of Hartford, Conn., read this paper. He spoke first of the etiology, and cited the following factors: (1) prolonged use of drainage tubes; (2) healing by secondary intention; (3) division of motor and trophic nerves.

The speaker, after advising the avoidance of these, entered into minute detail of the technique of his operation, in the course of which he emphasized the desirability of (1) electrical incision; (2) silver wire; (3) kangaroo tendon. These were to be removed at the end of ten days.

Cure of Inguinal Hernia in Men.—Dr. H. O. Marcy, of Boston, read this paper. He spoke of the great safety of the modern operation, saying that scarce a decade had passed since it was fraught with the greatest danger. He felt the cause of hernia to be rather a failure in the development about the internal ring than any influence of the infundibular process. He urged that the wound should be made wide enough to permit of easy removal of cord and sac. In closing the sac, he recommended a suture rather than a ligature, citing a case in which the latter had slipped, with a fatal result. Especially he emphasized: (1) that danger was hypothetical; (2) that suture material should be absorbable; (3) that dissection should be free; (4) that the canal should be reconstructed; (5) that the wound should be sealed without drainage. In closing he thanked the section for their generous recognition of his services toward devising the modern operation.

Dr. De Garmo, of New York, urged the crying need of curing children. He paid high tribute to the ceaseless work of Dr. Marcy, who had been the father of the modern operation. He said that very frequently the immediate cause of hernia in infants was constipation. Operation he did not consider indicated before the fifth year of age, for earlier in life the hernia could generally be cured by a truss. He disagreed with Dr. Ochsner in that he thought that no ruptured child should be confined in bed, every one realizing how badly children did when so confined. In repairing ventral herniæ, the layers should be most carefully approximated, and, in thin cases at least, relaxation sutures were distinctly indicated.

Dr. Fergusson, of Chicago, felt that he voiced the sentiment of the section when he said that whatever progress had been made by Bassini and Halsted in the treatment of hernia had been due to the untiring efforts of Dr. Marcy. He cited an interesting anatomical point bearing on the relative infrequency of indirect inguinal hernia in women, viz., that in the female the internal oblique reaches three-quarters up Poupart's ligament, while in the male it involves but half the same area.

Dr. W. J. Mayo, of Rochester, Minn., praised Dr. Ochsner's conservative treatment. He felt that the great value of the so-called Bassini operation was that the scar was divided. This principle he would apply to umbilical herniæ.

Dr. Marcy again thanked the section for their recognition. He felt that the hernia question was settled, and expressed a wish that the three million ruptured citizens of the United States—the truss-bearing army—might all be operated upon.

External Drainage of Superficial Lung Cavities, with Report of Two Successful Cases.—Dr. W. L. Wills, of Los Angeles, Cal., read this paper. He drew attention to the vast interest which Western surgeons took in pulmonic surgery, because it was to the West that the great tuberculous population trended. He could see no reason why these cases should not be operated on, and strongly indorsed external drainage, citing two successful cases, as follows: The first one was that of a ranchman, of fine physique originally, at the time of operation dying of sepsis from the absorption of pus in a large cavity in the left lung. The speaker was disappointed, on resecting a rib, to be unable to locate the focus. This was due to delay caused by the very critical condition of the patient after the opening of the chest wall. Two days later, however, during a fit of coughing, there was a great discharge of very foul pus externally. The patient progressed to complete recovery. The second case differed from the first in that no internal drainage—via a bronchus—existed. That gravity drainage by external incision was indicated in these pulmonic-cavity cases seemed strongly supported by the immediate and permanent fall of temperature after its establishment. The speaker closed by suggesting that the free use of bichloride of mercury in solution as strong as 1:4,000, for irrigating these cases, was of very probable importance. Singularly, it did not seem to cause ptyalism.

In discussing this paper, Dr. Murphy, of Chicago, spoke of the importance of external drainage for the chest. In order, however, to accomplish it successfully, there must be pleuritic adhesions over the area to be operated on. When these were absent, he recommended internal drainage by gaseous compression of the lung. He advocated the admission of air to the pleural cavity through a hypodermic needle. He deprecated the use of the cautery in lung surgery, and urged that a sharp knife was free from danger.

Dr. Wills, in closing, spoke of the beneficence of the California climate, and said that it had an important bearing on these cases. He recommended the generous use of 1:4,000 bichloride.

Surgical Errors in Skiagraphy.—Dr. Carl Beck, of New York, read this paper. He felt that careful study of skiagraphs would enable us to make more general use of them. Many errors, indeed most errors, were due to a faulty interpretation. In the extremities, for instance, the arrangement of the carpus and of the tarsus were such as, in many positions, to cause a shadow to be cast from one bone to the other. Projection was an important factor in causing error. In fractures special thought should be given to the whereabouts of the epiphysis, which, particularly in children and often in the adult, gave a skiagraphic line of apparent breakage. In closing, Dr. Beck aptly said that it was extremely unwise to allow patients to examine united fractures with the rays, for a good functional union thus seen appeared often distressingly crude.

Diagnosis of Calculous Diseases of Kidney, Ureters, and Bladder by the Roentgen Method.—This paper was presented by Dr. C. L. Leonard, of Philadelphia. He spoke of the great advances which had been made in the diagnosis of these conditions by bacteriology, by cystoscopy, by urinalysis, segregation, and sedimentation. Ureteral catheterization, the sound being wax-tipped, after the suggestion of Kelly, the recurrence of attacks, and the proper interpretation of pain—all had a very useful end. He wished to bring before the section the latest, and perhaps the most important factor of use in the diagnosis of this obscure condition. When properly used, the Roentgen ray was almost absolute—would probably be absolute when technical errors had been eliminated. His last twenty cases of affirmative diagnosis had been correct. The work had been equally successful in negative diagnosis, and this often in the face of eminent clinical opposition. The *x*-ray admitted of very early diagnosis, an advantage which could not be overestimated. He cited cases in which, because of the presence of albumin and casts, diagnoses of nephritis had been made. In closing, he said that because of the *x*-ray exploratory incisions could now be avoided.

Treatment of Injuries of the Ureter.—Dr. B. B. Davis, of Omaha, Neb., read this paper. He said that ureteral injuries had been much more frequent than was generally supposed, and cited cases to prove this fact. Before the possibility of anastomosing the cut ureter was shown to exist, there was open to the surgeon but one of three very unsatisfactory procedures: he was obliged either to perform nephrectomy, to stitch the ureter to the skin, or to ligate its proximal end. The result of the first was never an enviable one; the second left the patient in a pitiable plight, while the atrophy which was supposed to follow the third was by no means constant. So much advance had recently been made, however, that none of these procedures was justifiable. He then described a method of anastomosis which seemed to him better and simpler than Van Hook's. Implantation into the bladder, that viscus having been freed from its attachments to a sufficient extent—after Kelly's method—to reach the proximal end of the ureter without tension, or uretero-ureteral anastomosis, seemed to him to offer a happy solution of the problem. In support of this statement he said: (1) The normal channel was thus preserved. (2) There could be no fistulæ. (3) Stenosis was not probable. (4) There was no leakage. (5) Cicatricial contraction gave no trouble.

Dr. Kelly, of Baltimore, said that Dr. Leonard was doing the finest work of any one in the world with the *x*-ray. He had recently failed to locate a stone with his wax-tipped sound, and Dr. Leonard had found it for him. He therefore heartily welcomed so valuable an aid to diagnosis. He demonstrated his cartridge-like instrument for uretero-ureteral anastomosis.

Dr. Bevan, of Chicago, also congratulated Dr. Leonard. He spoke of the very great value of the *x*-ray in urinary calculus and cited a case in which very small stones were located by its aid.

Dr. Bouvé classified uretero-ureteral anastomoses as follows: (1) end-to-end; (2) end-in-end; (3) lateral of Van Hooke; (4) lateral, as is ordinarily done with gut; this last had been done twenty-one times. Cysto-ureteral anastomosis was the next best. He believed there was a great future for sigmoido-ureteral anastomosis, which operation had been done eighty times.

Dr. Winslow, of Baltimore, spoke of the anatomy of the renal pelvis. It was not, as usually described, a dilated pouch within the kidney, but consisted of a series of tubes which frequently persisted well beyond the organ. If in one of these a calculus lodged, as was frequently the case, it might be seen how Dr. Kelly's wax-tipped sound would fail and the *x*-ray be of incalculable use.

Dr. Beck, of New York, said that the *x*-rays had not yet been fully appreciated. He spoke of the great need of making at least four or five plates in order properly to correlate the distances.

Dr. Somers, of Nebraska, emphasized the value of Kelly's operation of lifting the bladder to meet the too short ureter.

Dr. Carpenter, of San Francisco, reported a successful case of uretero-cystostomy. He showed a button for this purpose.

Dr. Leonard, in closing, said that by careful technique even uric-acid calculi could invariably be detected by the *x*-ray. This technique consisted in using for the ray a tube of such low vacuum that one could just see the muscular outlines. Formerly the rays were altogether too penetrating.

Exstrophy of Bladder, with Exhibition of Case.—Dr. Morgan Vance, of Louisville, presented this paper. He detailed the technique of the operation, which was plastic in character, and which was repeated in more than five stages, over a period of two years. The case had been a peculiarly evil one, had required a vast amount of patience, and had yielded a very brilliant success. The patient was a young man nineteen years old, and he had been enabled to enter business life successfully.

Dr. Willard, of Philadelphia, gave his heartiest congratulations to Dr. Vance. He said that an inward turning of the flaps is responsible for many failures; likewise a deposition of urinary salts. He recommended the use of the upper sigmoid or colon as a reservoir. He spoke of the desirability of transplanting the vesico-ureteral valve in these cases, to avoid infection.

Dr. Kelly, of Baltimore, said he had tried in vain to obtain a cure in these cases by a loosening of the sacro-iliac joints. He now shelled out the bladder far enough to meet the divided ureter; this failing, he urged the use of the colon for a reservoir.

Dr. Herzel, of Chicago, urged the use of the colon. He said that few cases of infection had resulted.

Dr. Connell, of Chicago, supported the use of the upper colon, thus doing away with the use of a rubber reservoir.

Dr. Vance, in closing, said that his was a very exaggerated case, and that he thought all cases could be cured by his technique.

Surgical Asepsis of the Urethra and Bladder.—Dr. Ferd. C. Valentine, of New York, demonstrated a new device, called the auto-irrigator, made of sterilizable rubber. The instrument occupied a space five inches long, three inches wide, and two inches thick in the instrument bag. It weighed about six ounces. The device had a capacity of 1,500 c.c. (about three pints). Its purposes were: (1) Urethral and intravesical irrigations before and after operative ingressions, preventing urethral fever; (2) an aid to the treatment of gonorrhœa in such cases as could not be irrigated in the physician's office twice daily; (3) as near an approach as was possible to aseptic catheterism in prostatic enlargements. The author appended to his paper a résumé of the treatment of gonorrhœa, the diet to be observed, and advocated the prevention of gonorrhœa by self-irrigation after suspicious coitus. These explicit directions were worded especially for those practitioners whose experience in genito-urinary diseases was not large. In closing he showed the old methods of irrigation to be incomplete and faulty.

Treatment of Prostatic Hypertrophy.—This paper was presented by Dr. Parker Syms, of New York. He dwelt interestingly on the very great prevalence of this condition. In considering the symptoms he spoke of the almost invariable prominence of dribbling, due to the dilated bladder, and of the frequency of micturition. Almost invariably a chronic cystitis was present, which, from time to time, was provoked to acute exacerbation. Formerly, indeed until very recently, catheter life was the ultimate and unhappy ending of these cases. Now, however, two alternates had come into the field: (1) prostatectomy, and (2) prostatotomy, or Bottini's operation. Dr. Syms made only a passing allusion to the latter, saying that he felt that for certain cases it had a brilliant future. Of the former, he spoke at length, devoting most of his considerations to a new and interesting technique. That the death rate was high in this operation he could not deny, but he was convinced that this was due very largely to the extreme physical and mental depression present in almost all cases operated on. For this reason the operation should not be undertaken as a last resort, but practised rather at the inception of the hypertrophy, or, at any rate, just as soon as the habitual use of the catheter became necessary. Physiological old age, however, contraindicated operation. Of technique he spoke as follows: In 1898 he advocated the perineal route, crowding down the prostate through a suprapubic incision. Now, however, he had given up opening the abdomen, using by preference a small opening in the membranous urethra. Through this, and into the bladder, he introduced a rubber bulb, tied to the end of a soft catheter. After introduction, the bag was filled with water and the tube was clamped. Traction on this simple device readily drew the prostate into the perineal wound.

Dr. Thayer, of Clifton Springs, New York, said that cystitis was always of bacterial origin, and was characterized by a loss of tissue. As to Dr. Valentine's method of irrigation, he had nothing to offer but praise. It was impossible properly to disinfect the canal by any other method.

Dr. Glenn, of Alabama, thought Dr. Valentine over-enthusiastic. He did not feel it necessary to irrigate before instrumentation except in pus cases.

Dr. Young, of Baltimore, had been greatly interested in Dr. Syms' paper. Nevertheless, he felt that the Bottini operation was the better because the median lobe only of the prostate was the area usually involved.

Dr. Chesmore, of Philadelphia, was pleased with Dr. Syms' method of pulling down the prostate, and especially advocated the abolition of the suprapubic incision.

Dr. Beck, of New York, supported Dr. Valentine. Too much care could not be given to antisepsis.

Dr. Robbins, of Detroit, said that of all drugs he considered terotropin to be the most valuable. He thought Dr. Valentine's auto-irrigator no better than an ordinary syringe.

Dr. Eastman spoke of the value of potassium bichromate in gonorrhœa, used hot, often, copiously, and under pressure. He preferred a blunt syringe to the auto-irrigator.

Dr. Grey, of Jersey City, testified to the value of enucleation, although he supported the suprapubic incision. He suggested the stretching of the sphincter ani in order that pressure might be brought upon the prostate through the rectum.

Dr. Guitéras, of New York, said that washing invariably did good even if it was but with sterile water. The patient should not irrigate himself, unless with an absolutely bland solution, if obstruction was present. He considered the auto-irrigator as incomparably superior to the syringe. He congratulated Dr. Syms on his very able paper. Prostatic surgery was still in its infancy. Enucleation should not be thought of if the kidneys were damaged or in the face of arteriosclerosis. Touch was very necessary in the determination of mid-lobe enlargement. The vesical side of the prostate often differed very markedly from the rectal. Enucleation was suitable only in the greatly enlarged glands, whereas Bottini's operation was to be chosen in the slighter cases. The mortality should not be above five per cent. Enucleation, however, would for many years probably give a death rate of twenty per cent.

Dr. Valentine said, in closing, that Bottini's operation had been made much simpler by the introduction of an incisor with cystoscopic attachment. He defended the auto-irrigator.

Dr. Syms pointed out that his device was to be inserted through the membranous urethra, not through the penile part.

Fourth Day—Friday, June 8th.

Treatment of Tuberculous Knee Joint.—Dr. Wisner R. Townsend, of New York, presented this paper. He divided the topic into constitutional and local treatment. The first, of the gravest import, was generally neglected. Diet, climate, rest, and creosote he spoke of in turn. The second involved—(1) rest of the joint; (2) correction of the deformity; (3) removal of diseased bone; (4) treatment of complications. Of the varied means of getting rest, the Thomas knee splint was doubtless one of the best, particularly if combined with a rubber footpiece. Again, the dressing must be snug, else a great deal of deformity might take place beneath it. As to the correction of deformity, he mentioned (1) weight; (2) traction; (3) force, with or without an anæsthetic—in no case violent. He absolutely excluded brisement forcé. (4) Tenotomy; (5) osteotomy or osteoclasis; (6) excision; (7) amputation. Decalcified bone must be early and thoroughly removed. Septic knees demanded a very thorough draining, this often leading to happy results. Cold abscesses in the region of the knee must be treated as though fulminating, for at any moment they might become septic. The local treatment of sinuses by drugs was negative; they often took two or three years to heal. Dr. Townsend closed by saying how promising was the outlook in tuberculous knee-joint cases.

Dr. Barton, of Philadelphia, agreed with Dr. Townsend. He suggested the total extirpation of cold abscesses.

Dr. Ochsler, of Chicago, said that he lived amid a great tuberculous-knee-joint population. He emphasized the absolute need of good hygiene.

Dr. Bullett, of Louisville, said that the protective treatment had given far better results than the operative.

Dr. Sullivan, of Chicago, said that early diagnosis was very necessary, and rarely attained.

Dr. Townsend said, in closing, that he emphatically indorsed evacuation; that the involvement of the lower epiphyseal cartilage often resulted in nine inches of shortening.

Fractures of the Patella.—Dr. J. M. Barton, of Philadelphia, read this paper. He spoke of the unsatisfactory results of the expectant treatment. Out of seven hundred and eleven cases operated on by American surgeons there had been but three fatal cases. The necessity of operation was caused by a falling of the pre-patellar membrane between the fragments. He urged that in uniting them, heavy silver wire be used, and that the ligature should pass well into the bone substance. He spoke of the need of strict asepsis and of the importance of removing all blood clots. Postoperative rest should not be over three weeks, when gentle motion should begin.

Operative Treatment for Unreduced and Irreducible Dislocations.—Dr. A. D. Bevan, of Chicago, read this paper. He cited cases and showed skiagraphs of three elbow dislocations, four dorsal of the hip, and one of the astragalus. He urged the open method—free incision and no drainage. This, combined with an intelligent use of the *x*-ray, presented the modern surgical treatment of these deformities. He concluded as follows: (1) Operation was justifiable if asepsis was perfect. (2) Dislocation was frequently complicated by fracture. (3) The best incision for the elbow was a double lateral. (4) No drainage was to be used. (5) The elbow should be dressed in semi-flexion, with the hand in pronation. (6) Passive motion should begin early. (7) The mortality was less than five per cent. (8) The patient should be warned of this danger.

Dr. Blake, of Chicago, agreed with Dr. Barton in all respects. He felt that the patella might unite as did any other bone.

Dr. Tinker, of Philadelphia, spoke of aluminum bronze as specially useful in bone work. It was first used in Germany in 1895. It was to a considerable degree absorbed, due to the aluminum being acted on by the plasma salts. Thus all sharp edges were worn away, making the tissues very tolerant of it.

Dr. Ochsler recommended a transverse incision, and said that the knee should be well elevated after the operation. He allowed the patient to walk three weeks after the operation.

Dr. McFarland, of Pittsburg, spoke strongly against operating. It was very well for the great joint cavities to be opened by men trained in the rules of absolute asepsis. But to him it seemed a very unwise procedure in the hands of the average surgeon.

Dr. Barton, in closing, said that he wished to lay stress on the use of rubber gloves and on the penetration of the bone tissue by the suture.

Dr. Bevan, in closing, said that, singularly enough, he did not support the open operation in fractured patella. It seemed incompatible with the tenor of his paper, but he begged to make the knee joint his one exception.

Report of Five Cases of Tetanus Treated with Antitetanic Serum.—Dr. J. D. Blake, of Baltimore, read this paper. He spoke of the rapidly growing importance of serum therapy. He urged the giving of large doses of the serum, and cited his last five consecutive cases, all of which had resulted in recovery.

Dr. Whitmore, of New York, stated that nine cases had been experimented upon at Roosevelt Hospital last summer. These had been trephined and inoculated sub duram. Seven patients had died.

Two Cases of Growths in Frontal Sinuses.—Dr. W. D. Hamilton, of Columbus, presented this paper. He said that these growths were often osteomata; that the diagnosis was rarely established till the deformity was marked, and that because of the septic nature of the area they yielded a mortality of thirty-three per cent. Occasionally, because of the proximity of the brain, pressure symptoms developed early, particularly in the eye. He cited two cases of successful removal, and spoke of the need of an early diagnosis of malignancy.

Dr. Dawbarn, of New York, said that this early diagnosis could often be very easily and surely made. For years he had been in the habit of thrusting the blunt end of a sewing-needle against the questionable area. Very early in the malignant process the hard parts of the bone are absorbed, and this blunt instrument would readily penetrate it long before there was any external evidence of disease. A second point established by Dr. Dawbarn was that the technique of crushing a passage through to the nasal cavity from above was open to severe criticism. As was shown by him long ago, in Wood's "Reference Handbook," by bending a probe at a particular angle the natural passages could be passed through from above downward, thus avoiding unnecessary and prejudicial crushing of the bone.

Laminectomy for Diseases and Injuries of the Cord.—Dr. Samuel Lloyd, of New York, read this paper. He had recently operated on fifteen cases of Pott's disease, making a total of one hundred and thirty. This operation was not dangerous *per se*, but at best offered little hope; it was absolutely hopeless if the anterior portion of the spine was diseased. If the disease was strictly localized posteriorly, an early diagnosis having been made, there was ground for hope. The lower the region of involvement, the better. He considered that the myelitis was generally due to the pressure from accumulated débris rather than to granulation tissue. The operation was hopeless if this change was well established. In Pott's disease, operation was rarely indicated after the inception of paralysis, because of the probable establishment, by that time, of pulmonary or other foci. Tumors gave a fifty-per-cent. mortality, but this was due rather to their being usually malignant than to a fatal outcome of the operation. Fractures in the cervical region yielded a very small percentage of recovery. The type of fracture was also a factor. Most vital of all was the consideration of elapsed time. He gave the following indications for operation: (1) If the cord destruction was incomplete; (2) when the lesion was incomplete but was extending; (3) when recovery, almost complete, was interrupted by callus formation. In closing, he advocated operation as a desperate chance.

Dr. Dawbarn said that he rose to emphasize rather than to criticise. This emphasis was particularly directed to the crying need of early operation. He cited two cases—the first that of a woman who fell four stories, sustained a fracture, presented the typical symptoms, and was operated on by him within two hours. The result, after enucleation of a large blood-clot and the removal of a good-sized bony fragment, was perfect recovery. In the second case, under the advice of certain nerve specialists, the patient refused operation until myelitis was well established. Although the operation was helpful to the patient, the paraplegia had been permanent.

Dr. Hough, of Massachusetts, cited a favorable early operation.

Dr. Lloyd, in closing, said that the operation should not cease till the normal pulsation had returned in the cord. Its membranes should be unhesitatingly opened if necessary.

Operations for Injury of the Median and Ulnar Nerves.—Dr. B. B. Eads, of Chicago, read this paper. He cited a number of interesting cases of neurorrhaphy, emphasizing these points: (1) the need of a wide incision; (2) asepsis; (3) the evil effects of tension; (4) use of a relaxation splint.

Results of Surgery in the Aged.—This paper was read by Dr. J. P. Tuttle, of New York. He wished to establish the point that old people stood operation well. His data were gathered from 168 operations on patients over fifty years of age, and 133 in which the average age was sixty-nine years. The anæsthetic used in 226 senile cases was: ether, 183; chloroform, 13; cocaine, 30. The mortality from operative causes was less than two per cent. Albumin was not a contraindication, nor were hyaline casts. He argued that because patients were aged, *ipso facto* the constitution was good and the resisting-power high.

Dr. Dawbarn spoke of the development of a second childhood in disease, as well as in intellect. Microbic infection was a very important factor in the aged. They possessed but little bactericidal power.

Dr. Hart, of China, said that aged Chinese stood operation very well.

Sarcoma of Colon, with Report of a Case.—Dr. C. Van Zwalenberg, of Riverside, Cal., read this paper. He said there was but little analogy between sarcoma and carcinoma of the alimentary canal. Sarcoma was rare. He then detailed the technique of his operation, which embraced the resection of gut and the exsection of a large sarcomatous nodule from the belly of a child five years of age. The Murphy button did not reappear for six months, but this did no damage. In summarizing fifteen cases he said that the age limits were between one and fifty-two years. Nine cases were in males, five in females; five were below ten years of age. The small gut was affected ten times. Nine patients recovered. Sarcoma was more common than was generally supposed. Stenosis rarely accompanied it, dilatation being the rule.

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

Third Day—Thursday, June 7th.

Aseptic Minor Gynæcology.—Dr. Augustin H. Goelet, of New York, presented a paper on this subject in which he made an earnest plea for cleanliness in ordinary gynæcological examinations, laying stress upon the necessity for thoroughly sterilizing the hands and instruments. He outlined the method of arranging the examining-table, exhibiting a new clinical air-cushion. He described in detail the manner of washing the hands and cleansing instruments, for which purpose he used an antiseptic soap, which by actual bacteriological tests he had found would destroy all infecting germs. The advantages of a suitable reservoir and irrigating apparatus were specified, and an outline of the method of irrigation of the vagina for securing asepsis was given. As a lubricant for the examining finger and speculum he had abandoned all forms of grease because it was difficult to remove from the hands and genitals. To meet the requirements for aseptic gynæcological examinations and minor operations in private houses he exhibited an aseptic gynæcological emergency case made under his directions, containing all instruments needed, and in addition a clinical air-cushion and portable irrigating-reservoir with vulva-shield and nozzle, and leg-holder.

Dr. John M. Duff, in discussion of this paper, thought it was directed rather to the general practitioner. He emphasized the importance of thoroughly cleansing the vulva, laying greater stress upon this than upon the cleansing of the vagina because of the germicidal nature of the normal secretions of the vagina. The sterilization of the cervix was also important.

Dr. L. H. Dunning, of Indianapolis, thought that if the essayist carried out the technique in routine practice, much valuable time would be consumed. His own method in private practice was to have the nurse prepare the tampons and instruct the patient to make herself ready by douching, so that upon his arrival at the house everything would be ready.

Dr. J. W. Bovée, of Washington, thought it impossible to sterilize the hands in five minutes' scrubbing with antiseptic soap or with anything else; though the cultures might be negative, the hands were not sterile. For this reason he advocated the use of rubber gloves. He agreed with Dr. Dunn that the vaginal secretion was usually able to take care of the vagina. He was of the same opinion as Dr. Dunning, that if the elaborate technique was gone through, sufficient time would not be left for the calls on a busy man.

Dr. W. H. Humiston, of Cleveland, did not regard it necessary to go through all this detail in order to insure a proper amount of care and asepsis. He thought Dr. Duff correct in thinking the danger of infection was not so great from the vaginal secretions as from the vulva. He had met with hundreds of cases which, if properly treated aseptically while the condition was simple, would not have been converted into infected ones by wrong treatment. He quoted a case which he had been asked to explain. The patient had been treated by a general practitioner for a leucorrhœal discharge and difficulty in menstruation. The practitioner finally curetted her, as she got no better under other treatment. The result was a firmly fixed uterus, with the development of chill. Office work he thought should be limited to examinations, and further treatment for a chronic case should be carried on in the hospital.

Dr. Porter, of Indiana, thought that in the cleansing of the vagina or of any part harm was often done with a stiff brush; a few microbes he did not fear would do much damage in the presence of an intact covering. He had made it a rule to invite his nurses or assistants to speak of any lapses which might occur in carrying out his technique.

Dr. Goelet, in closing, said one thing which he had learned was the necessity for such a paper as this. The portable reservoir he had intended particularly for such work as examinations at the patient's house, for ordinary curettings, and for minor work when washing out the uterus. He recognized the difficulty of making the hands free from germs, but after scrubbing his hands with the antiseptic soap mentioned bacteriological tests had shown them to be absolutely sterile. He thought no man should complain of the time required for washing the hands in ordinary office work, and that a patient would appreciate the care taken. Five minutes he considered a sufficient length of time to give to this cleansing of the hands.

Dr. Engelmann, of Boston, chairman of the nominating committee, announced that Dr. H. P. Newman, of Chicago, had been nominated for chairman of the section, and Dr. C. S. Bonifield for secretary.

Technique of Vaginal Extirpation for Cancer of the Uterus.—Dr. R. B. Hall, of Cincinnati, read a paper by this title, in which he emphasized the necessity for careful preparation of the patient in vaginal hysterectomy. He advocated the extreme lithotomy position. The anæsthetic should be chloroform unless the drug was contraindicated. Should the case be far advanced with great sloughing, or one of epithelioma with a large mass of cancerous tissue, the operation might be done in two stages. The author preferred the ligature to the clamp. The technique was described.

Combined Abdominal and Vaginal versus Vaginal Hysterectomy for Carcinoma.—Dr. John B. Deaver, of Philadelphia, in this paper said that the choice of route for hysterectomy must be selected for each case. He gave a concise *résumé* of the reasons for the selection of each, with their advantages. He performed abdominal hysterectomy for the great majority of cases of uterine carcinoma, though granting that there were cases in which the vaginal operation might be better. He knew of no condition indicating vaginal hysterectomy which possibly could not be better dealt with by the abdominal route. He reviewed the anatomy of the lymphatic glands and their connecting channels involved in the morbid process of the uterus. In late carcinoma or even in the early stage of rapidly advancing disease, involvement of the broad ligament rendered worse than useless any operation short of total extirpation. The weak spot of vaginal hysterectomy, he stated, had always been the danger of injury to the ureters; though there was danger in either route, he believed there seemed to be less by the abdominal. He did not believe catheterization of the ureters an essential part of vaginal hysterectomy. There was also greater danger of hemorrhage in vaginal hysterectomy for carcinoma of the uterus, although this was liable to occur in either operation. The better command of the field of operation secured by the abdominal route aided in the placing of ligatures, and thus lessened the liability of hemorrhage. Another disadvantage of the vaginal route was the liability of the intestines to come in contact with fingers, instruments, and ligatures, which, having traversed the vagina in cases of carcinoma, were never sterile. Supra-vaginal drainage should be employed when drainage was needed in abdominal hysterectomy. Vaginal hysterectomies called for gauze drainage in all cases. Vaginal hysterectomy he considered applicable only in those cases in which the carcinomatous process was strictly confined to the vaginal portion of the cervix, the cervical or the uterine canal, and when the uterus was freely movable.

The Importance of Early Recognition of Cancer of the Uterus.—Dr. W. H. Humiston read this paper. He emphasized the importance of the early recognition by the general practitioner of malignant disease of the uterus. Immediate and complete operation should be insisted upon. The epitheliomatous variety he stated to be comparatively slow to give rise to metastasis and offered the best chances against recurrence after operation. The modes of recurrence were specified as follows: (1) Metastasis; (2) incomplete removal of infected areas; (3) by infection or direct implantation of malignant cells in previously healthy tissue at the time of operation. The principal import of the paper was summarized as follows: (1) Early differentiation of malignant growths of the cervix; (2) careful consideration of importance of lymphatic vessels and glands in their capacity of drains of different portions of the uterus; (3) abdominal section with complete removal of these special groups of lymphatics alone offered, in suitable cases, chance against a recurrence.

Treatment of Cancer of the Uterus.—Dr. William R. Pryor, of New York, read this paper. He quoted statistics to show that of all cases of cancer which came to the operator, but ten per cent. admitted of operation; that of these, 11.5 per cent. were fatal, and in the remaining but twenty per cent. resulted favorably after five years. He expressed his personal belief that all cases of clinical cancer occurred within five years, and that vaginal hysterectomy met none of the requirements of a successful operation. The operation of high amputation by means of the cautery gave few better results than abdominal hysterectomy, and was the operation for the ocasional operator to apply. He insisted upon the analogy of cancer in other parts of the body with cancer of the uterus, and stated that the anatomical requirements of successful operation were that the ovaries, uterus, broad ligaments, lymphatic glands, and upper third of the vagina should be removed; that this removal should be done in a bloodless field and in such a way as to prevent soiling of the field of operation by the cancer cells and mechanical forcing of the cancer cells into the absorbents. He advocated the application of the cautery by the vagina to seal the mouths of the absorbents, after which the abdomen was opened, the internal iliac arteries were ligated, and all tissues removed in which cancer was liable to occur. He quoted ninety-eight cases operated on by the Rumpf-Reis-Clark operation, by progressive ligation, and by ligation of the internal iliac arteries, showing a mortality of only 11.5 per cent. He insisted upon the abandonment of vaginal hysterectomy for cancer and the adoption of more radical work through the abdomen, stating that although not sufficient time had elapsed to show the remote results, observation demonstrated that by this method not more than one-half as many cases recurred in the first year as by the vaginal method.

Dr. H. J. Boldt, of New York, opened the discussion of papers on cancer of the uterus. He regarded the early diagnosis of cancer of the supravaginal portion of the uterus as most difficult. As to prophylaxis, it should be borne in mind that there was no form of disease which led to malignant disease as often as long-continued inflammatory conditions of the mucosa. He thought Dr. Hall's technique a most beautiful one, but questioned how many patients remained free from the disease after a time. The age of the patient was an important factor. He thought that the clamp must be used in an improper way if it could be said that as much broad ligament could be taken off with the ligature as with the clamp. Cases in which the broad ligaments had become infiltrated were better if not operated upon. The ultimate results so far as vaginal hysterectomy was concerned were not satisfactory. As to abdominal hysterectomy, his experience was too limited, and, as Dr. Pryor had said, experience *in toto* was too limited to admit of forming a positive opinion.

Dr. J. M. Baldy, of Philadelphia, said it was the practical aspect of the subject which appealed to him. In technique he agreed with Drs. Pryor and Deaver, that when a major operation was to be done the abdominal route was the one of choice. In the practical question of how many patients got well he did not consider it fair to consider the picked cases as was sometimes done. He believed that cancer of the fundus and cancer of the cervix gave very different results from operation; he did not know of a single case of cancer of the cervix in which he had been able to make a diagnosis clinically by hemorrhage and pain, upon which he had operated, in which the patient was alive to-day. On the other hand, of the cases of fundal cancer all the patients were well except four or five who had died at operation. He had done thirteen or fourteen operations in the eastern section of the State. The practical question was, by what means relief could be given. He thought that the curette used repeatedly, with scissors and knife, offered more advantages for the relief of the patients than operation in the cervical cases.

Dr. J. B. Massey, of Philadelphia, said that as long as the medical profession advised that cancer should not be touched until it became imperative, the limitations of surgical work would be very great. He called attention to a surgical method—though not surgical in the sense of being limited to the knife—a method of using the salts of mercury by electrolysis to destroy the cancer at once as thoroughly as the knife would do it. By the diffusion of the oxy-chloride of mercury a zone of sterilization was produced extending from one-half to one inch beyond the limits where the cancer was destroyed. Another advantage claimed was that the method was bloodless. He had used it upon four patients, of whom two were now living—one at the end of six years and one at the end of six months. The two who were not living had been temporarily benefited. In these the application was made daily for several months, controlling the hemorrhage and the odor. Both patients had been previously operated upon by the knife.

Dr. J. H. Carstens, of Detroit, urged that an honest survey be taken of all the cases of cancer of the breast operated upon with removal of the axillary glands and the glands beneath the clavicle, and a note be made of how many of these patients were alive to-day, three years after operation, without recurrence. His experience was that in all recurrence had taken place, and nearly all the patients had died, with rare exceptions. If all the glands in cancer of the breast could not be removed, he questioned how it was possible to remove all the glands in the abdomen in the soft tissues, and when it was sometimes necessary to work around the aorta. He was willing to predict that the gentlemen who practised abdominal hysterectomy would have as many recurrences in five years as the men who did vaginal hysterectomy. He had limited his operations, and indorsed the statement of Dr. Baldy that he could give his patients longer life by repeated curettings. Concerning electrolysis, he thought if cancer was due to a germ and electricity was a germicide, and if Dr. Massey could tell them of a method of killing the germs *in toto*, all should be under everlasting gratitude to him. He advised the greater use of the curette and microscope in the early stages.

Dr. Joseph Price thought that the point made by Dr. Baldy in regard to the malignancy of the upper and lower part of the uterus was the experience of many specialists. In the child-bearing woman malignancy occurred in the cervix and rarely in the fundus. In the desperate cases, those far advanced, with everything involved, he thought the curette and cautery, as Sims advised many years ago, offered the best results. With reference to the glands he observed that Dr. Humiston found three sets of glands, and Dr. Deaver, a very fine anatomist and excellent surgeon, found only two. He thought they would have to reconcile their differences between them. He felt that the general surgeons were neglecting their department and were too prone to take up the speciality of the gynæcologist.

Dr. Goelet emphasized three points in connection with the subject: (1) Early diagnosis. He thought the family practitioner could not be impressed too strongly with the importance of the early diagnosis of these cases. One case had been sent to him as one of cancer, which proved to be senile endometritis. (2) If a positive diagnosis of cancer was made, something should be done to relieve the condition. He cited a case in which he had advised operation, three years ago. A year later the daughter of the patient asked him to operate, and the excuse given for declining operation was that their family physician had advised them to wait. (3) If the cancer had attacked the body of the uterus the abdominal route should be insisted upon, which offered a better opportunity for more thorough work. He wished to place himself on record as being decidedly in favor of the abdominal route in these cases. He thought Dr. Humiston's diagrammatic illustration of the lymph channels one of the strongest arguments in favor of this route.

Dr. Byrne, of New York, agreed with Drs. Baldy and Boldt that what concerned the profession and the community most was the question of how many lives could be saved by operation for cancer of the uterus. He denied the legitimacy according to statistics of hysterectomy for cancer of the cervix in any case; in his opinion there was no case of malignant disease with adeno-carcinomata of the fundus for which hysterectomy was justifiable, according to the records. The primary mortality, he had observed, had increased from fourteen per cent. in 1892 to twenty and a fraction. For cancer of the cervix he advocated exsection, carefully and smoothly and thoroughly, of the diseased part with the heated knife, and deep cauterization of the cavity left by its removal. These patients he predicted would live from fifteen to twenty years. He knew of several instances in point. He hoped the day was coming when hysterectomy for cancer of the cervix uteri would cease to be popular in the profession. He believed the pendulum was swinging in the right direction, and felt that the reaction could not come too soon.

Dr. Phillips said he had been expecting to hear the converse side of the picture; it had been his fortune to see within the last six months several cases of complete hysterectomy which he believed were not for cancer of the uterus, but in which the condition was simple chronic erosion. He had seen many amputations of the cervix in cases which he was thoroughly convinced were never cancerous. Some of the diagnoses had been made by the general surgeon, the most by the general practitioner, and a few were made by the gynæcologist. He thought the general practitioner in every case before advising operation should have a thorough examination made by a microscopist.

Dr. Bonifield thought the general practitioner had been pretty well educated, and that rather the people should be taught to apply for relief early to the specialist. He thought, as Dr. Baldy had said, that the question was a practical one, and that until the friends who advised this radical operation of removing all glands in the abdomen and pelvis could prove by statistics their success, the majority of gynæcologists would continue to do the milder operations which relieved the symptoms and which seemed to offer about as good results.

Dr. Engelmann said he had never ventured to publish his results in this direction. It had been his experience to find improvement for a time, and then recurrence followed. He believed that an acknowledgment was due Dr. Byrne for his work. Our results showed the justice and correctness of his reports. He said that the position which gynæcologists now held on the subject was about the same as that of a quarter of a century ago—removal in the early stages, which would give relief for a time, freedom from pain, hemorrhage, and discharge, and then a rapid passing away.

Dr. P. F. Harris, of Paterson, N. J., called attention to the pre-existing leucorrhœa as an aid to early diagnosis. He thought it a mistake to wait for the appearance of blood.

Dr. J. G. Clark, of Philadelphia, stated that twenty-two years ago Froyne performed the first abdominal hysterectomy for cancer of the uterus, and quoted his present experience as of interest. He said that at times his confidence in his own operation had been shaken. He had tried all plans and all forms of local treatment, and was going back to the radical operation as being the best yet advised; but, like all others, he thought operative treatment at best very inefficient, and that it was necessary to have some other thing to look to for radical cure. In the early stage he performed a radical operation; in the more advanced stage he did vaginal hysterectomy, or simple curettage and cauterization.

Dr. Clark was glad to find Dr. Pryor advocating the radical operation from above. He felt that a combined method was advisable—first from above, and then the continuation by a very clever modification by Werder of Pittsburg.

Dr. Bovée said he was in favor of the abdominal route in operating for cancer of the uterus. He agreed with Dr. Clark as to the efficiency of the operation modified by Dr. Werder, one advantage of which was the avoidance of the contamination of raw surfaces by cancerous tissue. He had done fourteen operations without one primary loss, with one from recurrence; at least the patient had died of that which the family physician did not think cancer, but which Dr. Bovée thought from the description was. He believed that when the bladder had become involved it was too late to do any radical procedure.

Dr. A. J. Downes, of Philadelphia, referred to the electro-hæmostatic forceps modified after the method of Dr. Skene, with which he had been working with the view of having them control hemorrhage in thirty seconds. On the heated blade of these forceps a drop of water would boil in fifteen seconds. He had operated five times during the past winter.

Dr. Hall, in closing, agreed with the gentlemen who said we should conserve human life. He had always believed that in certain selected cases vaginal hysterectomy was the operation to be performed. He preferred the ligature to the clamp because it gave an opportunity to close the peritoneum, and thus prevented infection and the subsequent possibility of an intestinal obstruction, which those gentlemen using the clamp and a large quantity of gauze must admit was not an imaginary danger. He admitted that he occasionally did the combined operation. Cautery and curettage he believed should be done when cure was not possible. He recorded two patients living from four to six years after operation when the epithelioma had been entirely destroyed. The unfortunate fact that recurrence occurred in nearly all these cases made him hesitate to perform the radical operation.

Dr. Deaver said that with the involvement of the broad ligaments the radical operation promised nothing, and advised in those cases the use of the cautery and curette. He recommended early operation and removal of the glands before involvement.

Dr. Humiston said it was necessary in all cases of chronic disease of the uterus to examine carefully all tissue removed. If malignant disease of the cervix was found, he did vaginal hysterectomy; if malignant disease of the fundus, abdominal hysterectomy.

Resection of the Ureter.—Dr. Howard A. Kelly, of Baltimore, read a paper upon this subject. He specified cases in which the ureter was most liable to injury, with the character of the injuries received. The best methods of treatment of an injured ureter were considered, and the instruments needed were described. An essential point in the method of treatment was pulling up the bladder to reach the ureter, making a blunt dissection and holding it there without suspending the bladder to the psoas muscle. In anastomosing the ureter to the bladder he followed one of two plans: either bringing the ureter just to the vesical opening, or inserting it well into the bladder. He described a pair of alligator forceps which spread only at the jaws and which was pushed through the bladder. At the end of the forceps there was a long guide which prevented injury of the ureter when stretched. The forceps was practically that of Sanger, to which he had simply added the feature of the guide.

Acute Senile Endometritis.—Dr. L. H. Dunning, of Indianapolis, gave a detailed history of two cases upon which he performed hysterectomy. The cases were both in women sixty-three years of age, in whom the menopause had occurred many years previously. The clinical history in its main features was identical in both cases. The women had been well until a short time (one and three months) previous to examination. There had been no uterine discharge. At the beginning, the discharge was described as thin and irritating. Shortly it became sanguineous and offensive. Pain appeared in the pelvic region. General lassitude and rapidly growing ill-health followed. There were backache, bearing-down pains, and some vesical disturbance. The skin was dry and sallow. This was marked in the case of longest duration. In this case the general appearance suggested cancer. The uterus in one case was in normal position, in the other retroverted. A diseased tube and ovary could be palpated in one. The external os was patulous and the internal os permitted the easy passage of a uterine sound. There was senile vaginitis in both. Hysterectomy was done in both cases. Both uterine cavities were distended by a foul-smelling, sanguino-purulent fluid. A microscopical examination of both uteri was made, and the findings were reported. Microphotographs of sections were also presented. The author presented the following conclusions: (1) The lesion found in both uteri was an acute inflammatory process. It might properly be denominated acute senile endometritis. (2) The characteristic pathological features of the inflammation were: (*a*) a thickened endometrium, the free surface of which was devoid of its epithelial layer; (*b*) increased vascularity with peculiar arrangement of small blood-vessels; (*c*) round-cell infiltration; (*d*) diminished glandular elements; while a few glands were to be distinctly seen, in many of them the epithelium was desquamating and their lumen was filled with granular débris; they might be said to be functionless glands; (*e*) degeneration of the coats of the arteries of the muscular layer of the organ; in one specimen (No. 2) this degenerative process was distinctly hyaline; (*f*) in not one section examined from various parts of the organ could there be found any increase of connective tissue. (3) In one case the acute inflammation seemed to have developed without any preceding chronic inflammation. In the other case the acute attack might have been an acute exacerbation of a chronic inflammation. (4) The mucosa of both the cervix and body were involved in the inflammation, but it was more marked in both cases in the body of the uterus. (5) In the more acute case the small round-cell infiltration extended into the deeper muscular tissue, though the inflammation was more marked in the mucosa. (6) In both cases one uterine appendage was diseased; in one the ovary was cystic, in the other one ovary was cystic and the Fallopian tube was inflamed. In this case there were slight recent peritoneal adhesions. (7) The microscopical appearances in these cases bore but slight resemblance to those found in cases of interstitial endometritis. (8) In one case there was marked retroversion of the uterus, in the other the uterus was in normal position, and in neither case was there marked stenosis of the internal os, yet there was a considerable accumulation of fluid within the uterine cavity. (9) The presence of diseased appendages in both cases and of pelvic peritonitis (mild) in one would indicate that the inflammation was prone to extend beyond the limits of the uterus, and if such extension was demonstrable by combined examination an extirpation of the uterus and appendages was indicated.

Inflammation of the Fallopian Tube, with Special Reference to Specific Origin.—Dr. J. R. Guthrie, of Dubuque, read a paper on this subject. He referred to the fact that authorities differed widely as to the importance of the gonococcus as an etiological factor in tubal disease. A latent gleet in the male might be the cause of a fresh infection in the mucous membrane of the vagina. Only a few germs might be present, yet their development was incredibly rapid and they had a wonderful grasp on life. The speaker believed that in order to establish the existence of the gonococcus frequent careful examinations should be made before stating positively whether or not it was present. Failure to do this was often the cause of pronouncing tubal disease to be due to some other infection. The sources of infection were by the douche, unclean instruments, and careless examinations. The disease reached the tubes by extension. He advocated the appointment of a committee to investigate the effects of gonorrhœal infection in the female.

Tuberculous Peritonitis.—Dr. A. H. Cordier, of Kansas City, read this paper. He said that there were many demonstrable truths in surgery and medicine, and other facts plainly to be seen, yet no satisfactory explanation of the manifested phenomena had been discovered. Many explanations had been given of how an incision into the peritoneum cured a tuberculous peritonitis, yet not one had been accepted. He hoped, therefore, that he might be pardoned for advancing another theory which to him was new. He was disposed to believe that an explanation of how these patients were cured by a surgical procedure might be found in the production of a special antitoxin within the peritoneum owing to some unknown function of that organ. In no other way could he understand how a similar process in the pleura as a complication could be cured by a laparotomy. The bacilli present were killed, ceased to multiply, or were held in abeyance in the recurrent cases. The handling of the peritoneum and its contents at the time of operation stimulated that great organ to an increased activity in the production of an antituberculous toxin.

A Plea for the More Frequent Avoidance of Exsection of the Ovaries in Connection with the Removal of Diseased Tubes.—Dr. Philander A. Harris, of Paterson, N. J., read a paper with this title, in which he laid special stress upon the fact that the Fallopian tubes, when once infected by suppuration, so persistently harbored it that they became the natural habitats of pelvic suppuration. The ovaries should be regarded as the contiguous and comparatively unwilling participants in these suppurations. The ovaries generally recovered from the effects of inflammation when the adjacent suppurating structures had been cured. The author claimed that the good results which had followed removal of the tubes and ovaries for tubal suppurations could in most cases be secured without sacrificing menstruation, thus not entirely depriving such patients of the possibility of conception. The reader had observed one case of pregnancy following the removal of both tubes.

Appendicitis Operations in Young Women and Girls.—Dr. Joseph Price, of Philadelphia, in a paper with this title, said that for a number of years his experience in appendicitis had differed from that of many operators in that he had found the trouble to occur sixteen times in the male to once in the female; now the proportion in his practice was about even. It seemed to the author that young surgeons were more prone to the disease than any other class of medical men. He was satisfied that the error of treating appendicitis for typhoid fever was more common in the case of females than in that of males, the cause of this being that the pain and tenderness were at a lower level in the female than in the male. He believed that if it was made a practice to operate when the trouble was first recognized, without the delay of a day for consultation and for medical treatment, deaths would be few in number.

(*To be concluded.*)

AMERICAN ORTHOPEDIC ASSOCIATION.

Fourteenth Annual Meeting, Held in Washington, D. C., May 1, 2, and 3, 1900.

Harry M. Sherman, M.D., of San Francisco, President.

First Day—Tuesday, May 1st.

A Simple and Efficient Treatment of Calcaneus Paralyticus in Young Children.—Dr. V. P. Gibney, of New York, read this paper. He said that all orthopedic surgeons knew that the reverse catch was very prone to get out of repair. His experience had taught him that long-continued position contributed to the shortening of the paralyzed muscle. The treatment which he recommended consisted in the application of plaster of Paris with the part in complete extension, and changing the plaster every three or four months. Four cases were reported as evidence of the good effects of this treatment. He had not tried water-glass or leather splints on young children.

Dr. L. A. Weigel, of Rochester, spoke of the danger of producing excoriation in some cases of complete paralysis associated with much trophic disturbance, and instanced a case in which he had found it impossible to use any form of dressing without the danger of gangrenous ulceration occurring.

Dr. John Ridlon, of Chicago, pointed out that the treatment advocated in the paper was not new, as for many years the late Hugh Owen Thomas had treated his cases in this manner, and had claimed that it was entirely possible to get a return of function in all muscles that were not really paralyzed, if they were but retained in a position of relaxation. His apparatus for accomplishing this was, however, quite clumsy.

Dr. H. P. H. Galloway, of Toronto, felt that valgus would occur quite frequently after the shortening of the tendo Achillis. There seemed to be a class of cases in which the shortening of the tendo Achillis would cause either supination or pronation according to the direction the foot happened to be given.

Dr. A. B. Judson, of New York, said that he had abolished the joint at the ankle to make the apparatus more durable. The first effect of such an apparatus was to carry the weight of the body from the anterior part of the foot, by virtue of the strength of the muscles acting on the tendo Achillis, to the anterior side of the upper part of the shin. By these means, in cases of extreme calcaneus the gait could be made absolutely perfect.

Dr. Gibney, in closing, said that his experience had taught him to place very little reliance on the electrical examinations of the muscles in young children. He had not claimed to be presenting anything novel, but had simply advocated a simple method by which a permanently good result could be secured. His cases had presented the clinical appearance of paralysis, and without an electrical examination he was willing to have them go on record as poliomyelitis.

A Final Report on the Use of Pure Carbolic Acid in the Treatment of Tuberculous and Purulent Diseases of Joints and Bones.—Dr. A. M. Phelps, of New York, made this report. His practice had been to lay open abscess cavities, divide the capsule about two-thirds of its extent, and pull out the head of the bone. The joint was then irrigated freely with bichloride 1 : 1,000, after which pure carbolic acid was poured in and allowed to remain just one minute. This application was followed by irrigation first with strong alcohol, and then with a two-per-cent. solution of carbolic acid. He then inserted the largest possible glass drain that the joint would admit, and put the patient in bed with a weight and extension apparatus. In the last eighteen months he had operated on seventy cases, and had performed twenty excisions, whereas he would have ordinarily done fifty. In fifteen cases the head of the bone had been found separated from the neck, and lying as a sequestrum in the joint. In forty cases the capsule had ruptured anteriorly into the muscles. On an average, all of the cases requiring excision or extensive bone operations had been discharged from hospital at the end of three weeks.

Dr. Robert W. Lovett, of Boston, said that at the Children's Hospital the surgeons had endeavored to prevent the formation of these abscesses by putting the children to bed whenever there was a painful condition of the joint or deformity due to irritative muscular action, and they had learned to attach considerable importance to this as a preventive treatment. When an abscess occurred, it was the practice to open it up freely and drain, after irrigating the cavity with corrosive-sublimate solution.

The Movements of the Normal Spine in Relation to Scoliosis.—Dr. Robert W. Lovett, of Boston, presented in this paper the results of an elaborate study of this subject. He said that at present there was no satisfactory theory to account for the mechanism of scoliosis, and particularly the rotation. A large number of theories had been propounded, and the fact that they had not been generally accepted had led to the study on which this paper was based. The text-books on anatomy usually described four movements of the spine, viz., (1) flexion; (2) extension; (3) lateral flexion; (4) torsion. He had found that in side-bending in the flexed position a type of torsion was got in which the bodies of the vertebræ rotated toward the convexity of the lateral curve. In extension the rotation was more limited to the upper part of the spine than in flexion, and was the reverse of that seen in flexion. The construction of the spine being very complex, the next step in the present investigation had been to study, with the aid of the professor of mechanics of Harvard College, the action of a flexible beam or rod. The vertebral column apparently followed the behavior of a flexible rod—a matter well understood by students of mechanics. It was found, however, that one could not entirely leave out of account the articular processes. Apparently in side-bending in the extended position the articular processes merely served to accentuate what the column would do if they were not present. In the flexed position they appeared not to exert any influence. The author's conclusions were: (1) Scoliosis was a deformity that must always be acquired in the flexed position; (2) reverse rotation was possible on the ground of side-flexion occurring in the extended position; (3) extension exercises should be cultivated in the treatment of lateral curvature, and even forcible correction done in the extended position; (4) symmetrical exercises seemed much safer than the complex unilateral ones; (5) probably a safe and efficient method consisted in throwing the spine into positions which would bring the articular processes into play, and reversing the rotation acquired in the flexed position.

On Some of the Problems Involved in the Treatment of Lateral Curvature of the Spine.—Dr. Newton M. Shaffer, of New York, presented this paper, but spoke of only one of the problems. He said that clinical experience had taught him what Dr. Lovett had concluded from his mechanical studies, *i.e.*, that the treatment should be carried on in the extended position. He indicated the best directions in which to make pressure, by diagrams on the blackboard.

The Relation of Deformity of the Pelvis to Lateral Curvature of the Spine. — Dr. H. P. H. Galloway, of Toronto, read this paper. He said that the theory which considered the superincumbent weight the chief etiological factor in lateral curvature of the spine had been the one most generally accepted. In a faulty attitude, habitually assumed in a growing child, the conditions were ripe for this superincumbent weight to become a determining factor in the production of lateral curvature. His own observation had convinced him that the primary mechanical fault had received but scant consideration. Many writers had looked upon distortion of the pelvis as the effect of the lateral curvature, but his own belief was that cause and effect had here been confounded. It was not uncommon to meet with a sacrum the base of which was an incline. As the vertebral column was built upon this slanting foundation, the column must lean to one side, and this led the person to endeavor to restore the balance of the body. To his mind it was more logical to look for the faulty construction in the foundation than in the superstructure. It was unreasonable to suppose that the stable foundation, or pelvis, should fall a prey to faulty mechanical conditions belonging to the flexible vertebral column resting upon it.

Spasmodic Lateral Curvature of the Spine.—Dr. Arthur J. Gillette, of St. Paul, gave in this paper a record of a number of cases of hysterical curvature of the spine that had come under his observation.

The Results of my Observations in Lateral Curvature of the Spine, Clinically, Mechanically, and Pathologically.—Dr. B. M. Phelps read a paper with this title, in which he gave the results of an autopsy held on a patient with lateral curvature, dying at the workhouse of natural causes. The subject was a man about forty-five years of age, who had had a lateral curvature as far back as he could remember. There was extreme lateral curvature with rotation. The superficial layer of muscles was found in fairly good condition. Upon the side of the concavity the muscles were in fairly good condition, but upon the side of the convexity they were atrophied, and had undergone fatty degeneration. The quadratus lumborum and other deeper muscles were entirely destroyed by fatty degeneration and atrophy on the side of convexity, and on the concave side degeneration was present, but was not so far advanced. This condition of the muscles extended throughout the whole region of curvature. The intervertebral cartilages on the side of the concavity were completely destroyed. His conclusion was, that it was utterly futile to expect to cure a lateral curvature of the spine after bone changes had taken place. The most that could be hoped for from treatment was to prevent an increase of the curve. He was of the opinion that all of the machines for forcible correction now in use were of but little value.

Dr. E. H. Bradford, of Boston, said that while he agreed entirely with Dr. Phelps regarding the pathology, he could not accept the doctrine that there was no stage of lateral curvature in which treatment would benefit. There were certainly some cases in growing children which were benefited by treatment.

Dr. Weigel said that he had time and again seen patients with muscles as rigid as a bar of iron, in which absolute relaxation had been secured by forcible correction. This was certainly an improvement.

Dr. N. M. Shaffer said that if there was any one thing clear in his mind it was that lateral curvature was dependent primarily not on bone changes, but on changes in the muscles.

Dr. H. Augustus Wilson, of Philadelphia, suggested the possibility that asymmetrical hip action in apparently normal subjects might result in lateral curvature. In a number of cases he had found such action present, although the hips were apparently normal in other respects.

Dr. Phelps replied that in the early stages of mild cases of lateral curvature a very decided physiological curve was added. This latter curve could be cured, but in proportion as a curve developed in the dorsal region there was distortion of rib, and these patients could not be cured. It was not necessary to do myotomy in young children; nevertheless at the present time he was cutting more than one-third of all the cases of lateral curvature coming under his care. He did not believe any of the cases began in the muscles except those originating in a poliomyelitis.

Dr. A. B. Judson complimented Dr. Lovett on his ingenious and convincing model demonstrating the prevention of rotation by extension and its promotion by flexion of the spine. The speaker said that about 1876 he had himself advocated, and in one case practised, the application of a spinal brace for the production of extreme lordosis in cases of lateral curvature, on the ground that, as in rotation the anterior part of the column was affected by deviation from the median, just as it was affected by caries in Pott's disease, it was good practice to shift the weight of the body from the anterior to the posterior part of the column. If he had looked ahead as far and as keenly as had Dr. Lovett, he would have entertained a more favorable opinion regarding this method of treatment, which he now believed promised great advantages.

Anterior Support Supplementing the Taylor Brace in Pott's Disease.—Dr. George B. Packard, of Denver, read a paper on this subject. He said that plaster of Paris would be frequently the most satisfactory method of treatment were it not for the lack of adjustability. In the mid-dorsal region, in which there was apt to be the most deformity, the anterior support was of decided advantage. The sinking forward of the upper dorsal spine in these cases carried the ribs forward. The front piece could be made to extend higher than the apron.

A Suspension Pressure Chair for Scoliosis.—Dr. Phil. Hoffmann, of St. Louis, described this simple and inexpensive apparatus. It was the pressure chair that had been described by Dr. Bradford, with the lateral steel bars prolonged upward to the height of four and a half feet, and meeting overhead in the form of an arch, to which was attached an apparatus with compound pulleys. It was intended to be used only as an accessory to proper gymnastic exercises and other treatment.

A Brace for Cervical and High Dorsal Spondylitis.—Dr. Hoffmann also exhibited this apparatus, which belonged to the cuirass type.

Results of Treatment of Congenital Dislocation of the Hip.—Dr. E. H. Bradford, of Boston, presented this communication. It had been shown in recent years, he said, that congenital dislocation of the hip could be reduced, or apparently reduced, both by operative and by the bloodless method, and that relapses occurred after both methods. It had also been shown that both methods lacked precision. A specimen was presented illustrating the results of both methods. According to his study of this subject, one cause of failure in these cases was the covering of the acetabulum with what he called "the hymen of the acetabulum." By exposing this, and incising it deeply, and then retracting the parts, it would be found that there was usually a fairly deep acetabulum. He had operated about forty times by the bloodless method, and in only one case had there been no relapse. There were definite surgical conditions which were difficult to meet. If they could be met, a cure would usually result; if not, relapse would almost certainly occur. He had seen a few cases in which relapse had occurred after a year. He had endeavored to make the results more permanent by suturing the capsule. In his later operations he had made a straight incision from the greater trochanter to two or three inches below, or just above, the insertion of the gluteus maximus muscle. At the upper end the incision curved slightly upward between the tensor vaginæ femoris and the gluteus medius. He first exposed the lesser trochanter, and with the periosteal elevator pressed up the insertion of the psoas and iliacus muscles. He next opened the capsule by a transverse incision anteriorly and posteriorly, and inserted the finger into the acetabulum. After reduction the parts were kept immobilized for three or four weeks, and if then the head did not seem to be firm, he cut down and sewed it in. He felt that he could not operate successfully on patients over six years of age.

Dr. Gibney remarked that the suturing of the capsule, so as to make the results more lasting, seemed to him a capital idea.

Dr. Ridlon thought it was more important to control flexion than abduction. If the patient was young, and the head and neck were fairly well developed, it was possible to replace the bone by the bloodless method and retain it. This statement presupposed that very considerable abduction was maintained permanently, together with absolute control of both active and passive flexion.

Dr. Harry M. Sherman said that he had tried suturing in one or two instances, but had found it very inaccurate because he had to do it without the guidance of sight. He believed that the position of the head between the two lateral halves of the pocket made it as stable as if sutures had been used.

Dr. Galloway said that in one of his cases, a double dislocation treated by the bloodless method, apparently a perfect cure had been obtained.

A New Back Brace for Pott's Disease.—Dr. John Dane, of Boston, exhibited this brace. The object of the device was to combine the advantages of a plaster-of-Paris jacket with those of an antero-posterior brace. The two pad-plates were held by an arm which could be removed to facilitate fitting the pads to the child. There was a cross-piece very high up on the back, and straps passed around under the arms. The usual apron was dispensed with, thus giving the wearer a much better opportunity for deep thoracic breathing.

Tendon Transplantation in the Treatment of Paralytic Deformities.—Dr. W. R. Townsend, of New York, read this paper. He said that only during the past five years had tendon transplantation attracted much attention in cases of paralytic deformities. There were many patients suffering from drop-wrist whose deformities could be entirely done away with and the function more or less restored if this operation was done. Several cases were described, including one of his own—a case of equinus and drop-wrist. In this case the tendon was shortened by lapping one portion over the other. The method of fastening was that recommended by Dr. Goldthwait, and already reported to the association.

A Report of a Tendon Transplantation for Paralytic Club-Foot.—Dr. L. Porter, of Chicago, reported this case. The case was one of paralysis of the anterior and posterior muscles of the leg from poliomyelitis. All the muscles of the gastrocnemius group were paralyzed. The extensor proprius pollicis and the peroneus longus were intact.

Dr. Joel E. Goldthwait, of Boston, said that if tendons were to be transplanted, the more direct the route the better the result. He would certainly prefer the route taken by Dr. Townsend in going directly through the interosseus membrane, because in cases in which the anterior tendons had been carried around the leg and made posterior tendons, the result had not been very good.

Dr. Weigel said that in certain cases complete division of the tendon seemed an absolute necessity, particularly when the condition was the result of injury.

Dr. E. H. Bradford said that he had endeavored to avoid complete division by doing a myotomy, dividing the intermuscular septa, and over-correcting the hand. In that way the power of the muscle had been retained, and yet the contracted tissues had been overcome.

A Case of Tuberculosis of the Astragalus with Ankylosis and Subsequent Amputation.—Dr. V. P. Gibney reported this case. At first the case had seemed to be one of synovial tuberculosis, but it had gradually extended to the bone, and had involved the latter and the joint. A girl, aged sixteen years, had sprained her ankle. It had been treated at first by plaster of Paris, and subsequently by splint and crutches. She had kept up the latter treatment for about twelve years. A few weeks ago she had appeared at his clinic, with what seemed to be a typical example of tuberculosis of the astragalus. About eleven weeks ago he had made an incision over the astragalus, and had then found a mass of granulation tissue which the pathologist reported to be filled with tubercle bacilli. The surface of the bone was somewhat eroded, but the body was apparently intact. He had removed the astragalus and the surrounding tissues for about one-eighth of an inch in every direction. After a short time she had developed an abscess, and, after consultation, the knee had been amputated. The specimen showed an eroded condition of the inner facets of the malleoli, the rest of the bone being apparently normal. The astragalus was also exhibited.

(*To be Continued*)

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 9, 1900:

	Cases.	Deaths.
Tuberculosis	203	139
Typhoid fever	31	4
Scarlet fever	101	7
Measles	419	21
Diphtheria	294	43
Laryngeal diphtheria (croup)	7	5
Cerebro-spinal meningitis	0	8
Chicken-pox	20	0
Smallpox	4	0

Inoculation of Typhus Fever.—A Russian physician, Dr. Mochutkovski, has inoculated himself with the blood of a typhus patient. After feeling no ill effects for seventeen days he had a severe rigor on the eighteenth day, with fever, delirium, and a comatose condition lasting for a fortnight. The rash appeared on the fifteenth day of the disease and desquamation began eleven days later, he being convalescent on the twenty-third day after the initial rigor. This interesting experiment appears to prove that the virus in typhus fever resides in the blood. It should, however, be mentioned that Dr. Mochutkovski had previously attempted to inoculate himself with the blood of typhus-fever patients no less than seven times.—*The Lancet.*

The Nails in Insanity.—That acute diseases frequently involve defective nutrition of the nails, so that their occurrence at a previous date, which may be approximately estimated, is often indicated by transverse lines, is a well-known fact. According to Dr. Marco (*Gazetta Medica Lombarda*) this occurs with special frequency and regularity in the periodic psychoses known as alternating or cyclic insanity, folie circulaire, etc. "In patients so affected the periodic changes in the general and psychical condition are so countersigned on the nails in the form of grooves and ridges that a simple examination of the fingers will enable one in most cases to estimate the frequency and relative duration of the attacks. In some cases, especially cyclic forms, where the periods are frequent, short, and regular, the nails assume a characteristic aspect resembling in the richness of concentrically arranged dystrophic striæ the ridged shells of certain molluscs."—*Medical Magazine.*

The Failure of the Filters in South Africa.—*The Hospital*, referring to the large death list of the British troops in South Africa, and especially to the mortality from typhoid fever, remarks that it is doubtless due to a polluted water-supply, and speaking of the filters says: "Much of the knowledge which has been gained in recent years about filtration has tended to throw doubt upon the power of ordinary filters to produce a safe and drinkable water. Indeed a sort of despair has seized upon scientific men upon this subject. We are, however, by no means sure that the last word has been said upon the purification of water by mechanical and perhaps chemical means. Bacteriologists have set up so high a standard as to have condemned off-hand all the old-fashioned filters, and have given us instead some very beautiful and perfect arrangements, which, however, clog up directly with South African mud. But we are beginning to appreciate the biology of the subject, and to understand what a very tender organism the typhoid bacillus really is, and it is on the cards that some better way of getting rid of these microbes may be devised than the apparently simple but really very difficult method of straining them out."

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended June 9, 1900:

		Cases.	Deaths.
SMALLPOX—UNITED STATES.			
Colorado, Logan Co	May 25th	1

A MEMORIAL ADDRESS UPON DR. FESSENDEN NOTT OTIS.[1]

BY T. GAILLARD THOMAS, M.D.,

NEW YORK.

No man ever passes through life, who, if a careful, candid, and unprejudiced study were made of his character and career, would not furnish a lesson of greater or less moment for humanity. If he has achieved great results, profit would accrue from a consideration of the qualities and methods which secured him fame and fortune. If he has passed through his existence a sluggard and a dolt, the suggestion of avoidance would reward the biographer. If he has been a criminal and a malefactor, the interest of the investigator would grow in proportion to the depth of infamy to which his subject has sunk, and the brilliancy of the exhortation which could be based upon his depravity.

But to give to this consideration of individual careers the universal interest which I claim for them, it should be made with fairness, justice, fearlessness, and honesty; the investigator spurning the absurd maxim, "De mortuis, nil nisi bonum," and making truth the pivot of his work.

You have met together to-night to listen to the unvarnished and impartial account of one of our colleagues, whose life and character were such that I dare to tell the truth of both, holding up before them the mirror, showing you an honest reflection, and telling you a simple tale based upon an intimate acquaintance of nearly half a century.

In the year 1852, I was a member of the resident staff of Bellevue Hospital. One of the amusements of this staff on summer afternoons was to row upon the East River in the staunch yawl of the warden, and one day we called upon the resident staff of Blackwell's Island Hospital, which was then under the charge of the brilliant and lamented Dr. Kelly, who just after the time of which I speak was lost at sea, upon a voyage to Europe for the purpose of perfecting himself in the study of venereal diseases, of which he intended to make a specialty. To one of Dr. Kelly's staff I was particularly attracted by his kindly, genial manner, his simple, unostentatious ways, and his striking appearance. He was nearly six feet in height, of dark, almost swarthy complexion, with a head large and somewhat Websterian in shape. Meeting him casually, one might have supposed him to belong to one of the so-called "Latin races," from his raven-black hair and huge black moustache, which entirely shrouded his mouth and gave to his face a sternness of expression which ludicrously belied the gentle nature of the man.

I recall the fact that before the two staffs, strangers to each other up to this time, had conversed very long, Dr. Kelly arose, and, pointing to a fine life-size oil portrait of himself, told us that it had just come from the hands of the framer, and descanted upon its merits, its accuracy as a likeness, and the great pleasure which he experienced in its having been painted by a member of his staff, bowing as he went on to the dark and striking-looking man of whom I have just spoken.

From that day to the day of his death an intimate friendship existed between this man and myself, a period of forty-eight years. From this statement you may judge of the fulness of the knowledge from which I speak to-night. I shall endeavor in dealing with my theme to make candor and impartiality go hand-in-hand with knowledge.

Fessenden Nott Otis, the subject of this memorial address, was born at Ballston Springs, Saratoga County, N. Y., May 6, 1825. The family from which he was descended settled in New York State prior to the American Revolution, and is a branch of the Otis family which came from England toward the close of the seventeenth century, and settled at Hingham, Mass. Oran Gray Otis, the father of Dr. Otis, was one of the early graduates of Union College, Schenectady, N. Y. He became prominent as a lawyer, advocate, and legislator, although dying at the age of forty-one years. He was selected to deliver the oration on the one hundredth anniversary of the birthday of Washington, before the joint legislative bodies of the State of New York, at Albany, in the year 1836. On the maternal side Dr. Otis was descended from another well-known New England family of English origin; his father having married Lucy, daughter of David Kingman, a leading citizen and shipping merchant of Bridgewater, Mass.

Dr. Otis began the study of medicine in 1848, and came to New York City, matriculating in the medical department of the New York University; also entering the office of Dr. John Whittaker, demonstrator of anatomy, as a private student. Subsequently he left the university with Dr. Whittaker, who had received an appointment to the chair of anatomy in the New York Medical College, just then organized. In 1852 he was graduated from that college, receiving the competitive gold medal for his graduating thesis, as well as prizes in the departments of physiology and practice.

Immediately after his graduation, he was appointed one of the resident assistant physicians of Charity Hospital. At the close of this service he received an appointment as surgeon in the United States Mail Steamship Company, the service of which covered that portion of the route between New York and the Isthmus of Panama. Subsequently he continued in this and the Pacific Mail service up to 1859, when he left the ocean and settled in the practice of his profession in New York City in 1860.

In January, 1862, he was appointed to a lectureship in the College of Physicians and Surgeons, New York, which he continued to fill until 1871, when he succeeded to the clinical professorship of the department of genito-urinary and venereal diseases. This chair he occupied until his resignation from it, on account of failing health, in 1890, when he received the degree of professor emeritus. In 1861 he was elected a fellow of the New York Academy of Medicine, and subsequently was made a member of the New York County Medical Society, and also of the New York State

---

[1] Delivered before the New York Academy of Medicine, June 7, 1900.

Medical Society, the British Medical Association, and the Society of American Genito-Urinary Surgeons. He had also become a member of the medical board of Charity Hospital, and was attending surgeon at Blackwell's Island Hospital for over ten years.

Dr. Otis' career of professional activity extended over a period of exactly thirty years. During this time he labored as a practitioner, as an operative surgeon in his speciality, the genito-urinary organs of the male; as a lecturer; and as a steady contributor to medical literature. An enumeration of the most important of his contributions makes his industry quite apparent.

In 1883, "Practical Lessons on Syphilis and the Genito-Urinary Diseases," a work of six hundred pages, was published; and this was followed by "The Physiological Pathology of Syphilis," in book form. Soon after the following brochures were published·

"The Limitation of the Contagious Stage of Syphilis, Especially in its Relations to Marriage"; "Some Important Points in the Treatment of Deep Urethral Stricture"; "Temporary Overstrain of the Bladder, Producing Localized Atony and Chronic Retention of the Urine;" "Résumé of the Experience of Seventeen Years in the Operation of Dilating Urethrotomy"; "The Perfected Evacuator in the Operation of Lithotrity"; "Reflex Irritations and Neuroses, Caused by Stricture of the Urethra in the Female"; "The Radical Cure of Urethral Stricture," a work of three hundred pages. For him who has not written for publication, the enumeration of an author's works may signify little; for him who has done so, it will carry home a meaning which will appeal to his memory.

In the course of his practice, and in order to carry out his special surgical procedures most completely, Dr. Otis invented various instruments of precision, which came into very general use. A case containing these was ordered, in 1889, by the surgeon-general for every post of the army of the United States. I remember quite well the peculiar pleasure which the inventor experienced from this act on the part of the medical executive.

In this most wonderful era of the world's history; this age in which progress, advancement, and development in all things are startling the minds of men by their exuberant growth; this magic age in which the science of medicine is rapidly being elevated into the position of one of the bulwarks of society and one of the mainstays of civilization—it is most difficult for one, strive he ever so hard, to score for himself more than a mediocre success; and most happy should be the man who succeeds in writing his name among those whose works shall live after him and be recognized as deeds which will prove of lasting good to his fellow-men. This claim can honestly and fairly be made for the subject of this memoir; for he has so decidedly left the imprint of his labors upon the whole subject of urethral pathology and treatment that it would be idle to dispute his claim. So long as the God-given art of surgery lives, its history will be impossible without reference to his name and acknowledgment of his contributions to it as a science and as an art.

In some of the views advanced by Dr. Otis in his public teachings he was opposed by leading authorities at home and abroad. This resulted in much spirited discussion in the various medical societies and journals, and also in the publication of the last work mentioned in this enumeration. This was soon after republished in London. Previous to this publication, Dr. Otis, by invitation of Prof. Berkeley Hill, had addressed the profession from Professor Hill's chair in the University Medical College of London, and had also presented his advanced views at the meeting of the British Medical Association at Edinburgh, in 1875.

Now that the laborer is at rest, it becomes a matter of deep interest for those who stood near him during his life and watched his efforts, to inquire into the forces and methods which crowned them.

Where and how shall we class Fessenden Nott Otis among the workers in our calling? Among the brilliant geniuses, like Marion Sims, who like a meteor swept athwart the dark field of gynæcological surgery, flooding it with light? No. Shall we place him among the deep thinkers, the profound philosophers, like John W. Draper? No. He was not in any respect a quick, brilliant, striking man. He belonged to an entirely different class; to the class which holds within itself the greatest number of men who have lifted up humanity and advanced civilization; that class occupied by men who are slow of thought, deliberate of speech, and cautious of action; the class to which belong George Washington and Ulysses S. Grant. I count upon you not to do me the injustice of supposing that I am in any way comparing the subject of my essay with either of these great men. The class is large and it is comprehensive. From my standpoint, there are men in all positions of life who belong to the same class as those whom I have mentioned. As we look back upon our comrades of college life, we will recall them as belonging to three classes: First, the thoughtless, giddy youths, whose aim was pleasure and whose lives were froth; second, the talented, brilliant, witty, fascinating fellows, who gave great promise for the future, and who held among their number the "first-honor man" and those of lesser note; and third, the quiet, slow, well-balanced fellows, who, while not in the front ranks of college scholarship and college honors, always held positions of dignity; men of reserved force who took life gravely, avoided scrapes, and plodded on through the college career, the real bone and sinew of the class. To this class of men we all look back as that which has furnished the largest number of those of our classmates who have shed lustre upon their alma mater, gained honor for their own names, and accomplished worthy deeds for society. To this class belonged Fessenden Nott Otis. What he accomplished in his profession was attained by careful, devoted thought, devotion to details, strict and unbiassed examination of results, and honest regard for truth.

Upon his reading a paper before a European society, a man eminent in the specialty to which both belonged rose against it with undue warmth and uncalled-for severity. He appeared to feel that the slow-talking man who was opposed to him would readily fall before his flowing, flowery logic, and leave him undisputed victor upon a stricken field. A friend who was present described the encounter to me as a signal exhibition of methods between the brilliant and rather superficial man, and the deep, thoughtful, slow-moving one, whose staying powers wear out only after long conflict. Success on that occasion undoubtedly rested with the subject of this memorial and added largely to his then growing reputation.

But Dr. Otis presented other bright and attractive sides to his character, apart from that connected with his profession. He was an artist by nature, and to a certain extent by practice; for he always kept in touch with artists and with art, even to the end of his life. A mutual friend, the late W. H. Beard, once said to me in discussing his character and career: "The gain of your profession in attracting Otis was the loss of mine. Had he followed his natural bent, as in my judgment he should have done, he would have made an artist of merit and distinction, perhaps even of renown." An accident received in early life to a certain extent modified the course of his career. At this time and owing to this fact, perhaps, he devoted himself to landscape drawing and perspective.

with such success as to result in the subsequent publication, through the house of D. Appleton & Co., New York, of several books on these subjects. Their excellence and his reputation as a lecturer and teacher were recognized by the faculty of Union College in the presentation to him of the honorary degree of Master of Arts in 1849. And thus it was that on my first introduction to him in 1852, when he was twenty-eight years of age, I heard Dr. Kelly allude with enthusiasm to a life-size portrait in oil, painted by him.

It is quite evident that when Otis in due course came to the parting of the roads, one of which led to the temple of Æsculapius and other to that of art, he considered the course which would be his path in life with all that coolness, caution, and judgment which always characterized him, and decided definitely. Nevertheless, he loved art to the day of his death, and always kept in affectionate touch with it. Among his most intimate friends were artists of world-wide fame, such as Church, Beard, Winslow, Eastman Johnson, Bristol, and many others. But it was not only, or especially, the well-known and distinguished devotees of art that he cultivated. He was to my certain knowledge the medical adviser and counsellor of a host of poor students, who in time of need sought his guidance and aid, and sure am I that they never sought him in vain. In many an artist's humble home his loss will be deeply felt, and from many a studio prayers from grateful lips have ascended to heaven in his behalf.

In 1849 he published two volumes, entitled "Lessons in Drawing," and "Studies of Animals and Landscapes" ; and later he put forth a brilliantly illustrated work upon "Tropical Journeyings." In 1860 he published an illustrated "History of the Panama Railroad, and its Commercial Connections."

But I have kept back for you the most charming phase of his character, the loveliest feature of his nature, until the close of this address. A few words only, as I tell those of you who did not know him well, of his social, genial, humorous personality, and his gentle and affectionate nature. His friendships were tenacious and lasting, and his enjoyment of the society of his friends almost childlike. Fond of a good joke, he was an effective raconteur, and he had one virtue rarely seen in such men: he enjoyed the jokes told by others. I cannot refrain from telling you how deeply he enjoyed the following incident. Some years ago a dinner was given at the old Delmonico's restaurant to an eminent English surgeon, by some physicians of New York, and for a part of the evening I had the honor of sitting next to the guest of the occasion. For some reason I found it very difficult to interest him in my conversation, and, growing desperate, I pointed Otis out to him and said, "I have just returned from London, and on a visit of exploration I saw in a hostelry in the 'Seven Dials,' a portrait of that man in a picture hanging there which represented him standing not ten feet from Queen Victoria." Had I set off a bomb under his chair I could not have aroused the attention of this true Englishman more effectually. He was eager for an explanation, and evidently suspected me of insanity, or worse. You are all aware of the fact that when the British ship *Resolute*, which England sent out to search for Sir John Franklin in the Arctic Ocean, and which was lost, was recovered and returned with honors by the United States, Otis, in full naval uniform, and with a huge sword hanging by his side, was acting in the capacity of secretary to Commander Hartstene of our navy. The queen and the prince consort came on board to receive the ship, as Commander Hartstene delivered her to the English government. This striking scene was committed to canvas, and large engravings of it were struck off. It was one of these that I had seen hanging in a saloon in the questionable precincts of the "Seven Dials," and which represented Otis and the queen within ten feet of each other. After this the Englishman was eager to be presented to the enviable American, and to Otis' astonishment, I soon placed him in my seat and gave him my place of entertainer. The Englishman's extreme warmth and delight in knowing him, and his great desire to cultivate his acquaintance, amused him ever afterward, and was the subject of much merriment.

In his own home he was the soul of hospitality, and many of his friends will recall with pleasure the hours spent with him in his cottage upon the magnificent bluffs of Montauk Point, overlooking at once an endless expanse of ocean and hundreds of acres of pasture land, which recalled the prairies of Colorado. Here, surrounded by wife and children, and free from the cares of an arduous practice, the guest saw his true nature face to face, and learned to comprehend the charm of character which made for him in his three-score years and fifteen such a host of friends. Brilliancy, wit, and eloquence make men rich in admirers; simplicity of nature, sincerity, and kindliness produce, in their place, friends.

Dr. Otis was for many years a member of the New York Century Association, to which he was very deeply attached; of the New York University Club; the New York Medical and Surgical Society; a member in perpetuity of the New York Metropolitan Museum of Art; medical examiner and honorary member of the New York Artist Fund Society; and a life member of the New England Society.

For the last nine years of his life, failing health caused him to spend his winters in milder climates than that of New York, and he sought health in Southern California, Jamaica, Thomasville, Tallahassee, and New Orleans. He even tried lengthy journeys to India and Japan. On my last meeting with him I urged him to write a guide-book to the best winter resorts for invalids; but with a smile he rejected the proposal, saying: "Too late, too late, I am up to no more work." Then came to my mind the lines of Whittier,

> "Of all sad words of tongue or pen,
> The saddest are these, it might have been."

Such a work from such a man would have filled an important place as an aid to the physician of our day; for his dicta would have been freighted with a plentitude of practical knowledge.

His last winter was spent in New Orleans, where, in the early part of April, he was attacked by double pneumonia. During his convalescence a carbuncle appeared, and in his already debilitated state of health resulted fatally on May 24, 1900.

He leaves a widow, two daughters, and a son to mourn his loss. To them his death was a dire calamity, but to him it was not so. He fell like ripened fruit in due season, and as it is allotted to all men once to die, what happier ending could have come to any man than that which took our colleague from us? His career was one of honor and usefulness; his hour had fully come; no task was left unfinished, no demand of duty unfilled.

As we draw the pall over the quiet face which we shall look upon no more, we murmur, "A fitting exit for a true and noble man."

Snake Bite in India, on the recommendation of Major Lyons, is to be treated as follows: Bind a string or handkerchief as close as possible to the wound on the proximal side. Wash with a fresh solution of hypochlorite of lime diluted to 1 : 60. Inject a dose of antivenomous serum into the subcutaneous cellular tissue of the flank.

A NEW PLAN FOR WASHING THE BLADDER, WITH A DESCRIPTION OF APPARATUS.

By WILLIAM F. FLUHRER, M.D.,

ATTENDING SURGEON TO MOUNT SINAI AND BELLEVUE HOSPITALS, NEW YORK.

In the general practice of washing the bladder, the repeated filling and emptying of the organ is apt to excite contractions and limit the duration of the procedure. If, to avoid inducing bladder spasm, the irrigation is made more gently, it is mechanically less efficient.

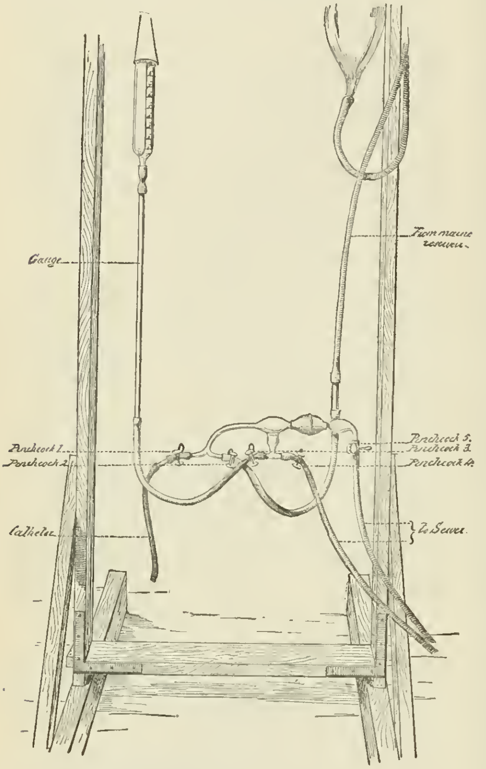

Fig. 1.

For the most thorough washing of the bladder, in the writer's opinion, two conditions must be realized: First, the bladder must be held in a state of comparative rest in any given capacity of contents, during the procedure, and, second, while the bladder is thus at rest, the liquid it contains must be more or less agitated. If the washing can be practised while the bladder is at rest, spasm of the organ can be avoided; the procedure can be prolonged, and the probability of disinfecting a foul bladder correspondingly increased. Ordinarily, the antiseptic impression made upon the bladder is brief. If it is lengthened by increasing the strength of the antiseptic, it is with the chance of causing irritation. If, however, the conditions allow a lengthening of the period of antisepsis without increasing its intensity, irritation may be avoided and a more thorough disinfection attained without subtracting from the energy of the bladder. A thorough freeing of the bladder of its foul contents, and a prolonged extension of the period of disinfection without undue irritation, brings into view the possibility of accomplishing the complete cleansing and disinfection in a few prolonged sittings rather than spreading many, perhaps ineffectual efforts over weeks and months, with the attendant risks.

According to the first proposition, not only should the bladder be washed while at rest, but in varying degrees of capacity of contents from a state of very small contents to that of full capacity and distention. It is understood that the gross impurities are best removed when the bladder has only a small amount of contents; but it should also be appreciated that for its thorough cleansing the bladder should be washed while filled sufficiently to smooth out its folds and expose all pouches and depressions to the action of the irrigant. To suppose that a trabeculated bladder with all its numerous pouches can be cleaned by simply a repeated filling and emptying of liquid contents is unreasonable. Such a bladder should be washed while held at comparative rest in different capacities of contents from partial to full distention.

Over-distention, unless for the special purpose of increasing the absolute capacity of the bladder, is to be avoided. Straining the bladder by overpressure upon its wall is apt to excite spasm and limit the washing procedure, and is consequently to be avoided. The reaction of the bladder to internal pressure is a characteristic special to the individual and is best determined by a gauge connected with the bladder. This consideration also has its application to a dilated and insensitive bladder.

That the liquid contents of the bladder should be agitated during the procedure of washing will be conceded. Apart from the mechanical washing of the bladder, the disinfection of its wall is best accomplished while it is held at comparative rest and the contained liquid is made to circulate within it. By this means the whole disinfectant energy of the irrigant is utilized. It should be remembered that the time element is an important factor in disinfection.

In the usual procedure of washing, care is taken, very properly, not to have the end of the catheter project far into the cavity of the bladder, for the collapsing organ striking against the catheter may be irritated and thrown into spasm. In the washing according to the plan of the writer, this restriction to the position of the end of the catheter is removed, except while emptying the bladder. Indeed, when the bladder contains considerable liquid it is an advantage to have a free length of catheter in its cavity, for then the loose end takes different positions and the currents of agitated liquid take different directions.

To carry out the foregoing ideas, the writer has striven to contrive an apparatus, after many changes in design, that will give the surgeon complete command over the irrigation of the bladder, and that shall at the same time be simple in construction and operation, inexpensive, and easily cleaned.

The apparatus comprises a main and secondary reservoir with a distributing or washing apparatus. The smaller, or graduated measuring-reservoir, contains about eight ounces, and is mounted only high enough above the bladder to make the attached gauge operative. The main reservoir, which should contain a large amount of irrigant, should be at a higher level than the upper level of the smaller or measuring-reservoir, for it is convenient to be able to fill the latter from the former through simple gravity. The main reservoir is connected with the washing-apparatus proper through rubber tubing which is attached at the intake (*a*). To the bottom of the measuring-reservoir is attached by a rubber coupling a glass tube about twenty inches long, of three-sixteenths of an inch bore. This tube is to serve as a gauge upon the bladder. The lower end of this glass tube or gauge is attached by a rubber tubing to the washing-apparatus at the branch tube from the trap. This form of gauge and its attachment were adopted after using mercurial and other gauges attached to the washing-apparatus itself. The washing-apparatus proper consists of two glass bulbs with tubular glass extensions, which for controlling the circulation or distribution of the irrigant connect with properly attached rubber tubings. The flow of liquid is checked and controlled in its distribution by pinch-cocks, the glass construction being so designed as to bring these pinch-cocks under the easiest manipulation. The glass bulbs expose the charge of irrigant to convenient inspection. The larger glass bulb creates a partial dead water when the apparatus is in action, allowing clots and coarse particles, grit, etc., to fall into the trap constructed on its lower side. This trap communicates through a branched tube with a pipe leading to the sewer, and also with the gauge and measuring reservoir.

Attached to what may be called the distal end of the bulb is a common rubber bulb. This rubber bulb is the means by which the irrigant may be pumped to determined points of distribution, and also serves as an agitator to give motion to the contents of the bladder. It is an injector and aspirator, and by its suction, controlled by the hand, the bladder contents can be withdrawn with gentleness. Attached to the distal end of the rubber bulb is another and smaller glass bulb terminating in a bent short glass tube which by means of rubber tubing communicates with the sewer. This smaller glass bulb serves as a tell-tale to indicate when charging the apparatus that the unseen contents of the rubber bulb are clean. There are therefore two courses to the sewer, one through the trap and the other through the distal end of the apparatus.

The rubber coupling and small glass tube at the proximal or bladder end of the apparatus are to facilitate ready attachment to a soft-rubber catheter. It is premised that only a soft catheter of simple construction should ever be used in washing the bladder. The apparatus is brought into action by expelling its contained air and filling with the irrigant. This is done by opening pinch-cocks 2 and 5, while at the same time holding the distal end of the apparatus upward. Any imprisoned bubble of air can by appropriate handling be driven toward the sewer. The connection with the catheter should be so managed as to avoid pumping any air into the bladder. Perhaps this is best done by allowing some urine to flow through the proximal end of the apparatus down through the trap. The ingress and exit of the bladder liquid are controlled by a pinch-cock upon the catheter, or upon its rubber coupling. For the first emptying of the bladder, it is advisable that the eye of the catheter should be just within the bladder cavity. The urine in the blader is siphoned into the sewer through the trap by opening the catheter pinch-cock and cock No. 4. If any air is caught in the apparatus, it is driven out for good. The surgeon now has it in his power to introduce a definite quantity of irrigant into the bladder, it being practically empty. He will probably, however, by compression of the rubber bulb, throw some of the charge in the apparatus into the bladder and by releasing the compression withdraw it, repeating the manœuvre. He has thus stirred up any residuum, slightly cleansed the bladder, and correspondingly fouled the charge in the apparatus. He now replaces the foul charge in the apparatus by a clean one; opening pinch-cocks 2 and 4 or 2 and 5, for that purpose. The apparatus has been thus flushed from the reservoir of supply, and a new charge of pure irrigant stands ready to be shifted back and forth, in communication with the bladder and with any degree of force of agitation.

A definite amount of irrigant may be sent into the bladder by first transferring a definite amount from the main reservoir to the measuring reservoir, either by opening direct communication with the main reservoir or through the medium of the forcing rubber bulb. In the same way it may be injected into the bladder from the measuring-reservoir, either by the force of gravity, at low pressure, or by means of the rubber bulb with any degree of pressure. To operate the gauge, the liquid is drawn off from the measuring-reservoir into the sewer till its level in the gauge is near the presumed level in the bladder; then the bladder level or pressure can be exactly taken by opening the catheter and gauge pinch-cocks. Vice versa, the amount of liquid withdrawn from the bladder can be definitely known by forcing it into the measuring-reservoir before directing it into the sewer. It will be seen that some study and a little practice will be required for the surgeon to develop the full capabilities of the apparatus. In manipulating the rubber bulb, injecting and withdrawing liquid, through delicacy of touch quite a knowledge may be gained of the sensitiveness of the bladder. The patient can feel a forcible churning of contained contents and may complain of the force of the agitation. The least force necessary to clean the bladder should be used. Sometimes there is a diminishing sensitiveness as the washing proceeds and the bladder is cleansed. The sensitiveness of the bladder wall, as it is drawn by aspiration against the eye of the catheter, may be well observed. The surgeon has control over the eye of the catheter to prevent its obstruction. Perhaps the bladder wall persistently blocks the eye of the catheter; then it is easy to shift the position of the catheter eye, by allowing the partially collapsed rubber bulb to fill by opening pinch-cock No. 2, then injecting more liquid into the bladder and pushing the catheter further into its cavity. Many little features that need not be described, that will be met with in practice, can with little thought be easily dealt with.

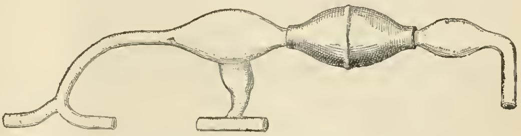

Fig. 2.—Rubber Forcing N-Bulb. Glass connections.

Having freed the bladder, while containing a small amount of liquid, of its principal impurities, a larger, definite amount of irrigant may be introduced, and by means of the rubber bulb the contents of the bladder can be kept in motion and mingled with the charge in the apparatus. By constantly renewing this charge and repeating the commingling, the bladder contents, without being materially varied in quantity, are constantly approximated in quality to the purity of the irrigant fed to the apparatus. The smaller reservoir may be used to inject a different liquid from that contained in the main reservoir, the washing-apparatus serving quite simply as a manageable means for distribution.

The washing-apparatus is thrown out of use by first emptying the smaller reservoir and gauge through the trap. The connecting rubber pipe is then detached from the lower end of the gauge. A little suction is made by opening and closing pinch-cock No. 5, at the distal end of the apparatus. The apparatus is disconnected from the catheter and is thus freed without spilling any liquid.

Finally, the apparatus is cleaned by connecting its proximal or catheter end with the hydrant and allowing a stream of hot water to course through it and the attached pipes by opening the different pinch-cocks. If desired, although to the writer it has seemed unnecessary, the apparatus may be taken apart and disinfected. It can be readily reassembled.

CERUMINOUS AND EPITHELIAL IMPACTIONS IN THE EXTERNAL AUDITORY CANAL.[1]

By SAMUEL KOHN, M.D.,
NEW YORK.

Impacted cerumen in the external ear, to the mind of the general practitioner, is a condition at once simple and benign; the diagnosis is usually made by him from the subjective symptoms alone, without recourse to local or any other examination; we cannot wonder, therefore, if, with this mistaken idea of the positive harmlessness of the affection in mind, he accords the treatment and the sequelæ scant attention. Be it understood that these prefatory remarks do not refer to otologists or to those physicians who are versed in otology; but so many cases of all forms of aural disease, and of this affection in particular, are treated, for a time at least, by the general practitioner, that it is a matter of moment to direct the attention of the profession to the great importance of aural affections in general, and of the greater importance of treating them properly in their incipiency.

No pretence to an exhaustive treatment of the subject-matter is made for this paper, its object being mainly to throw light upon conditions in the external auditory canal, whose power for ill to the organism is much underestimated. This can best be accomplished by considering the subject under the following headings: Frequency, classification, causation, dangers, symptoms, diagnosis, prognosis, treatment.

Frequency.—In ear clinics, the frequency of the affection has been shown statistically to be from ten to twelve per cent. of all cases (Roosa, Burkner). This is a large proportion, but I am convinced, from my personal experience, that in a general practice the percentage of cases is relatively even larger than this, because accumulated cerumen may for a long time cause no noticeable symptoms, and the patients do not, therefore, come under observation. The number of persons who are found upon examination to have accumulations of cerumen in one or both ears, but who consider their ears perfectly "clean," is surprisingly large; the percentage of cerumen inspissatum will in my opinion amount to fifteen per cent. of all cases of ear disease.

Classification and Causation.—The variety of aural plug most frequently met is that consisting of the more or less thoroughly inspissated secretion of the ceruminous and sebaceous glands of the integument lining the external auditory canal. It is caused either by an individual tendency to hypersecretion of the glandular elements of the skin, or by a sudden bend or narrowing in the canal obstructing the outflow or evaporation of the secretion; or both causes may be at work in the same case.

The fresh accumulation of secretion is light yellowish in color and so soft that it exercises no pressure on the surrounding tissue; even though it entirely fills the canal it usually does not markedly reduce audition. In time the watery constituents evaporate, the plug shrinks somewhat, receding from the walls of the canal and from the drum; this slight air space about the plug accounts for the absence of symptoms for a long time in many cases, as sound waves reach the drum not only through the plug itself, but outside of it, between it and the wall of the canal. This plug, seen through the speculum *in situ*, presents a light yellowish, yellowish-brown, or black oval surface, corresponding to the circumference of the canal; it is usually concave, owing to the evaporation of its watery constituents, and about one-half inch from the external meatus. If it is recent, the probe lightly applied will sink into it, but if it has been in process of formation for years, as is often the case, it may be of considerable hardness, the probe in touching it sometimes producing a perceptible sound.

When such an old ceruminous plug is removed *en masse*, as is often the case, it is at times found enclosed in a perfect epithelial cast, the lining of the external auditory canal, its inner end presenting an impression of the drum with its prominences and depressions well marked. The plug consists of fat globules, hairs, epithelial cells, detritus, and water. It may have for its nucleus some foreign body introduced years previously, which was the original cause of setting up the irritation which resulted in the hypersecretion, such as a piece of cotton, a pea, a small button, or a dead insect. The size of the plug varies; it may be 3 cm. in length, or there may be only a thin layer of dried waxy scales lying upon the drum, and so lustrous as to escape the observation of the specialist.

The second variety is the epithelial plug; it is formed principally of epithelial scales, and is due to a chronic desquamative dermatitis of the external auditory canal; the concentric layers of epithelial scales thrown off by the recurring attacks of inflammation finally form an occlusive plug, which may be dry, crumbly, and without shape, or the scales may be rolled up into round balls, or if there be an accompanying hypersecretion of the ceruminous glands permeating the epithelial lamellæ, a more or less cohesive homogeneous mass is formed. This is seen through the speculum to be of a grayish or pearly hue, usually not so smooth as the ceruminous plug, and removable with considerable difficulty.

The third variety is cholesteatoma of the external auditory canal, showing through the speculum as a pearly-gray mass. It originates most frequently in the mastoid cells, and by bone absorption works its way toward the external auditory meatus, or it may originate in the external canal and eat its way by erosion toward the mastoid. Cholesteatoma may complicate the epithelial plug, and vice versa. Absorption of the osseous portion of the auditory canal may proceed to such an extent that its enlarged lumen may permit the finger to be pushed down to the drum. Strange to say, the drum membrane is rarely injured by cholesteatomatous tumors, but bone readily yields to them; a fissure or foramen is formed, the growth finds its way through this into the mastoid, and, unless thoroughly removed by operation, the case may end fatally, through mastoid involvement and its consequences.

The fourth variety is associated with chronic suppuration of the middle ear and perforation of the drum. Appropriate treatment may have caused the disease to become quiescent for a time; the patient ceases to attend to his ear trouble. A slight perforation remains, however; a very scanty secretion, which the patient scarcely notices, starts up in time; before it reaches the external ear its watery elements have evaporated. Or it may also be that a ceruminous plug interferes with the outflow of the secretion, and a desquamative otitis externa may cause the scales to be intermixed; all of these constituents combine to form a hard, grayish, ill-smelling plug, which closes up the perforation in the drum, and which requires much care, judgment, and skill in its dislodging. It forms an admirable nest for the bacteria of putrefaction. In the case of the epithelial plug or the one just described, associated with suppuration of the middle ear, the ceruminous secretion may so predominate as to mask its real character; great care must, therefore, be exercised in the making of diagnosis and prognosis, as the removal of the mass may, if improperly performed, lead to an acute exacerbation of the inflammation of the middle ear with its unfortunate train of sequelæ.

---

[1] Read before the Metropolitan Medical Society at the meeting of Tuesday, March 27, 1900.

Causes and Dangers.—It has been claimed by Roosa that every case of impacted secretion in the external ear is due to an existing or to a pre-existing inflammation of some part of the auditory apparatus. While this view is admitted to be true in the majority of cases by most otologists, it is deemed too sweeping in attributing every case of impacted cerumen to inflammation. As has been pointed out in the classification, external desquamative otitis is the cause of the epithelial plug; or a chronic suppurative otitis with scant secretion may be the causative factor primarily.

It has been claimed that chronic pharyngitis with its accompanying derangement of the glandular secretion of the mucous membrane may, by extension, lead to catarrhal otitis media, which in turn may cause hyper-activity of the ceruminous glands resulting in the accumulation of cerumen in the external auditory canal. It has even been said that diseases of the labyrinth may cause hyper-activity of the ceruminous glands, nerve anastomoses being the supposed etiological factor.

That, as a rule, after the removal of the ceruminous plug there is not that complete restoration of hearing which the general practitioner and the patient confidently expect, is the experience of every otologist. As long ago as Toynbee's time the observation was made that in sixty per cent. of the cases of impacted cerumen there was more or less impairment of hearing after the complete removal of the plug. This corresponds with the experience of specialists to-day; whether the impairment is due to a chronic otitis media sicca, or to the long-continued pressure of the plug upon the drum, with the consequent interference with the motility of the ossicles, must be determined by the further observation of the individual case. In some cases it is impossible to decide positively which is the causative factor.

Dangers.—From what has been said, it is evident that the simple ceruminous plug, being nothing but the result of hypersecretion, is harmless to the patient; still it is well not to be too positive in venturing a prognosis; for, as stated, an old ceruminous plug may have caused a chronic dry otitis with intractable deafness. Dench observed an effusion of serum, completely filling the tympanum, in a case of impacted cerumen of twenty years' standing. The drum may be depressed to such an extent as to become adherent to the promontory, which condition naturally causes radical impairment of hearing. Epithelial plugs, either simple or associated with cholesteatoma, may cause perforation of the drum, although this is rare; these accumulations cause absorption of the osseous canal more readily; they may, through admixture with cholesteatoma, eat into the mastoid, and produce conditions requiring immediate operative interference; if not promptly and thoroughly treated they may lead to sinus thrombosis, cerebral or cerebellar abscess, or meningitis. These plugs are often associated with slow suppuration of the middle ear.

Symptoms.—A fulness in the ear may have been noticed by the patient for some time; but since the plug is often dry and shrunken, hearing is not sufficiently impaired to attract the patient's attention, sound waves still reaching the drum through the air space; as a result of a bath, either in the tub or surf, the plug absorbs water, swells up, and completely occludes the canal; the patient notices the sudden onset of deafness in one or both ears, and hurries to the physician with the idea that the sea bath has produced the hardness of hearing because of water being left in the ear, as he supposes. Other symptoms that have been noted are dizziness, due to pressure on the labyrinth through the ossicles; at times, pain due to the desquamative inflammation of the external canal, or to the middle-ear catarrh; tinnitus is oftentimes a symptom. Both auditory canals may contain plugs for years without causing any symptoms to attract the patient's attention, when a sudden jar of the body, as in jumping aboard a car, a fall, or a mis-step, may cause such a shifting of the plug as to occlude the entire canal, producing deafness which arouses the patient's anxiety. A patient may never have noticed any trouble whatever with his ears, until, after a sea bath, as I have frequently had occasion to note, he becomes suddenly deaf. Other symptoms which have been noted in rare cases are facial paralysis, melancholia, reflex cough, bronchitis. In isolated cases audition may be improved by the presence of the hard plug. In a case recorded by Roosa the brain symptoms were so marked that a diagnosis of sunstroke was made by the attending physician, who tortured the patient with blisters, etc., until the true nature of the disease was discovered. A case of convulsions and coma has been recorded by Rischawy as due to impaction.

Objective Symptoms.—The writer would here lay emphasis on the dictum that no physician should attempt to do anything locally for any case of ear disease, who is not versed in the use of the ear speculum and forehead mirror; and he would add, as a corollary, that every practising physician should familiarize himself with the use of these instruments. The practice of ordering laudanum, glycerin, sweet oil, or camphorated oil for patients who complain of ear trouble, without a careful local examination with the speculum, is so vicious and so fruitful of evil consequences as to merit the severest condemnation. By means of the speculum and head mirror, the ceruminous plug is easily recognized as a black or brownish-yellow mass completely filling the external auditory canal. The epithelial plug presents a grayish appearance consisting either of a number of detached scales or small round masses; if admixed with thin pus, the fetor is intolerable; if with cholesteatoma, it presents a lustrous, pearly-gray color. The tuning-fork applied to the forehead or teeth is heard with exaggerated loudness in the ear containing the impaction. After the removal of the plug, which frequently brings with it the epithelial lining of the canal, this and the drum are often seen to be deeply red from congestion; sometimes there are erosions from which there is slight bleeding, which at times may be considerable from granulations from old fetid, purulent inflammations of the tympanum with perforation. The older the plug, the more apt is the epithelial lining to be macerated and to come away with it.

Diagnosis.—This is the division of my subject upon which I desire to lay most stress for the benefit of the general practitioner. I want to make an urgent plea for a better knowledge of ear diseases, for a greater familiarity with the proper modes of examination, and familiarity with the simple methods of treatment which are, after all, most efficient. It seems almost supererogatory to say that the ear speculum and the forehead mirror are absolutely necessary to make a diagnosis; but we are only too familiar with the laxity prevailing among many practitioners when brought in contact with ear diseases; without a proper examination they hazard treatment which, not being based on even a partial knowledge of the cause or nature of the affection, results in making matters worse; and frequently the specialist is called upon to repair the mischief, in addition to the getting rid of the original disease.

A patient who complains of deafness coming on suddenly, fulness in the ear, dizziness, perhaps of autophony, who hears the tuning-fork applied to the middle of the forehead more markedly on the deaf side than on the normal, has in all probability an occluding plug in the external auditory meatus; the speculum will reveal it. In some cases the plug is so near the external meatus that it is visible without the aid of the speculum.

Prognosis.—From what has been said, it is evident that the prognosis as to audition should be guarded. The general practitioner, having made the correct diagnosis, is prone to tell his patient that the function of hearing will be completely restored with the removal of the plug. As stated, this is true of only a small percentage of cases, from thirty to forty per cent. Even in cases of simple ceruminous accumulation of long standing, hearing will be found markedly lessened on account of the prolonged pressure of the plug upon the drum and ossicles, and through these upon the delicate labyrinthine structures.

In an epithelial or cholesteatomatous plug, seemingly harmless, it should be borne in mind that an old purulent otitis media or a cholesteatoma of the mastoid may lurk behind it, markedly lowering the function of audition if not abolishing it entirely; not only this, but the forcible or improper removal of the plug may light up a train of grave symptoms, which hitherto had been kept quiescent by the plug *in situ*, through its acting as a bar to fresh infection. With the improper removal of the accumulation, the perforative otitis is laid bare, and an infection may occur which will result in serious consequences.

Treatment.—Even among authorities opinions differ as to the proper method of removal of these accumulations. The consensus of opinion is that gentle and careful syringing with warm water, all things considered, is the best method. Peroxide of hydrogen, more or less diluted, and neutralized with sodium bicarbonate, or pure, is used by many physicians; to the writer, pure sterilized water is preferable, for the reasons, first, that whatever matter may have occluded the canal emerges unchanged with the water, thus aiding the diagnosis materially; and second, that the delicate and sensitive epithelial structures of the auditory apparatus are unduly irritated by the peroxide.

Buck prefers the small curette, forceps, and probe, in the hands of the otologist throughly conversant with the auditory apparatus, and cognizant of the danger of wounding or injuring the delicate structure of the ear with steel instruments. This method of removal through the speculum and under ocular inspection is safe in skilful hands, though damage may be done by instruments in the most practised hands by involuntary starts or movements of the patient's head, the integument being lacerated and a new source of infection opened up.

For syringing the ear, the first requisite is absolute cleanliness. A glass and-metal syringe, if possible, which can be thoroughly disinfected and which holds two or three ounces, having three rings, one for the thumb and one each for the second and third fingers, should be used. The water should be of a temperature easily borne by the back of the hand, say about 80° F. About a pint of water unmixed with anything else should be used, although corrosive sublimate 1 : 5,000, physiological salt solution, and bicarbonate of sodium one per cent., have been recommended; I give the preference to lukewarm water which has been boiled. A sterilizable syringe is to be preferred; this can be purchased of any instrument maker. The latest in this line, from Germany, is Professor Jacobson's "aseptische Ballon-Ohrenspritze," consisting of a rubber ball with ivory or bone nozzle encased in a removable glass tube; the entire syringe is to be boiled for from five to ten minutes before use.

The second requisite is gentleness of manipulation. Any undue force must not be used in expelling the water from the syringe into the ear. The reason for these warnings is manifest from what has been said. If an old syringe which has been lying about, exposed to dust, is used, and the case be one of otitis media with small perforation, masked by the plug, a new infection may be introduced by the syringe which will set up a violent inflammation; or, if too much force be applied, the stream may force its way into the middle ear through the perforation, and drive the cholesteatomatous particles or inflammatory products into the mastoid cells or antrum, setting up mastoid disease. Too much force in using the syringe also may cause, by sudden pressure upon the drum, transmitted through the ossicles, circulatory changes in the semicircular canals, producing extreme dizziness and syncope; even the cerebral centres may be temporarily affected in this way.

After removal of the occlusion, continued syringing should be done with caution, as the danger of causing labyrinthine dizziness is increased. Too forceful a jet of water communicated through the plug to the drum, and thence through the ossicular chain to the membrana tympani secundaria, causes increased intralabyrinthine pressure, whence such dizziness may ensue as to compel a cessation of the syringing process. It is frequently the case in old, dry masses that four, five, even six syringefuls of water make scarcely any impression; in such a case the hard mass must be softened, in order to be more readily removable; for this purpose a saturated solution of bicarbonate of sodium, or a two-per-cent. solution of carbonate of potassium in equal parts of glycerin and water, may be dropped into the ear three or four times a day. The drops should be warm. From five to ten drops should be instilled into the ear, and these should be allowed to remain *in situ* for about three minutes, when they may be allowed to flow out. Two days' treatment of this character will so soften the plug that its removal by gentle syringing with warm water is a matter of the greatest ease, the first syringeful frequently dislodging the whole plug, especially if it be entirely ceruminous. Epithelial plugs, as already stated, even after softening need care, time, and patience for their removal. They frequently require several sittings for their thorough removal and the complete cleansing of the external canal of all scales and detritus. The amount of force in using the syringe must be graduated according to the needs of each case. Skill in the use of the ear syringe is acquired only by long practice. The rule is to commence the ear syringing by gently forcing the piston home so as to send the jet of water into the ear under the minimum of pressure. The next may be a trifle more forcible, gradually increasing the force but never sending a powerful stream of water against the delicate mechanism of the auditory apparatus, with its intimate relationships to the brain. Another rule worth remembering is that these cases should be, if possible, attended to at once when they present themselves for treatment. A patient should not be sent home with instructions to syringe the ear himself, or use certain drops. As soon as the diagnosis is made, the physician himself should attempt to remove the plug either by syringing or otherwise (Dench). If the syringing seems insufficient after a few syringefuls have been injected, it will be wise to follow the advice of Blake and remove portions of the periphery of the plug by means of a small curette; the water can then pass through the opening thus created to the space between the drum and plug, and force the latter outward.

Roosa relates a case in which the plug was so hard that he was forced to have recourse to fuming nitric acid to soften it. In such old, hard masses, Blake advises the use of liquor potassæ for the purpose of softening. It should be mentioned that some authorities are opposed to syringing altogether, and advocate the use of the curette and probe.[1] In the case of epithelial plugs, it is well to use a bichloride of mercury solution 1 : 5,000 for syringing. The rules of asepsis should be observed in every case as thoroughly as possible. The use of olive oil in the ear should be absolutely discountenanced, as it favors the growth of the aspergillus fungus in the accumulation.

After the contents of the canal have been removed, it is well to inflate the tympanum with a Politzer bag because of the possible depression of the drum from the plug. A small, loose wad of cotton should be placed in the canal, to protect the sensitive and oftentimes denuded integument of the canal from the cold air and dust.

The tendency to recurrence is one of the characteristics of ceruminous accumulation; it is attributable to the hyperactivity of the secretory glands, which has not been in the least affected by the removal of the impaction. The same patient frequently returns after several months for the purpose of having his ears syringed. To prevent this, it is advisable to instruct the patient to wash out his ears thoroughly with a mild alkaline solution (ʒ i. of aqua ammoniæ to the quart of warm water, and castile soap) once every week. The ordinary tub bath, which the patient considers efficacious, has, in my experience, no effect whatever in removing the accumulation of wax in the ear.

In closing this paper the writer again would urge upon the general practitioner the necessity and desirability of some knowledge of otology, the more the better for him. So many cases of incipient ear disease are, of necessity, first seen by the family physician immediately after measles, scarlatina, and diphtheria, etc., and the consequences of even the simplest ear disease, if improperly treated, are so lamentable, that a better knowledge of this branch of medicine in the profession must save many lives. The organ of hearing, besides being of incalculable importance to the individual, stands in intimate relation with the brain and nerve centres; improper, injudicious, or careless treatment at the outset of affections of this organ may, as has been shown, result in fatal disease of the sinuses and brain. It seems almost incomprehensible to the writer why this important organ is accorded such scant attention by the general profession, and if he has succeeded, in this paper, in awakening a new interest in diseases of the ear, his object will have been accomplished.

Women as Surgeons.—An interesting speech was made at the annual meeting of the new Hospital for Women, London—of which all the physicians, surgeons, and students are women—by the eminent surgeon Sir Henry Smith. He stated that he had lately been present at a number of most serious operations performed by the lady surgeons, and had come to the conclusion that the small hands and delicate touch of women were particularly suitable for surgical work. The same tactile skill that makes a good needlewoman, he intimated, is of the highest use in modern "conservative" surgery; and he added that the results gained in that hospital would compare favorably with those recorded anywhere else.—*London News.*

DAMPNESS OF THE SOIL AS A FACTOR IN THE PRODUCTION OF HUMAN TUBERCULOSIS.[1]

By RICHARD COLE NEWTON, M.D.,

MONTCLAIR, N. J.

If an apology be needed for taking up the time of the association with the histories of a few cases of tuberculosis and an imperfect and crude discussion of the points which the cases seem to emphasize, I think that the importance of the subject chosen will provide the excuse. I will first recite a few family histories which have come under my observation.

The D—— family, Germans of vigorous stock. No cases of phthisis have been known to occur among the ancestors of this family for generations. The father, a farmer, died of some non-tuberculous trouble at a good old age. The mother is living, over seventy, and in good health. They had twelve children. The first-born, a son, is now living and in good health. When he was one year old, the family moved into a small stone house, now standing, which was exceedingly damp. Eleven children were born in this house, in the eleven years during which the family lived there. Then they moved into another house, which they had built on the same premises. It was built of wood, was much less damp than the first one, but had too many shade-trees around it. The second child, a female, died of consumption, "following grippe," at thirty-nine. The third child, male, died at thirty-seven of apoplexy. The fourth child, male, died at forty of consumption "following grippe." The fifth child, female, had consumption, for which she went into Sullivan County, New York State. This change of residence, she says, saved her life. She has lost a child from tuberculosis and is herself still suffering from chronic bronchitis. The sixth child, female, died at twenty-six of pneumonia. The seventh child, female, died at twenty-seven of consumption "following grippe." The eighth child, a male, is living and in good health at thirty-six. The ninth child, a male, is living and in good health at thirty-four. The tenth child, a male, is living and in good health at thirty-two. The eleventh child, a female, died in childbed. She had a diarrhœa for four weeks after the baby came, and had had a cough. She is not known to have had lung trouble. The twelfth child, male, died at eighteen of dropsy. He had no cough. He was said to have fallen and "bruised his liver."

C—— family, Irish laborers and carpenters, lived in a damp house. Their kitchen was in the basement and there the family lived a great part of the time. The children were frequently seen lying in their cradles in the basement. There was no phthisis so far as known among ancestors. The father and his sister and mother's sister are now living. The mother died of heart disease. They had twelve children, all of whom except two died of consumption.

H—— family, Irish laborers. The father is living; the mother died of some disease not tuberculous. Their house was built for them thirty years ago. They had three children living when they moved into it. The place was very damp. The fourth child was born there. In about twenty years the oldest daughter died of phthisis at the age of twenty-two. Seven years ago the son, a printer, died of phthisis at the age of thirty-one. In the year 1900 the youngest daughter died of phthisis at the age of twenty-seven. One daughter, now living, has a sensitive throat and abnormally red cheeks.

B—— family, American. They explicitly deny all traces of phthisis among their known ancestors.

---

[1] Read before the American Climatological Association at the fifth triennial session of the Congress of American Physicians and Surgeons, held at Washington, D. C., May 1, 2, and 3, 1900.

The eldest daughter complained of cough, indigestion, nervousness, etc. She got well after going into central New York to live. The second daughter, a teacher, has advanced tuberculosis, and is now in Colorado Springs under the care of Dr. Hart. The eldest son is anæmic and very "nervous." The younger son is delicate, slender, and pale. The house has been very damp. Now the surroundings have been improved by drainage.

These are all cases that have fallen under my personal observation. I dare say that by taking the experience of others the list might be indefinitely extended.

However, there have been enough cases cited to serve as a text for what I wish to say. I have long felt, as no doubt many other observers have, that something besides direct contagion by the reception of the tubercle bacilli into the body is necessary to establish the morbid process which we know as phthisis pulmonalis.

Jaccoud says:[1] "The tubercle bacillus belongs to a class of pathogenic microbes called 'etiological dualisms,' because they exist in healthy organisms indefinitely without injury to the latter and become noxious only in consequence of changes in the organism itself from other causes." If this be so, the bacillus of Koch acts as we know that the Klebs-Loeffler bacillus, the pneumococcus, and the streptococcus act. That is to say, it may be present in the human body and produce no overt symptoms. And it is reasonable to suppose that we are exposed over and over again to this infection. Perhaps our bodies never are free from the presence of the tubercle bacilli, and yet only ten or twelve per cent. of the inhabitants of the Atlantic seaboard die of consumption. Why does not the entire race perish from this disease? It may be said that the contagion is rather feeble and takes a long time to develop, and that the organism must be in a fit state to receive and nourish the germs, else they will not grow.

It is so easy to glide off into glittering generalities and to hide our ignorance under some half-statement, or the plausible conjecture of some writer. It is a fortunate thing that we have at last adopted more exact methods of studying disease. Still, with all the care that has been bestowed upon the study of tuberculosis there is still very much that requires elucidation.

Squire[2] and Kanthack[3] assert that some other influence or influences must be acting in conjunction with the bacillus before the latter can produce consumption in human beings. This being so, the latter argues: "It is likely in practice to be far easier to remove the conditions causing this predisposition than to eradicate the bacillus so long as fitting conditions for its development are left. The problem then is no longer a matter of isolation and antiseptics, but of improved surroundings and better conditions of life." He mentions in this connection the divergent conditions regarding the behavior of certain animals to anthrax infection; as, for example, "pigeons, which are usually resistant to anthrax, are rendered susceptible by starvation, and dogs, horses, pigeons, and frogs are made susceptible by being deprived of water. So a predisposition may be established in some animals by continued over-exertion, fatigue, loss of blood, and by unsuitable diet. Guinea-pigs and white mice, which are ordinarily resistant to avian tuberculosis, can easily be infected after being kept for a time in a warm chamber at 33°–35° C." Precisely what changes are produced in the animals by these disturbances of their ordinary mode of life we do not know; we only know that whereas before we interfered the animal was insusceptible to the action of these various pathogenetic germs, afterward it was easily infected. The war against tuberculosis then becomes a matter of sanitation rather than of disinfection and isolation, against the surroundings of the people rather than against a microbe, which can grow only when a predisposition is set up.

On the other hand, we have long known that under certain conditions the bacillus of Koch does little harm to the animal into which it may be injected. You will all remember Dr. Trudeau's rabbits. All of those which had been injected with the tubercle bacilli and allowed to run at large got well, while all of those which were closely confined after inoculation died of tuberculosis. Perhaps one of the most conclusive experiments recently tried is reported from the Storrs Agricultural College in Connecticut.[1] Four cows were subjected to the tuberculin test in March, 1896 and did not respond. In October, 1896, they were again tested and all responded. They were then placed in a light, airy stable, where it is estimated that each animal had fifteen hundred cubic feet of air space. In January, 1897, another test was made and all responded, but in April, 1897, after a test, only two responded, and in July of that year none of them responded. For two years their milk was fed to eight healthy calves, only one of which contracted the disease, and that calf showed evidence of tuberculosis only six months after it had ceased drinking the experimental milk, so that the tuberculous infection was probably due to some other cause.

Admitting, then, that the infection is wellnigh universal, and that it cannot become effective except under certain conditions, is it not our obvious duty to pay more attention to these conditions?

The whole trend of present scientific opinion is to minimize, if not to deny, the danger of tuberculous infection from cow's milk. The discovery of the timothy-hay bacillus and its resemblance to the tubercle bacillus has cleared up some of the threatened danger from the alleged discovery of the latter bacilli in milk, butter, etc., the bacilli so discovered really being the timothy-hay bacilli. Baldwin,[2] Guthrie,[3] Carr and Northrup,[4] Bouviard, Still,[5] Moore,[6] and others are disposed to deny that the mode of infection by the bacillus is through cow's milk or other food. On the other hand, Law,[6] Smith,[6] Park, Robison, and others believe that while there may be danger from infected milk it is small compared to the danger from human infection. And human infection itself is doubtless, as a general thing, comparatively weak. I will quote a few examples. Knopf[7] shows that the villages of Goerbersdorf and Falkenstein have had fewer deaths from consumption since the sanatoria were established there than before. W. S. Searle[8] says that twenty-two hundred and eighty-six patients have been treated in the Brooklyn Home for Consumptives during fifteen years. The number of employees besides the staff is at present twenty-one. Of these three nurses have been employed over three years. In not one of these employees has consumption developed. Solly[9] says that in spite of every neglect of hygiene and cleanliness in the poorer lodging-houses at Colorado Springs not over one case a year of tuberculosis originates there.

Da Costa[1] had traced the histories of the doctors and nurses in the Pennsylvania Hospital for a period of seventy years without finding a case of phthisis transmitted by contagion. In a discussion before the Glasgow Medico-Chirurgical Society Dr. Alexander Robertson and Mr. H. L. Clark,[2] one from his long experience in the town hospital and the other from his experience of surgical tuberculosis in the wards of the Royal Infirmary, stated that no case of infection among patients or attendants had come under their observation.

I think that we must agree with Professor N. S. Davis,[3] who says that if the bacillus of tuberculosis had been as infectious as that of variola and rubeola the human race would long ago have become extinct. If, then, we have a feeble contagious element, which is apparently inoperative except under certain conditions, are we not neglecting our duty if we do not more fully investigate the entire surroundings, including the conditions of the soil in those localities in which the disease is rife?

As has been from time to time pointed out, the disease flourishes in some quarters of a town or settlement, and will not flourish in others. Flick[4] showed that for twenty-five years (1863–87) all the deaths from tuberculosis in the fifth ward of Philadelphia occurred in less than one-third of the houses. The famous communication of Dr. Bowditch to the Massachusetts Medical Society in 1862 proved beyond question the influence of the soil in the propagation of phthisis. The varying prevalence of the disease in certain localities he attributed chiefly to the dampness or dryness of the soil, and modern criticism has not been able to refute this conclusion. So, also, the fearful mortality from consumption in the German prisons has been shown by Baer and Cornet[5] to be due in part, at least, to the damp and unsanitary buildings. And Buchanan's[6] observations in England scarcely need comment, in which, for example, he showed that the general death rate for Salisbury had been reduced nine per cent. by drainage, while that from phthisis had been reduced forty-nine per cent., and in other localities the reduction of the death rate from tuberculosis was nearly as startling. Professor Welch[7] says: "Although the nature of the relationship between the conditions of the soil and the presence of tuberculosis is not well understood, practical experience has shown that many localities have secured by good drainage great reduction from the mortality from this most deadly scourge of the human race, a reduction amounting in some places to nearly fifty per cent. of the former death rate."

I may have taken up too much time in endeavoring to prove what few will attempt to confute. But the great importance of the subject and the extreme desirability of drawing the attention of the profession and of the laity away from the contemplation of direct contagion by the bacilli and of the contagiousness of milk and meat as the only dangers to be guarded against, must be my excuse. Buller,[8] Unterberger,[9] and Revillod[10] point out that tuberculosis originates in certain areas in much the same fashion as other infectious diseases. It has, however, this difference: one class of people in a community will suffer from it and another will not. And people will contract the disease by a change in their habits or occupation, as, for example, "the percentage of Indian boys and girls that develop tuberculosis after giving up their out-of-door lives for the school-room is enormous. . . . Tuberculosis in all of its manifestations has increased among the Mexicans in the same ratio as among the Indians."[1]

So also at present the American negro, at one time considered immune, suffers severely from this disease.

Dr. J. H. Girdner informs us[2] that in tuberculosis it is change rather than a particular climate that does good. He had spent the first twenty years of his life near Asheville, N. C., and could assert positively that the percentage of tuberculosis among the inhabitants of that region was fully as great as on Manhattan Island. His father, who had practised medicine in that region, was accustomed to send his tuberculous patients away from home to the seaside. Cases of tuberculosis in the Adirondacks are by no means rare among the natives, where poor food and unhygienic surroundings counteract the beneficial influence of the fine climate.

As Dr. Samuel West has wisely observed,[3] it should be remembered that no climate is proof against the emanations of a filthy soil either in city or country. And Dr. Robert Barnes, who as long ago as 1855 was a health official for a part of London, wrote graphically of the dangerous properties of the superficial soil of cities, "the investigation of which," he asserted, "would solve some of the mysteries of high civic mortalities. After solving the problems of the water supply, the problems of the soil will become urgent, and as they, too, are solved, life-saving will begin in good earnest." After speaking of the so-called "pest stratum," that is, surface soil made up mainly of refuse, organic matter, excreta, etc., he says: "If this 'pest stratum' could be kept dry, laden as it is with putrescent matter, it would be comparatively harmless. Moisture is a necessary element for the evolution of its pestiferous properties."

That disease is not engendered by a residence on the water itself is rendered very probable by the following facts (I still quote Dr. Barnes): "The population actually living on the Thames, whose every breath is a distillation from its water, is not especially liable to fever, not so much so indeed as the population whose dwellings skirt the banks." Solly says:[4] "Apparently humidity of the air apart from other factors does not in itself produce phthisis. The comparative immunity from consumption among the men of the British navy contrasted with those of the army, and the rarity of the disease in many islands, such as the Faroe, the Hebrides, the Shetlands, and Iceland, show this."

Referring back to the history of the D—— family, with which this paper began, we see that the second, fourth, seventh, and probably the eleventh and twelfth children died of tuberculosis. The fifth contracted the disease and probably still has it. All of those who escaped were males, and were, of course, less in the house than their sisters. The oldest one was not born in the infected house, and the younger ones lived in it a very short time. They were all exposed to the same contagion and all lived under the same conditions. It seems to me that it is more reasonable to impute the high mortality of this family to the unsanitary condition of their residence than to any other cause. In other words, I think that the damp and polluted soil over which they dwelt supplied the necessary factors to make the inroads of the tubercle bacilli upon their bodies efficient. In the case of the B—— family I think it more reasonable to impute the consumption that attacked Miss M—— to her place of residence than to any other cause, and especially will this seem to be true if, after the improved drainage of the house, the other children shall escape tuberculosis, particularly as they have been more or less exposed to infection from their sister.

Not to take up more time, I feel thoroughly convinced that I have proved my case, and that we had better, instead of expecting to annihilate the tubercle bacillus, turn our attention to altering the surroundings of our patients and correcting their vicious methods of life. We must agree with the editor of the MEDICAL RECORD,[1] who says: "The causes of the health-giving properties of a change of air are obscure; at any rate up to the present time they have not been explained." No doubt frequently all that is needed to arrest phthisis is that the vicious combination of a damp and polluted soil, and want of sunlight and ventilation, together with poor food and perhaps an unwholesome occupation should be broken up by the withdrawal of one or more factors. The results of sanatorium treatment have so far been practically identical, so that while a life in Colorado is desirable, it is not necessary to save at least a third of our incipient cases of phthisis. And while sunlight and life in the open air, and pure milk and a wholesome occupation are necessary and essential, a dry, properly constructed cellar to one's dwelling, which should be built over a pure, well-drained, sandy subsoil, is just as essential to the alteration of the predisposition so that the bacillus of Koch cannot gain a foothold in the human organism, as any of the means named. And it is our duty to insist upon this point over and over again, until our patients shall cease to worry about milk and meat, and while not neglecting to burn tuberculous sputa, they shall insist in living over properly constructed cellars and away from swamps, cesspools, sluggish streams, and all stagnant and unwholesome bodies of water.

Colonel Wingate's remarks on this head are to my mind quite applicable, and I don't know that I can close this paper more fitly than by quoting them. He says:[2] "I am inclined to think that the health of the community is more affected by the sanitary state of the soil than by all other influences. If Manhattan Island could be thoroughly drained, consumption would undoubtedly diminish."

A Large Dermoid Cyst of the Ovary in a Child of Seven Years.—James Herbert McKee reports a case from the history of which he draws the following conclusions: (1) In attempting to make a diagnosis of an abdominal tumor in a female infant or child, one should bear in mind that ovarian tumors must be considered as possibilities. (2) As aids to diagnosis, rectal examination under anæsthesia, as recommended by Carpenter or Kelly, should be performed as a routine measure; and whenever possible, the services of the *x*-ray should be enlisted. (3) An exploratory incision is not only a justifiable procedure, but it is to be advised whenever a large tumor of the abdomen is found in a child.—*University Medical Magazine*, April, 1900.

The Relation of Eye-Strain to Epilepsy, Insanity, and Allied Conditions.—T. E. Satterthwaite relates a series of cases bearing on this subject, and makes an earnest plea for the addition of an eye specialist to the staffs of institutions devoted to the care of nervous patients. Eye-strain is a frequent cause of various neuroses, and its relief will often afford a cure when medication, rest cure, travel, and other means have utterly failed. Whenever an excess of nervous expenditure is made by one organ over the normal amount which should be furnished, this excess must be at the expense of other organs, which in consequence must suffer sooner or later.—*Medical Age*, April 25, 1900.

Indigestion.—T. Lauder Brunton lays down the following rules for the treatment of chronic functional dyspepsia: The first rule is to eat slowly, masticate thoroughly, and insalivate completely, three things which are by no means always the same. The next rule is to take solids and liquids separately, the latter in the shape of hot water on rising in the morning, between eleven and twelve in the forenoon, about four or five in the afternoon, and at night before going to bed. When these rules do not suffice to remove the dyspepsia, the patient must take his farinaceous and proteid foods at different meals alternately, a farinaceous meal at breakfast time and again at five o'clock, and meat or fish meals at midday and at eight o'clock. In some cases it will be found advantageous to supplement the gastric juice with a little acid and pepsin. A little alkali with calumba may be given before meals, or if there is gastric catarrh some substance containing tannin, such as infusion of gentian, may be preferable. In cases with flabby tongue, perchloride of iron with quassia will probably be of more service. When there is gastric dilatation which will not yield to the measures above mentioned, it may be necessary to wash out the stomach in the morning or at night.—*The Clinical Journal*, April 25, 1900.

The Alleghanies for Our Tuberculous.—Under this title Charles F. Spangler enters a plea for a trial of the Alleghany Mountains in the climatic treatment of tuberculosis. All that portion of the Alleghanies extending through the middle west and northern section of Pennsylvania is suitable, but the section that offers the most natural advantages for the tuberculous is the summit region comprising the vast plateau extending northward through McKean County into the State of New York, with an average elevation of two thousand feet. Kane, in the southern end of the county, is the gateway to this region, which has been appropriately termed the health belt of the State, and has been frequented for many years by asthmatic and hay-fever subjects, an occasional consumptive, convalescents, and many others suffering from general debility. The soil, for the most part, is sandy and porous; the surface is undulating and moderately well covered with timber.—*Pennsylvania Medical Journal*, April, 1900.

On Heredity in Disease.—J. Hamilton gives the following conclusions to his article: (1) There is no evidence proving that diseased conditions of body, excited by external agencies, using the term in its broadest sense, can be transmitted hereditarily through generations; (2) that the various hereditary tendencies or predispositions to disease of the hereditary type have arisen as variations in the germ-plasm; (3) that these predispositions to disease probably extend far back into the history of the human race, and break out only occasionally, in accordance with the laws of atavism; (4) that external agencies are merely the means of bringing them to light; (5) that there is little if any reliance to be placed in the evidence bearing upon the influence of maternal impressions; (6) that there is no reason to believe that telegony may not prevail in the case of hereditary predisposition to disease, as it evidently does in regard to other characteristics.—*The Scottish Medical and Surgical Journal*, April, 1900.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, June 23, 1900.

MANILA FROM A HEALTH STANDPOINT.

WIDELY conflicting views are held in this country as to the healthfulness or otherwise of Manila and of the Philippines generally. By many, perhaps by the majority of Americans, the belief is current that the island of Luzon is a hotbed of malignant fevers, and that it is indeed a veritable death-trap for white men. This is undoubtedly a pessimistic manner of regarding the situation, which is not borne out by facts. The diseases that flourish in Manila and in the Philippines are either those which are almost entirely confined to the natives or prevail owing to the lack of prophylactic and sanitary precautions. It is undeniable that Manila is under the existing conditions an unhealthy town, but not more so than any other town in the tropics over which the Spanish had held sway for generations. For instance, both Havana and Santiago were at the time of the outbreak of the Spanish-American war in quite as bad a sanitary state as Manila is at the present time. Mr. George Becker, writing in the June number of *Scribner's Magazine* concerning the Philippines and speaking of the climate of Manila, says:

"It is almost identical with that of San Juan de Puerto Rico, and is comparable with that of the Gulf States during the warmer portion of the year. The climate, too, is equable. The mean temperature of the year is 79° F. The coolest month is February; the mean temperature is 76° F. The hot season at Manila includes March, April, and May, the last being the hottest month. May has an average temperature of between 85° and 86° F. The sun is far less trying than in British India. The rainy season lasts from June to November. The total rainfall at Manila during the drier months is about ten inches, and during the wet season sixty-seven inches. Although a swampy country, there is comparatively little malaria. The census of Manila has recently been taken, and discloses the fact that its population has been greatly overestimated. Former censuses and estimates have given the city a population of 300,000. The new census, which has been carefully conducted, gives a population of 190,714, of whom 30,000 are Chinamen. This numbering does not include several villages within the city limits nor the Americans and Europeans and priests in the monasteries, which will add about 50,000 more to the previous total. The death rate is calculated at over forty per cent. Some of the causes of death were: Beri-beri, 570; tuberculosis, 385; bronchitis, 314; dysentery, 229; fevers, 287. Three diseases are now epidemic in Manila, bubonic plague, beri-beri, and smallpox. The latter and leprosy are always present to a greater or less extent. So far as beri-beri is concerned, being a malady resulting entirely from diet, it is in no wise feared by members of the white race. The prevalence of smallpox among the natives is due to lack of efficient vaccination; and lastly the bubonic plague, which has invaded Manila on a somewhat extended scale, is doubtless chiefly owing to the filthy habits of the native and Chinese population. There have, it is true, been several cases of smallpox, some of which have resulted fatally among the American troops, but there has been nothing resembling a widespread epidemic, which, considering the risk of infection to which the soldiers have been necessarily exposed, speaks volumes for vaccination as a safeguard against the disease. With regard to the bubonic plague, as in India and throughout the far East, the authorities in their endeavors to stamp out the pest have not only to contend with the unsanitary condition of the districts inhabited by the natives and Chinese. but also with superstition and misguided religious sentiments. Every person dying of plague should be cremated, but it is found impossible to carry out this measure, as any attempt at compulsion would result in concealment of cases and possibly in serious riots. The rainy season, it is hoped, will wash away the plague, and even if it does not have that effect the surgeons in Manila have no fear that they will be unable to control its ravages, considering that it is an easier disease to deal with than is yellow fever. The statement may then be made that for a tropical country Luzon is not peculiarly unhealthy, and that Manila is not so bad in this respect as it has been painted. The truth should not be lost sight of, that as yet comparatively little has been done toward improving Manila from a hygienic point of view, partly because the requisite funds have not been forthcoming and partly because the military authorities have been compelled to concentrate their energies upon crushing the rebellion. The city has no sewers; a few houses drain into the waterways, but as a rule cesspools under the courtyards or streets are loaded with the accumulated filth of years. When the war is ended sanitary engineers will be able to devote their attention to rendering Manila a clean city, and there would seem to be no reason to doubt that methods tending to this end will be as successful as in the case of Havana and Santiago."

TRAINING NATIVES IN MEDICINE.

THE policy of expansion to which this country has now committed itself will, as a matter of course, bring in its wake many responsibilities. The acquisition of territory situated in the tropics will necessitate the teaching in our medical schools of all that is known concerning the diseases common to those climes and of the best manner in which to treat their victims. It is also to be hoped that, following the example of Great Britain, the government of the United States may see fit to recognize the advisability of establishing schools of tropical medicine, by means of which investigations may be conducted with the object of discovering the origin and cause of several of the maladies peculiar to dwellers in the torrid zone, in regard to which our knowledge is lamentably defective and vague. Much missionary work, too, will be undertaken in our new possessions, and the missionary of to-day is required to possess a competent acquaintance with the healing-art, so as to be able to administer to the body as well as to the soul diseased. Unfortunately the supply of medical missionaries is not equal to the demand, and as representatives of this praiseworthy class of men are to be found in every part of the world, native help must be relied on in order to enable them to perform their arduous labors efficiently. Consequently the training of natives in medicine is one of the most important duties of the medical missionary.

The proposal has lately been made, both here and in Great Britain, that a larger number of natives than will be needed for the medical work of the mission should be educated with the view that they should practise independently among people of their own race. Dr. Albert P. Peck, dean of the medical department of North China College, recently read a paper in New York on the above subject, and referring to this question said: "The peculiar conditions of the various countries where our interests lie will determine largely our attitude. But broadly speaking, if we recognize and admit the value of the medical profession as a social factor in our own civilization, we shall be ready to see the importance of such an element in the infusion of a new life into the effete civilization of the East. When the medical missionary, as a pioneer of a new civilization, can come in touch with the old order so as to give to the adult generation of practitioners even a little empirical instruction, it will be time and labor well spent." Dr. Peck is, however, of the opinion that it is upon the members of the younger generation that the hopes of the future rest, and therefore advises that the native youth should be educated in medicine after a sound preliminary general education, and concludes as follows: "The average intelligence of such communities as, for instance, we have in China is not very high. They cannot follow very advanced hygienic teaching, nor appreciate the most scientific practice. A plain, practical and somewhat empirical education is the best for an undeveloped state of society, teaching the best uses of the imperfect equipment, the rude surroundings which they must have." Dr. Peck's recommendation is rather for what we would now call an old-fashioned education for our native medical students.

The points to be discussed, before passing an opinion, is as to whether the idea, if capable of realization, is a rational one; whether it would be for the benefit of the natives themselves to have doctors of their race who have received a thorough medical training on modern lines, and again whether it would be to the advantage of the dominant race. *Health*, an English journal, thinks that the plan is both desirable and feasible, and argues thus:

"If the natives by their own sons are made acquainted with the ravages of diseases peculiar to their own race or special district, if they are further taught that many of them are curable and others are preventable, we are sure that common sense, which some of these people possess to a large extent, will induce them to use the precautions which study of medicine has discovered to be useful and which can be best taught by those who have passed a medical curriculum."

With all due deference to the views of the writer in *Health*, and while freely admitting that it is possible, nay, in a high degree probable, if such a plan could be carried out, the natives would greatly benefit by it, yet at the same time we are rather inclined to agree with Dr. Peck, and to imagine that the time is scarcely ripe for so radical an innovation. Of one thing, however, there can be no doubt—that much more attention should be paid to the study of tropical diseases in this country than is at present the case. In fact, it may be asserted without much fear of contradiction that the knowledge of some certain tropical diseases possessed by the average medical graduate from American schools would not warrant him in posing as an instructor in these matters. At present it may be said that the training given to natives in medical missionary colleges is sufficient for the purpose.

News of the Week.

International Medical Conferences at Paris.—There has been organized at the International Hospital, 95 Boulevard Arago, Paris, a system whereby all French and foreign physicians may hold clinics, lectures, and scientific demonstrations without cost to themselves. The idea which has led to the establishment of this service of conferences is that, owing to the great number of international congresses to be held in Paris, the attendance of medical men will be very large. Many of these will have demonstrations to make for which there will be little or no time in the section meetings, and it is for the accommodation of such that the extra service has been organized. Those desiring to avail themselves of this are requested to communicate with the organizer of the conferences, Dr. S. Bernheim, No. 9 Rue Rougemont, Paris.

The Association of American Medical Colleges.—At the annual meeting of this association, held at Atlantic City, June 4th and 5th, fifty-six colleges were represented. Amendments to the constitution excluding "sun-down" medical colleges were adopted, to take effect in July, 1901. Officers were elected as follows: *President*, Dr. Albert R. Baker, of Cleveland; *First Vice-President*, Dr. Thomas H. Hawkins, of Denver; *Second Vice-President*, Dr. W. H. Earles, of Milwaukee. Drs. Parks Ritchie, W. W. Keen, and J. M. Dodson were added to the judicial council. The Cooper Medical College of San Francisco, the Medical Department of the University of Kansas, and the American Medical Missionary College of Chicago were elected to membership. A committee was appointed at the request of the federation of State examining-boards to co-operate with a similar committee appointed by them, to consider common interests. This committee consisted of Drs. W. J. Holland, Dudley S. Reynolds, W. E. Quine, W. J. Means, and Parks Ritchie. The papers and proceedings of the Association are published in the *Bulletin of the American Academy of Medicine.*

The New York County Medical Association.—At a meeting of this association on Monday of this week, the following officers were elected: *President*, Dr. Parker Syms; *First Vice-President*, Dr. J. Riddle Goffe; *Second Vice-President*, Dr. Emil Mayer; *Recording Secretary*, Dr. Ogden C. Ludlow; *Corresponding Secretary*, Dr. J. W. Draper Maury; *Treasurer*, Dr. Charles E. Denison.

The Harlem Medical Association.—At a meeting of this society, held June 11th, the following officers were elected: *President*, Dr. Montrose R. Richard; *Vice-President*, Dr. Joseph E. Lumbard; *Secretary*, Dr. William H. Luckett; *Treasurer*, Dr. William F. Farrell; *Trustees*, Drs. Henry W. Mooney, David Franklin, and M. C. O'Brien.

A Tale without a Moral.—There exists in Chicago an excellent organization among schoolboys, known as the Cook County Anti-Cigarette League, the laudable aim of which is expressed in the name of the association. According to a story in the New York *Times*, the league had a field day on June 15th, and one of the events was a fifty-yard dash. Just before the start a newsboy with a cigarette stump in his mouth came along and requested permission to enter for the race. The superintendent of the games, who thought this was a good chance for a telling object-lesson, readily gave permission, and the "fiend" lined up with the other boys—and won the race.

Deaths from Lightning.—In a report on thunderstorms recently issued by the United States Weather Bureau, it is stated that the number of deaths from lightning in the country, reported to the bureau during the year 1899, was 562. The total number of those struck was 1,382, 820 of whom survived the stroke. It is believed that this record is fairly complete, though doubtless some cases occurred of which the bureau had no cognizance.

A Woman Medical Graduate in Sweden.—Miss Anna Stecksen has recently received the degree of M.D. from the University of Stockholm. It is said that this is the first time this degree was ever given to a woman in Sweden.

The Alumni Association of St. Vincent's Hospital, of this city, was organized at a meeting held on Monday evening. The following officers were elected: *President*, Dr. Charles H. Lewis; *Vice-President*, Dr. Charles L. Weeks; *Secretary*, Dr. Joseph A. Dillon; *Committee on By-Laws*, Drs. Charles Benedict, Francis Murray, and John Curtin. Meetings of the association will be held every three months.

The American Institute of Homœopathy held its fifty-sixth annual meeting in Washington this week, in union with several societies of homœopathic specialists. Of the latter the Ophthalmological, Otological, and Laryngological Society elected officers for the ensuing year as follows: *President*, Dr. Thomas L. Shearer, of Baltimore; *Vice-Presidents*, Drs. Thomas M. Stewart, of Cincinnati, and F. D. W. Bates, of Hamilton, Ont.; *Secretary*, Dr. Herbert D. Schenck, of Brooklyn; *Treasurer*, Dr. C. Gurnee Fellows, of Chicago. The Surgical and Gynæcological Society adopted a constitution and by-laws and elected the following officers: *President*, Dr. James C. Wood, of Cleveland; *Vice-Presidents*, Drs. W. Louis Hartman, of Syracuse, and Horace Packard, of Boston; *Secretary*, Dr. J. Wylis Hassler, of Philadelphia; *Treasurer*, Dr. G. C. Jefferey, of Brooklyn.

Yellow Fever is reported to be prevalent in all parts of the isthmus of Tehuantepec in Mexico. Several hundred Americans, principally from Ohio, Indiana, and Illinois, have settled on the isthmus during the past few years, engaging in the cultivation of coffee, and a number of these, as well as many of the railway employees, have been attacked and have died. The disease has also made its appearance in Vera Cruz, and fears are entertained by the health authorities that it will spread to all the Gulf ports of Mexico. From Cuba it is reported that yellow fever has broken out at Quemados, eight miles from Havana, where United States troops are stationed. Thus far there have been fourteen cases, three of which proved fatal. At present six are under treatment, and all are expected to recover. This is the first time in several years that there have been any cases of yellow fever at Quemados. Havana city is exceptionally clear, only three cases being under treatment, less than during any month of the winter.

The Methodist Episcopal Hospital in Brooklyn.—The new pavilion for surgical operations in this hospital was opened for inspection on the afternoons of June 12th, 13th, and 14th. There was a large attendance each day of medical men and of friends of the hospital.

A New St. John's Guild Hospital.—The cornerstone of a new hospital building to be erected on the Seaside Hospital grounds of St. John's Guild at New Dorp, Staten Island, was laid on June 12th. The building is the gift of Mrs. Frederick Elliott Lewis, in memory of her son. The building will be known as the Cottage Hospital. It is to be a frame structure one hundred and three feet long and about thirty-one feet wide. It is expected that the building will be ready for this summer's use.

A Gift to the Presbyterian Hospital.—An anonymous benefactor has offered to erect a new building for the Presbyterian Hospital in this city. It will be for the accommodation of the nurses and house staff, who now have quarters in the main building. It will stand on the northwest corner of Park Avenue and Seventy-first Street, directly opposite the hospital, on property already owned by the trustees. Room for no less than one hundred additional beds will be secured by the change, increasing the capacity of the hospital one-third. Work on the new building will begin soon, and it is expected that it will be ready for occupancy in the spring or early summer of next year. The style of architecture will be the same as that of the other hospital buildings.

The State Orthopedic Hospital.—At a recent meeting of the board of managers of the New York State Hospital for the Care of Crippled and Deformed Children, the committee on site reported that it had leased the residence of Dr. Angell, Paulding Avenue, on the Hudson River, in Tarrytown. The changes necessary to equip the building for hospital use will be made at once, and the work will be formally inaugurated early in the autumn. The following were elected members of the consulting medical board: Drs. Francis Delafield, Robert F. Weir, W. Gilman Thompson, Joseph D. Bryant, Lewis A. Stimson, A. Alexander Smith, and Reginald H. Sayre, of New York; Roswell Park, of Buffalo, and L. A. Weigel, of Rochester.

Medical Examination of School Teachers.—It has been decided by the board of education of Chicago that all applicants for appointments as teachers in the public schools must submit to a medical examination before coming up for their technical examination. A corps of woman physicians has been appointed to examine all applicants for admission to the normal school.

Women's Medical Institute in Moscow.—A society has been formed in Moscow to collect funds for the establishment of a medical institute for women in that city. The annual subscription is 5 rubles; life members pay 100 rubles, and the donor of 5,000 rubles becomes an honorary member. In addition to the income from these dues, money will be raised by means of lectures, concerts, benefit performances at the principal theatres, balls and fairs. It is hoped that a sufficient sum will be secured to permit of the inception of the work within a short time.

Smallpox on the Hudson.—An epidemic of smallpox has prevailed for some time among negro brickyard laborers at Stockport. The State board of health ordered all negroes vaccinated, and the local board carried out the order as far as they could, but about fifty of the negroes refused to submit. Quarantine was ordered on all suspected cases, including the men who had defied the vaccination order, and a company of the State militia has been ordered to Stockport to enforce the quarantine rules.

The Late Dr. Landon Carter Gray.—At a meeting of the Medical Association of the Greater City of New York, held at the New York Academy of Medicine on June 11, 1900, the following minute was presented and adopted:

"Dr. Landon Carter Gray, a charter member of the Medical Association of the Greater City of New York, died on May 8, 1900. Dr. Gray was well known to the profession in Manhattan and also in Brooklyn, the latter being the scene of his earlier activities. He had attained a high reputation by his varied work in the special branch of medicine to which he had devoted himself. Dr. Gray was essentially genial in his temperament, and especially cordial in his relations with the younger members of the profession. He had held many positions of honor in the various societies with which he was affiliated, and his removal from a busy career in the prime of life will be a loss to the profession.

"*Whereas*, It has pleased an all-wise Providence to remove our colleague from our midst; be it

"*Resolved*, That while we submit to the decree, we, as an association, desire to express our sorrow in our loss, and direct that this resolution be spread on the minutes of the association, and that a copy thereof be forwarded to the family.

"Edward D. Fisher, chairman, Frederick Peterson, W. H. Katzenbach, committee."

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended June 16, 1900:

		Cases.	Deaths.
SMALLPOX—UNITED STATES.			
California, Oakland	May 12th to June 2d	5	
Colorado, Arapahoe Co	May 28th to June 4th	1	
Archulita Co.	May 28th to June 4th	1	
El Paso Co.	May 28th to June 4th	2	
Logan Co	May 28th to June 4th	1	
Mesa Co	May 28th to June 4th	1	
Delaware, Wilmington	June 2d to 9th	1	
District of Columbia, Washington	June 2d to 9th	4	
Illinois, Cairo	May 26th to June 2d	4	
Chicago	June 2d to 9th	4

Manila	April 7th to 28th	41	30
San Pedro Macote	April 20th	Reported.	

The Pan-American Medical Congress.—The Academia de Ciencias of Havana has appointed the following committee on organization of the third Pan-American Medical Congress: *President*, D. Santos Fernández; *Vice-President*, Dr. Gustavo López; *Secretary*, Dr. Coronado; *Treasurer*, Dr. Acosta. The secretary of state of Cuba has been requested to issue official invitations to all the governments of the republics and colonies in America.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending June 16, 1900. Appointment: Charles N. Fiske to be an assistant surgeon from May 15, 1900. June 8th.—Surgeon T. A. Merryhill ordered to the naval laboratory and department of instruction, Brooklyn, N. Y., June 14th. Passed Assistant Surgeon F. C. Cook ordered to temporary duty at naval hospital, Norfolk, Va. June 11th.—Medical Inspector G. E. H. Harmon detached from the *Oregon* upon reporting of relief, and ordered to the naval hospital, Yokohama, Japan, as the relief of Surgeon F. Anderson. Surgeon Frank Anderson detached from the naval hospital, Yokohama, Japan, upon reporting of his relief, and ordered home to wait orders. Surgeon P. Leach detached from the *Yosemite* upon reporting of relief, and ordered to the *Oregon*. Surgeon F. A. Hesler detached from the naval hospital, Chelsea, Mass., upon reporting of relief, and ordered to the *Yosemite* as the relief of Surgeon P. Leach, sailing from San Francisco, via *Doric*, June 30th. Passed Assistant Surgeon C. D. Brownell detached from the naval training-station, Newport, R. I., upon reporting of his relief, and ordered to naval hospital, Chelsea, Mass. Assistant Surgeon C. H. DeLancy detached from the naval hospital, Washington, D. C., and ordered to the naval training-station, Newport, R. I. June 12th.—Passed Assistant Surgeon J. F. Leys ordered to temporary duty on the *Franklin*. Surgeon G. M. Pickrell detached from the naval station, Cavite, P. I., and ordered to the naval hospital, Yokohama, Japan. Passed Assistant Surgeon Horace B. Scott, retired, died May 20, 1900.

Obituary Notes.—Dr. S. Burke Pillsbury died at his home in Middletown, N. Y., on June 17th, from the results of an operation. He was a graduate of the Harvard Medical School in 1876.

Dr. George M. Beabes died at his home in Bloomingburg, N. Y., on June 15th, at the age of sixty-eight years. He was a graduate of the Albany Medical College in the class of 1856. During the Civil War he served as surgeon in the Fifty-Sixth New York Volunteer Infantry. He served two terms in the legislature of this State in 1890 and 1891.

Dr. William Pierson, of Orange, N. J., died at his home there on June 12th. He was born in Orange on November 30, 1830, and was graduated in medicine from the New York University in 1852. He had been secretary of the New Jersey State Medical Society for over thirty years, and was elected president, although then ill, at the recent annual meeting of the society. He was the first president of the board of education in Orange, and held that position for twelve consecutive years. Dr. Pierson was descended from a long line of medical ancestors, the first one of the name having begun practice in Orange in 1764.

Thermo-Cautery should not be used on the cartilaginous septum on account of liability to perforation. In cauterizing turbinates, the septum should be protected by tinfoil.—H. H. Curtis.

Progress of Medical Science.

The New York Medical Journal, June 16, 1900.

A Contribution to the Technique of Modern Uranoplasty.—J. F. McKernon advocates the performance of a preliminary tracheotomy, packs the cavity of the mouth for a week or more, treating it as any other wounded surface, and feeds by the rectum. He has never had any difficulty with nourishing his patients. If no vomiting has taken place, the packing should be removed at the end of forty-eight hours, the wound gently cleansed, and the packing replaced. This should then be done daily, and the stitches carefully inspected. If any are found drawing, they should be severed at once, but not removed until the next day. The tracheotomy tube should be retained until the twelfth day, by which time the patient is able to take food by the mouth. The introduction into the bowel of a warm saline solution diminishes thirst, adds to the general comfort of the patient, and seems to be an adjuvant to nutrition. The advantages claimed for the method are as follows: The restoration of speech function, complete or partial. It allows the patient to eat without regurgitation of food, giving little or no trouble thereafter, so far as deglutition is concerned. It allows the patient to mingle on a par with his fellow-beings. It does away to a very great extent, if not entirely, with the facial contortion while trying to speak. It lessens the catarrhal inflammation of nose and throat, and improves the deafness, when existing, as well as relieving the distressing subjective sounds so frequently complained of by these patients. There will be a decided increase in weight, and when persistent headaches have been present and can be attributed to no other cause, and have received treatment without avail previous to the operation, they will often clear up completely when the cleft is closed, allowing a normal nasopharyngeal function to take place.

Juvenile Hysteria and Neurasthenia.—C. L. De Merritt believes that much of the neurasthenia of adult life has had its foundation laid in childhood. He condemns the introspective methods of the educational system of the present day, claiming that children are overworked in school and are not given proper exercise. Other causes are poor food, anæmia, and infectious fevers. Treatment should begin with the parents. If they are neurotic, we must get them into some sort of trim before we can secure a proper regimen for the child. Tonics such as hæmic reconstructives are generally indicated. Bathing is a useful adjuvant, followed by small doses of hyoscyamus. Attention should be paid to exercise, and if the child's school has a gymnasium, it is often better to have the child continue at school, for the resultant effect is better than that from no school and no gymnasium.

Hernia Abdominalis.—H. A. Duemling submits the following propositions: (1) A hernia is the escape of a viscus from the abdominal cavity covered with the structures peculiar to its point of exit. (2) The folds and depressions of the peritoneum, occasioned by the passage of various structures under it, create weak points in the belly wall. (3) The success of a radical cure depends on the restoration of the muscular and fibrous tissues to their pristine relationship and elasticity. (4) The production of scar tissue, artificial or accidental, lessens materially the possibility of a permanent cure. (5) Destruction of the inguinal canal and suture of the external abdominal ring do not prevent recurrence. (6) Destruction of the inguinal canal and of the internal abdominal ring (or its fortification) offers the largest percentage of cures.

A Case of Tetanus Treated with Antitetanic Serum.—By J. F. Clarke.

Typhoid Infection of the Uterus.—By A. J. Lartigau.

Perimetric Diagnosis.—By J. W. Sherer.

Philadelphia Medical Journal, June 16, 1900.

An Experimental Study of the Origin of the Epidemic of Tetanus following July 4, 1899; Report of Case with Recovery.—H. Gideon Wells calls attention to the large number of wounds made by blank cartridges which were followed by tetanus. He records an instance of recovery; the only one in five occurring at the same time which did not prove fatal. The patient was a laborer, forty years old, who was shot above the knee. Stiffness of the jaw began to come on ten days after receipt of the injury. Two pasteboard wads were found at the bottom of the wound, and from them as well as from the pus was isolated the tetanus bacillus according to the Kitasato method. Tetanus antitoxin 10 c.c. was injected and repeated twice at intervals of twenty-four hours. Chloral and bromides were given regularly, and perfect quiet was secured. Morphine was also given hypodermically to a point of maintaining drowsiness. Bacteriological investigations with various makes of blank cartridges failed to show that the origin of the infection was attributable to the blank cartridges, while this origin was not absolutely excluded.

A Case of Hereditary Ataxia with Generalized, Bilateral, Choreiform, and Athetoid Movements.—Bernard Oettinger relates the history of a girl aged six years, who was the only one in the family to be affected so far as known. Developmental defect was believed to underlie the condition. The pathology, symptomatology, prognosis, and treatment are all considered. Under the continued administration of small doses of bromides the involuntary movements diminished noticeably.

The Necessity for State Aid in the Treatment of the Consumptive Poor.—By Howard S. Anders.

Mütter Lectures of the College of Physicians of Philadelphia.—By John B. Roberts.

A Contribution to the Study of Exophthalmic Goitre.—By Alfred Gordon.

Angina Pectoris.—By Clifford Allbutt.

The Boston Medical and Surgical Journal, June 14, 1900.

The Mechanics of Lateral Curvature of the Spine.—Robert W. Lovett sums up thus a study of the subject: Torsion and side flexion of the spine are parts of one compound movement, and neither exists to any extent alone. Lateral deviation of any part of the spinal column is therefore necessarily associated with torsion (rotation) at the seat of the deviation. In flexed positions bending is associated with torsion in one direction, in extended positions by torsion in the opposite direction. From the kind of torsion observed in scoliosis it is obvious that the deformity originates in the flexed position of the spine. The correction of the rotation would therefore seem to be logically made by throwing the spine into extended positions, and in taking side bendings from extended positions. The immediate cause of lateral deviation is, as a rule, to be found in some asymmetry of development or posture which leads to an oblique direction of superincumbent weight, causing the spine to deviate from the middle line.

Malaria and Mosquitos.—Irving G. Rosse opposes the modern theory that mosquitos transmit the malarial organism to man, and thus cause malaria, basing his belief on the fact that Arctic voyagers do not suffer from the disease after encountering the insect in so great abundance that they actually interfered with the use of instruments in taking observations. On the Chesapeake peninsula, which has a notorious reputation for malaria and mosquitos, a healthy New England crew escaped malaria, although distracted by the annoyance of the mosquitos. On the other hand, he is told that malarial fevers are common in the foothills of Virginia, as at Charlottesville, where mosquitos are such a negligible quantity as to be almost unknown.

Closing Statement for the Remonstrants to the Massachusetts House Bill No. 917, Entitled "An Act for the Further Prevention of Cruelty to Animals," before the Joint Committee on Probate and Insolvency, March 15, 1900.—By Harold C. Ernst.

Realism in Medicine.—By A. J. Cabot.

Journal of the American Medical Ass'n, June 16, 1900.

Medicine and Disease in the Philippines.—D. J. Doherty gives in condensed form the data gathered from various authorities. There are two seasons: that in which the northeast monsoon blows (October to February), and that in which the southwest monsoon prevails (June to October), with an interval of calm. The second is the wet period. The climate is the most healthful of any in the tropics. Among diseases fevers occupy the first place, malarias predominating; next in order come dysentery, phthisis, and other pulmonary affections, skin diseases, leprosy, smallpox. Endemic diseases due to telluric, paludal, microbic infections, as well as rheumatism and dyscrasias, are studied. Hemorrhagic smallpox is the most frequent form seen. Barcones is quoted in loud condemnation of the vices incident to the introduction of opium and the abuse of tobacco and alcohol. The curanderos are akin to the barber surgeons of Europe. They use native plants. The Spaniards are given much credit for regulation of sanitary matters, vaccination, and medical education. Rules for Americans going to the islands are laid down.

Neurasthenia, Some Points in its Pathology and Treatment.—G. W. McCaskey points out the probable antiquity of nerve prostration. He finds that it is often most difficult to determine whether the neurasthenia or gastro-intestinal disease was the primary condition. If it is true that primary gastro-intestinal disease can cause neurasthenia, it follows, as a necessary corollary, that gastro-intestinal disease, even when secondary to the neurasthenia, will act as an auxiliary etiological factor. For this very reason the sequence of events in the evolution of any given case is a matter of subordinate importance from a clinical point of view, although always of the highest scientific interest. The real practical question is whether or not the gastro-intestinal disease is capable of exerting a prejudicial effect on the progress of the case. The stomach tube is advocated for a large number of cases. There is often much reflex irritation from the colon, which must be cleared out by local treatment.

Report of Case of Splenectomy, with Attempted Surgical Cure of Ascites due to Cirrhosis of the Liver.—T. N. Rafferty reports a case, with death on the fourteenth day, due to embolism. The patient, a widow, thirty-one years old, measured fifty inches at the umbilicus. No tumor could be made out with certainty. Three gallons of fluid were withdrawn. Twenty days after an exploratory incision the spleen was removed.

Periods in Gynæcology.—Henry J. Garrigues reviews the changes in gynæcological practice which have taken place in the last quarter of a century. In describing the operation for abdominal hysterectomy as he performs it at the present day, he says that he can the more freely recommend the method described, as he does not claim any part of it as his invention. Paul Ségond has adopted it, and calls it the "American method." As American gynæcologists, it behooves us to give due credit to Henry O. Marcy for the use of the buried continuous animal suture (1881); to J. A. Emmet for the retroperitoneal treatment of the stump (1884); to Lewis A. Stimson for the substitution of the direct ligation of arteries for the unsafe mass ligature (1889); to William R. Pryor for having shown the advantage of coming from below upward on the second side (1894); and to Howard A. Kelly for having combined most of these ideas in a clear, precise form (1896).

Causation and Relative Frequency of Typhlitis, Perityphlitis, and Appendicitis in Infancy and Childhood.—By Joseph Henry Byrne.

The Prophylaxis and Control of Leprosy in this Country.—By Prince A. Morrow.

The Lancet, June 9, 1900.

On Suprapubic Lithotomy in Old Men with Enlarged Prostate.—W. T. Thomas believes that calculi are frequently lodged in the pouch behind the middle lobe of an enlarged prostate, and that they may lie there for months even before their presence is suspected. The special steps for the removal of these small calculi are thus described: After the bladder is reached and opened the finger is passed in to locate the calculus and ascertain its size. If small, the stone can be readily extracted by Tait's gall-stone forceps, which takes up less room than the unnecessarily clumsy lithotomy forceps; if large, the wound in the bladder is extended, the mucous membrane being divided to a lesser extent than the muscular coat; blunt hooks are inserted above and below to keep the opening on the stretch, and a pair of lithotomy forceps is used to seize the calculus. The bladder wound is sutured, continuous chromic gut for the mucous membrane and continuous silk à la Lembert for the muscular coat being employed. The bladder suture is now tested by air distention, and if secure a few ounces of lotion are used to wash out any small blood clot that may be in the bladder. A small incision is made through the skin to one side of the middle line to accommodate a small glass drainage tube passed down to the neighborhood of the sutures in the bladder wall. The original skin incision is closed by sutures and a gauze dressing under a double spica bandage is applied. The catheter is left in the bladder, tied in position, and by means of a rubber tube attached to it, it conducts urine into a vessel containing lotion for a few days.

On the Relative Value of Symptoms of Acute Peritonitis.—Collating symptoms given by various authors, E. S. Bishop makes the following list: Sudden and continuous pain; tenderness; hot, dry skin; temperature elevated, normal, or depressed; hard, "wiry" pulse; quickened respiration; tympanites; clear note on percussion, unless effusion has occurred, when there is dulness in the flanks; distended abdomen; altered facial expression; flexed thighs and characteristic position of the body; and, later, vomiting. None of these is absolutely pathognomonic, but he pins his faith on the existence or non-existence of rigidity of the abdominal muscles. With acute peritonitis there is always rigidity of the abdominal muscles. This rigidity is temporary, lasting only three or four days; it is therefore useless as a sign of chronic peritonitis. True rigidity must be carefully distinguished from mere stiffening of the abdominal muscles. In making the examination the surgeon must find time to sit down. His hand must be warm, warmer, if possible, than the patient's skin. The tips of the fingers are not to be used. The entire hand should come in contact with the abdomen like a feather, so that it is almost impossible for the patient to say when actual contact is made. It should then lie without any weight, almost entirely supported by the surgeon's own muscles for a few moments motionless, then gradually and gently move with an imperceptible sliding action over the surface. Thus, and thus only, will he be qualified to say whether or not there is actual muscular rigidity.

Monogamy in its Relation to Longevity and the Diseases of Late Life.—H. Campbell believes that all non-accidental deaths occurring before the end of reproductive life are racially considered deaths of the unfit, such deaths acting beneficially on the race by limiting the production of unfit offspring. The majority of men among the civilized have children by one wife only, and she is generally about the same age as the husband. The effect of this is to reduce the age-limit of reproduction in the man to that of the woman. A man, therefore, marrying a woman about his own age and possessing the power of propagation into advanced life leaves no more children to inherit his superior death-resisting powers than the inferior man who dies at the age of forty five. Monogamy in such a case reduces the superior man to the reproductive level of the inferior one, and robs the race of a number of individuals whose birth would diminish the racial tendency to disease in the later years and increase the racial span of life. The effect of monogamy in fact is to increase the racial tendency to disease after middle life, and to shorten the vital span.

Addison's Disease following Enteric Fever.—A case of this rare pathological sequence is reported by H. W. Evans, his patient being a girl aged seventeen years, who after an illness of six weeks presented symptoms suggestive of a typhoid relapse, though no fever was present. The pulse rate markedly increased, and spots were found on the abdomen, around the nipples, and in the axillæ. The further course was one of steady decline, and she died in about three months from the time of the initial typhoid symptoms.

The Primary Disorders of Growth.—By H. Gilford.

British Medical Journal, June 9, 1900.

Personal Experiences of Gout Terminating in Acute Myositis of Entire Left Lower Extremity.—A. S. Myrtle records his own case. Following an injury in which the knee was crushed, gouty symptoms supervened. In November, 1899, he awoke one morning at four o'clock with a sharp pain in the left adductor longus. The entire left extremity from the hip to the ankle was swollen, hard, and painful. Pressure over muscles alone was painful. After taking colchicum, lysidin, and potassium citrate regularly for three days the acute pain disappeared. Eczema supervened. Six hay-flower baths at 98° F. gave relief. Loss of power in muscles of leg and soreness continued. After ten constant-current electric baths the œdema disappeared and a mile walk could be taken. The doctor believes that gout had been silently at work for months and broke out thus violently, invading cellular and muscular tissues, avoiding joints, tendons, and vessels.

Treatment of Chronic Gout.—William Bane, basing his notes on experimentation and clinical investigation, finds that uric acid at least plays an important incidental part in the pathology of gout. There is little evidence in favor of the theory of uric-acid formation by the kidneys. In treating chronic gout our aim should be to prevent the formation of abnormal proteid decomposition substances, and the accumulation of these and other waste products in the system, and to promote their elimination. The question of diet and exercise is considered and the relative values of various drugs are discussed. Gouty subjects should take a relatively large amount of water between meals.

A Case of Persistent Adenoids in a Middle-Aged Woman.—E. F. Potter records an instance of typical chronic mouth breathing with impaired hearing. The post-nasal space was occupied by a considerable mass which obscured the upper half of the septum, extending across the vault from tube to tube. The mass resembled somewhat a sarcoma, but microscopical examination, after removal under anæsthesia, showed it to be adenoid which had undergone inflammatory changes. The age (forty-seven) is considerably below that of Solis-Cohen's case (seventy), still it is of sufficiently rare occurrence at this time of life to warrant comment.

A Note on Gout.—James Edmunds says he has discarded sodium salicylate for the potassium salicylate, "cardiac depression" not being observed. As long as the urine becomes turbid on cooling from deposition of urates he uses potassium bitartrate. None of the remedies impudently advertised for uric acid can compete with some very simple and inexpensive ones. As an aperien the gives: ℞ Pulv. guaiaci, potass. bitart., sulphur. præcip., āā ℥ i.; pulv. trag. co., ʒ ii. M. S. A teaspoonful at bedtime in a wineglassful of gruel.

Berliner klinische Wochenschrift, May 28, 1900.

Congenital Lack of Nerve-Structure. — O. Heubner describes a case of the variety to which Moebius has given the name of "infantiler Kernschwund." It is that of a child aged eighteen months, who was backward in respect to power of standing, walking, and speaking. In addition there were a lack of control over both abducentes of the eyeball, complete paralysis of the left facial nerve, diminished activity of those muscles supplied by the left motor oculi, a complete paralysis with considerable atrophy of the left half of the tongue, and a complete lack of tear secretion. There was also complete lack of response of the affected structures to both faradism and galvanism. The condition is referable to congenital structural defects in that part of the cerebro-spinal axis from which the nerves going to the affected areas arise.

Experiences in and Reflections upon the Treatment of Gonorrhœa.—L. Casper gives a general review of the treatment of gonorrhœa, stating that up to the present time nothing has been discovered which can be regarded as a therapeutic specific in this affection. A simple, uncomplicated case is not to be looked upon as a dangerous malady. The condition is quite otherwise as soon as complications develop. Many of the latter are induced by a purposeless and careless therapy. The abortive treatment is a myth so far as practical success is concerned. All instrumentation is contraindicated in the florid stage. The author has had good results with injections of thallinum sulphate, which seems to have, in his judgment, a distinct specific antigonorrhœic effect. Of the antiseptic salts those of silver are the best and the oldest; the nitrate is the best of all.

The Criminal Insane.—E. Siemerling gives a general review of the literature of this subject, calling attention to the various eras which have been characterized by the introduction of new symptomatological terms and the changes of medical opinion relative to the care of this class of unfortunates. He calls attention to the efforts which have been made to study this class of persons on the basis of anthropology and biology as inaugurated by Lombroso in 1887–90. He does not regard the latter's views as entirely correct, for he thinks that Lombroso has gone further than facts warrant in making his classification so definitely on the basis of various physical stigmata of degeneration.

Influenza and Chronic Cardiac Disease.—Concluding article by Dr. Schott (Bad Nauheim).

Experimental Irritation of the Spinal Marrow of Decapitated Persons.—By A. Hoche.

Deutsche medicinische Wochenschrift, May 31, 1900.

A Case of Carcinoma of the Œsophagus Treated with Permanent Cannula.—C. A. Ewald describes with illustration a case in which a man, aged sixty-four years, was admitted to the Augusta Hospital in Berlin for difficulty in swallowing. There was almost complete stenosis of the œsophagus opposite the bifurcation of the trachea. A cannula was introduced and considerable relief was experienced. Silk threads attached to the instrument were brought out through either nostril and tied beneath the septum. He gained in weight for some time. Rectal alimentation was finally resorted to. A month and a half later the patient died. At the autopsy the tube was found well engaged in the centre of the growth, and the view was taken that the cancer had grown downward beyond it so that its function was interfered with. Curschmann has had good results from permanent tubes in fourteen cases. The writer demonstrates the technique in the clinic twice a year, and finds that the introduction presents no difficulties; his results, however, do not equal those of Curschmann.

Observations on Diseases of the Pancreas.—J. Israel relates an instance of extirpation of a movable cyst of the pancreas. The interesting feature was the abnormal mobility of the tumor without a long pedicle being present, or descent of the spleen, and without the slightest trace of enteroptosis. It depended upon abnormal mobility of the whole pancreas. The history is given in full. Three other instances of pancreatic disease are given. In one case there was permanent and decided benefit from entire emptying of the sac by means of puncture. Four years later the cyst was found never to have filled again. At intervals there had been attacks of vomiting and pain which made it seem probable that pancreatic calculi were in process of formation. The history is also given of necrosis of the pancreas with peripancreatic abscess formation, and of a case of cyst in which double-sided incision resulted in cure.

On the Symptomatology of Hysterical Deafness.—Ernst Barth relates an instance of sudden deafness after fright in a girl aged eleven years. This was suddenly recovered from, and again, after an interval, came on after a second fright and persisted, but the appreciation of musical tones was found, by tests, to be still present, as though regulated from an acoustic centre disconnected with or as a subdivision of the sense of hearing.

New Observations upon the Changes in the Pyramidal Giant Cells in the Course of Paraplegias.—By G. Marinesco.

French Journals.

The Treatment of Dysenteriform Entero-Colitis of Infants by Guarana Powder.—R. St. Philippe says infantile diarrhœas vary in form, aspect, cause, and pathogenesis, and no single treatment can be laid down for all. They should be carefully distinguished from one another, and the appearance of the stools themselves will lead to the proper treatment. The glairy dysenteriform entero-colitis is a variety apart, characterized by special etiology, symptoms, and therapeutic indications. This variety of enteritis is favorably modified by fresh guarana powder, which should be used after cold maceration and should be prepared some time in advance. The dose varies with the patient's age, from 50 cgm. to 2 gm. in the twenty-four hours. The physiological action is evidently complex, but it appears to act in a substitutive and tonic manner. The remedy should be ranked with other anti-dysenteric drugs.—*Le Bulletin Médical*, June 6, 1900.

Ovarian Cyst with Twisted Pedicle in a Young Subject.—L. Monnier successfully removed a cyst from a girl aged sixteen years, the pedicle being found twisted. He concludes that moderate-sized cysts in young women have a natural tendency to become twisted. This complication is to be diagnosticated by finding a fluctuating tumor which has been the seat of sudden, violent pain, extending over the entire belly, but more severe in one groin, accompanied by vomiting, the peritoneal facies, and also at times by a scarlatiniform or rubeoliform eruption. Such a rash was present in another of the author's cases in a girl aged fourteen years, as well as in the present instance. Immediate operation is proper if the symptoms are severe, with aggravation of the peritoneal signs, agitation, insomnia, etc. Otherwise the acute symptoms may be allowed to subside before operation.—*Journal de Médecine de Paris*, June 3, 1900.

Sterilization of the Hands.—Pierre Delbet, after a series of experiments, finds that it is possible to render the hands aseptic even after contact with most septic substances. He washes in very hot water, not flowing, but in a basin so as to get a good soap solution. This is kept up for five minutes, changing the water once. He then brushes with ninety-per-cent. alcohol until a bichloride solution stays evenly upon the whole surface, showing complete removal of fatty matter. He ends by immersion in corrosive-sublimate solution for one minute. He concludes that surgery can be done as aseptically without as with rubber gloves.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, June 7, 1900.

Trichorrhexis Nodosa.—Paul Paymond presented a man with small nodosities along the hairs of the mustache. This is a rare localization for the infection in his experience. The node formation and subsequent breaking of the hair so as to form a brush-like end is due to a diplococcus constantly found by the author. Antiseptic treatment has not given important results. It is better to shave the parts for a few weeks, practising rigorous antisepsis of the skin surface. The toilet articles must be carefully looked after, since nodosities have been observed upon hair-brushes.—*Journal de Médecine de Paris*, June 3, 1900.

Archives of Pediatrics, June, 1900.

Remarks upon the Treatment of Whooping-Cough.—Francis Huber finds that in some cases, when intubation is not practicable, one of the following methods gives good results: Sending the children much in the open air, or out upon the water; giving more food as soon as vomiting is over; pushing forward the jaw, as in anæsthesia, in many cases has relieved the paroxysm and prevented the vomiting. A third method is the use of codeine in small and repeated doses to the verge of slight narcosis, sufficient to overcome the spasm of the glottis. A few cases treated in this way have been carried safely over the danger point. As a rule it is not necessary to employ the remedy for more than a few days or a week, at the end of which period the severity of the attack is relieved, food is retained, and the usual routine treatment may be continued.

A Cretin Successfully Treated with Thyroid Extract.—H. Oliphant Nicholson reports the case of a little girl two years and eight months old, who, up to the age of eight months, had seemed to be normal. At that time a change occurred, and when seen by the author she presented the evident signs of cretinism. Thyroid treatment consisting of about 2¼ grains of thyroid powder daily, was instituted, and in about three months' time very few traces of cretinism remained. Two photographs illustrate the condition before treatment and that after four months' taking of the remedy, the difference being very striking. Unfortunately the child contracted measles of a malignant type and died.

Acute Glandular Fever.—W. F. Boggess describes the course of this disease, the high, irregular fever, chills, pain in the back, and involvement of lymph nodes. Rest in bed and careful nursing, with local applications to the neck of belladonna and ichthyol, he found useful, combined with calomel to unload the bowels, followed by intestinal antiseptics, salol, naphthalin, dermatol, and the use of tonics and reconstructives.

Clinical Observations upon the Operative Treatment of Tuberculous Peritonitis.—By Augustus Caillé.

Pancreatic Digestion of Casein.—By B. K. Rachford.

Bulletin of the Johns Hopkins Hospital, May, 1900.

Urinary Anomalies.—T. R. Brown describes a simulative nephritis after nephrotomies and nephropexies. The characteristic feature is the presence of an enormous number of casts, the urine quickly clearing up in the course of a few days. The condition is referable to the handling of the kidney, taking sutures through the renal substance, ether irritation of the renal tissue, and diminution in elimination of fluids almost invariably seen after ether anæsthesia. Brown further describes post-operative glycosuria, which he divides into toxic, those associated with diseases and injuries of various kinds, and puerperal. He also alludes to "malingering mellituria," narrating the history of a young girl who placed in the vessel containing her urine lumps of sugar taken from food brought to her on a tray, and who for a long time eluded detection.

Acute Leukæmia in Childhood, with Report of a Case.—T. McCrae reports the case of a boy aged three years. A full description of the patient's various symptoms is given, the acute stage running a short course. Thirteen other cases in children are reported and briefly analyzed. Eleven of the thirteen cases were males. A bibliography of the literature bearing on the subject is given.

Personal Experience in Operations for Stone in the Bladder.—By A. T. Cabot.

The Practitioner, June, 1900.

Acute Phagedæna of the Nose, Eye, and Face in a Syphilitic Subject.—A. Phillips relates a rare case in a soldier, aged twenty-six years, who contracted syphilis in India two years ago. There was at first a small ulcer in the roof of the mouth which spread rapidly. Fourteen days after first seen the nasal cavities were filled with fetid sloughs, and the cartilaginous septum had necrosed. A sloughing ulcer occupied one ala of the nose, and gangrene attacked the opposite side. The entire external nose was necrotic within three weeks of the first observation. Succeeding patches of skin became red and œdematous and melted away. Death occurred by septic infection one month from the onset. Treatment was without effect, but scraping and cauterization arrested the oral ulcer.

Tabes Dorsalis.—James Taylor gives in the form of a clinical lecture the history of cases of tabes, illustrating the various phases and stages. Two were in women—one only twenty-three years of age. She did not show the Argyll-Robertson pupil reaction. There is little doubt of the relation of syphilis in the large majority of cases. The argument that one cannot cure tabes by antisyphilitic treatment has no force. The most common symptom is the pain; the next most common the girdle sensation. A large proportion of subjects have difficulty in walking. A common affection is that of the sphincters, especially of the bladder. The three large divisions are: (1) those with marked ataxy; (2) other symptoms presenting without ataxy; (3) optic atrophy and usually no ataxy.

On Some Points Connected with the Management of Stricture of the Urethra.—W. H. Bennett takes an unusual case as a text for a clinical lecture, and goes through the various steps of urethral exploration and treatment. After internal urethrotomy the proper-sized sound should be freely movable in the canal. The meatus should always be slit in withdrawing the urethrotome. If it is not cut, urethral spasm will occur and cause the sound to be grasped. Organic stricture is not curable in the strict sense of the term by any means at present at our disposal. Avoid a too slavish devotion to traditional routine methods: approach each case with an open mind, common sense, and gentleness.

The Static Method in X-Ray Work.—By A. D. Griffiths.

Cream and Fat in Infant Feeding.—By G. F. Still.

Treatment, May, 1900.

Healed Phthisis.—H. W. Syers says that the evidences of healed phthisis will be constantly found in the post-mortem room when systematically looked for. He believes that there is no remedy, no panacea for the cure of phthisis. He protests against the use of creosote. He has seen improvement follow the use of counter-irritation, using equal parts of the tincture and the liniment of iodine painted on over the affected apex sufficiently often to roughen the skin, but not to make it sore. Six-per-cent. iodine vasogen acts equally well. Most cases will and must be benefited from judicious feeding, judicious clothing, and from access to pure air.

Infection through the Tonsils.—Frederick A. Packard calls attention to the secondary lesions following angina; among these are endocarditis, pleurisy, albuminuria, skin lesions, such as erythema nodosum, purpuric, multiform, morbilliform, scarlatiniform, urticarial, herpetic, and indeterminate, chorea, phlebitis, acute yellow atrophy of the liver, peritonitis, acute hydrocele, strabismus, palsy, in some rare cases pyæmia, and very frequently acute articular rheumatism. In the few fatal cases of rheumatism in which the tonsils were examined after death, streptococci and staphylococci have been found.

Dublin Journal of the Medical Sciences, June, 1900.

The Dublin Method of Effecting the Delivery of the Placenta.—H. Jellett contributes a polemic article maintaining the following propositions: (1) That the method of effecting the delivery of the placenta by external manipulations, as opposed to its manual removal or its delivery by traction on the funis, was originated in Dublin; (2) that Credé's method, when originated *de novo* in Germany, was identical in principle with the Dublin method, and that it rapidly came to assimilate itself to the Dublin method in its most important details; (3) that, consequently, there is no difference between the Dublin method and Credé's method, and that inasmuch as the method originated in Dublin many years before the time that Credé discovered it for himself, its name is and ought to be "the Dublin method."

Toxins and Antitoxins.—A. C. O'Sullivan reviews our knowledge of the source of antitoxins and the nature of their action. He states his general conclusions as follows: (1) The toxin enters into chemical, or molecular, combination with the cell protoplasm, and when in this combination is neutralized—*i.e.*, is innocuous for other cells. (2) The toxin enters into chemical combination with the antitoxin, and when in this combination is neutralized. (3) The antitoxin is produced by the cell, and is thrown off by the cell into the blood. (4) The cells which produce the antitoxin are the same cells as those which combine with the toxin.

On Commercial Pepsin.—By C. A. Cameron.

The Journal of Tropical Medicine, May, 1900.

Ankylostomiasis in the Leeward Islands.—H. A. Alford Nicholls says that the facts concerning the life history of the parasite of this disease show: (1) that the worms in their larval stages are intimately connected with the soil; (2) that the adult worms develop from larvæ after the latter are introduced into the digestive canal of man; (3) that the worms act as minute leeches, extracting blood and causing little bleeding points by their bites; (4) that, owing to their minuteness, a multitude of the worms are necessary to produce any serious deterioration of the vital organs; (5) that the worms cannot multiply within the body, and that, therefore, in most instances, fresh infections are necessary to prolong disease; (6) that as the larvæ are developed in the soil from eggs deposited thereon in human dejecta, certain obvious and simple sanitary measures are all that are necessary to arrest the propagation of the parasite, and therefore to rid any district of ankylostomiasis.

A Note on Mosquito Nets and Malaria.—R. W. Felkin recalls the fact that Gordon Pasha gave him the advice never to sleep in Central Africa except under a mosquito net, as he was convinced that it acted as a filter against malarial poison, as well as against the mosquitos and other insects which he thought might cause the fever. The author describes the portable mosquito netting which he made and constantly used. For one week in Fatiko, where he thought there were no mosquitos, he failed to use the net, and a short time afterward had a bad attack of fever. This might have been a mere coincidence, but he slept under the net thereafter. A few insects are usually to be found inside the net. By holding a light at one corner and outside the net, they usually fly to it and can then easily be killed. Urinals with covers should be used inside the net.

What Becomes of the Mosquito during the Dry Season?—St. George Gray, from experimentation with mud from a dried pool and with grass picked from its sides, found that mosquito larvæ developed from the grass. He thinks there is no doubt that the eggs of Anopheles remain fertile for a long time after drying, and would suggest as a prophylactic, wherever possible, burning the grass where Anopheles' breeding-places are known to exist, so as to destroy the eggs before they mature, and thus prevent the pools becoming a source of danger to man.

Upon the Part Played by Mosquitos in the Propagation of Malaria.—By George H. F. Nuttall.

The Endemic Centres of Plague.—By Frank G. Clemow.

The Edinburgh Medical Journal, June, 1900.

Has Antitoxin Reduced the Death Rate from Diphtheria in Our Large Towns?—Louis Cobbett, from statistics collected in London, Edinburgh, Glasgow, several other large British towns, Paris, and Berlin, concludes that antitoxin can have but a slight and indirect influence upon the prevalence of diphtheria. The prophylactic use of the substance, in the case of children known to be exposed to infection, might be employed with benefit more largely than it is. The really effective weapon that modern discovery has given us is the bacterial test. It should be brought home to the minds of people that diphtheria is not spread by bad drains and insanitary surroundings, but by direct transference of the bacillus from mouth to mouth. All persons with suspicious sore throats should be examined by the bacterial test, and if the bacillus is found they should be isolated. All persons recovering from diphtheria, however mild the attack has been, should be isolated until the specific micro-organism has disappeared from their throats. A competent bacteriologist should be appointed in every large town to make the necessary examinations.

Cross Infection, So-called, in Fever Hospitals.—Claude B. Ker holds that most of the "cross infection" does not come from other parts of the hospitals, but from outside, being introduced in various ways. First, it may be due to a wrong diagnosis made outside, difficult cases of scarlet fever and diphtheria, or scarlet fever and measles, being often confused. Secondly, it may be due to a patient being admitted with two diseases, only one of which has been diagnosed. Thirdly, it is due to the admission of patients who are suffering from one disease and incubating another. The second infection, in the great majority of cases either measles or varicella, is developed some days after admission. This is by far the most common of the causes of so-called cross infection, and it is quite impossible to avoid.

The Theory and Practice of the Treatment of Ringworm of the Scalp.—W. Allan Jamieson says that the entire scalp must be kept bare of hair, by razor or curved surgical scissors, until the cure is complete. The scalp must be kept rigorously clean, by being washed twice daily with a fluid superfatted potash soap and warm water, the soap being poured on a piece of wet flannel and moderate friction employed. The application then to be made consists of: precipitated sulphur, ʒ i.; salicylic acid, beta naphthol, and ammoniated mercury, āā grs. x.; lanolin, ℥ i. The ointment must be rubbed in carefully and slowly for ten minutes twice a day.

Points of Practical Interest in Surgical Gynæcology: II. Some Pitfalls in Gynæcological Diagnosis.—By H. MacNaughton Jones.

On Some Medical Superstitions. By J. L. Bunch.

Annals of Surgery, June, 1900.

Permanent (Congenital) Dislocation of the Patella.—J. S. McLaren analyzes previously recorded cases and gives notes of one seen in his own practice. His patient was a girl aged nineteen years, whose left knee had always been weak. She presented evidences of having had rachitis in childhood. The condition of the left leg is thus described: Marked genu valgum on the left side; the leg is rotated outward. When the knee is extended, the patella lies somewhat to the outside of the normal position; when the joint is flexed, it passes farther and farther out till it lies on the outer side of the external condyle of the femur, its anterior surface directed outward and forward. It may with force be held in or near the middle line while the knee is being flexed to a certain extent, but on being released it flies out and back. The fossa patellæ of the trochlear surface of the femur can be felt to be partially filled up, as it were, on its outer side, as if the external condyle projected into it, while the outer edge of that condyle, on the other hand, seems to fail altogether and leave a gap under the outer edge of the patella. The x-rays show the position of the patella to be higher up the femur than normal, and give a faint indication of the altered shape of the external condyle.

The Leucocyte Count in Surgery.—Theodore Dunham states that large hemorrhages are usually followed by a marked leucocytosis. After ether operation of any magnitude, the count is as a rule much increased. He is inclined to think that a similar result follows the absorption of iodoform. The increase has also been noticed in carcinoma and sarcoma. The best service, however, which the leucocyte count renders the surgeon is in the diagnosis of acute inflammatory conditions. The leucocytes may help us to infer the presence of a suppurative process not only by their greater abundance but also by qualitative changes which they exhibit. In cases in which a progressive suppurative process is present, a larger or smaller proportion of the polymorphonuclear neutrophiles stains with iodine. This reaction is not found in normal blood and is said not to occur in any disease which could well be confounded with acute abscess.

Splenectomy for Congestive Hypertrophy.—J. W. Bovée reports his third case. His patient was a woman aged thirty-nine years, who had noted the presence of an abdominal tumor two years before, with a small ulcer on the inner side of the anterior surface of the left leg. Diagnosis of enlarged spleen was made, and in due time the latter organ was removed. After a somewhat prolonged convalescence she was allowed to leave the hospital, and her subsequent history was uneventful. Examination of the spleen showed a simple congestive hypertrophy. The limitations and dangers of the operation are discussed by the writer, who takes a conservative view of the general question.

Thyroid Medication in the Treatment of Delayed Union of Fractures.—After a brief review of cases reported by others, F. W. Murray gives his personal experience with one case —that of a man who was struck by a locomotive and sustained two simple fractures of the left femur. Non-union followed, and the man had had several operations before he came under the writer's care. He was again operated upon, but also without result. The administration of thyroid was begun and for a time seemed to offer promising results. The later history of the case, however, was disappointing, and the writer confesses that the result of thyroid treatment in this particular instance was a distinct failure.

Report of a Case of Exstrophy of the Bladder, with Remarks upon the Operative Treatment of that Condition.—By Bransford Lewis.

Operation for Cure of Large Incarcerated Hernia of Long Standing.—By J. C. Weidman.

Interscapulo-Thoracic Amputation for Osteo-Myelitis of the Humerus.—By G. R. Fowler.

Radical Treatment for Curvature of the Penis.—By Eugene Fuller.

Zeitsch. f. Tuberk. u. Heilstätt., Vol. i., Nos. 1 and 2, 1900.

Some of the Problems Involved in the Tuberculosis Question.—Cornet says that one of the points of the disease deserving attention is that concerning mortality statistics. The figures published heretofore have dealt only with isolated countries, or districts of countries, and have appeared sporadically at uncertain intervals. What is needed is a systematic and searching numerical investigation of deaths from tuberculosis, which shall be an international affair, shall be conducted regularly, and shall embrace not only pulmonary phthisis, but also tuberculosis of every other part of the body. The mortality coefficient to be attributed to the tubercle bacillus is furthermore to be estimated not by comparison with death rates, but rather from the living population, and to this end census taking at five-yearly intervals becomes a necessity, and statistics should also be available concerning the number of inhabitants affected by the disease. A defect that is manifest in much of the work that has been done on tuberculosis, as well as in other branches of medical science, is the habit of hasty generalization from a limited number of case histories or animal experiments. Questions that require further investigation are those dealing with the biology of the bacillus, its life history in the body, the conditions that determine its rate of proliferation, virulence, etc. The significance of the lymph glands in influencing the establishment of tuberculous foci, as well as the possibility of the tonsils as affording portals of entry for infection, and the changes produced in the course of the disease by mixed infections, are not yet well determined. Of the aids to diagnosis the diazo reaction of Ehrlich and the Roentgen rays have both yet to establish definite claims for recognition. The question of therapy is still very unsettled, especially the treatment of hæmoptysis and hemorrhage, which has not advanced beyond the purest empiricism.

The Conditions of Infection by Tubercle.—Arthur Ransome says that the conditions necessary for infection by the tubercle bacillus to take place are: (1) A virulent state of the microbe; it is often overlooked how easily the bacillus loses its power of infection. (2) The bacillus needs a certain kind of organic impurity upon which alone it can sustain its virulence. Tuberculosis is essentially a "filth disease," and seldom spreads unless organic impurity is present in houses, workshops, or places of public assembly, and this is generally to be discovered in the aqueous vapor of the air of these places. (3) The third condition of infection is that it must have a susceptible body to attack; race, age, and hereditary tendency all influence this factor. (4) The danger of infection from food is the last and least important factor, inasmuch as perfect sterilization by heat is possible; although the bacillus stands freezing, desiccation, and putrefaction, and resists nearly all the aerial disinfectants, it is easily destroyed by a moderately high temperature. In deducing from these conditions the factors necessary to prevent infection he concludes: (1) All tuberculous matter, sputum, etc., must be destroyed or rendered innocuous by disinfection. (2) Houses inhabited by consumptives should be subjected to a thorough cleansing and disinfection, preferably by Delépine's method of washing all surfaces with a one-per-cent. solution of chloride of lime. (3) Local sanitary authorities should use all the means in their power to render the districts under their control healthily habitable; the same obligation rests on owners of property. (4) Legislation should enforce ventilation of workshops, theatres, etc., and forbid expectoration in public places. (5) The State should insist on the use of the tuberculin test for cattle; meat and milk should be sterilized by thorough heating before use.

The Choice of Tuberculous Cases Suitable for Sanatorium Treatment.—Moeller deprecates strongly the tendency common among both the profession and the laity to consider the sanatorium as the forlorn hope of the consumptive. The always beneficial and often absolutely curative effects of sojourn in pure air, suitable diet, and strictly regulated habits, coupled with avoidance of psychical excitement and bodily exertion, have been too incontrovertibly demonstrated to permit of any difference of opinion as to the value of sanatorium treatment, and the difficulty is mainly one of, firstly, recognizing the disease at a sufficiently early stage, and, secondly, of persuading the patient that his condition is serious enough to demand such radical measures. Cases in which the prognosis is most favorable are those in which the lesion is unilateral and involves the apex; when there is no febrile movement, the digestive organs are not affected, the urine is free from albumin and does not give the diazo reaction, and the general condition has not greatly depreciated. Very unfavorable, on the other hand, is the prospect in those patients the victims of typical "consumption," commonly hereditary in young individuals of markedly phthisical habit; in those who have tuberculous lesions in other parts of the body in addition to the pulmonary involvement, also in those stages of the disease in which cavity formation has taken place, or both apices or a lower lobe are affected.

"Drop-Infection" of Tuberculosis and its Prevention.—B. Fränkel advocates the use of masks of gauze covering mouth and nostrils as almost a necessity in preventing dissemination of the bacilli by patients in the acts of coughing, sneezing, etc. The use of the handkerchief in place of a mask is uncleanly and not a sufficient protection, for the suddenness of onset of a paroxysm of coughing nearly always means infection of the air before the handkerchief can be applied. Inoculation of guinea-pigs with portions of material cut from the masks after twenty-four hours' use by patients in whose sputum the tubercle bacillus was demonstrable, gave a positive result in every instance. This was so even though care was taken to use for the experiments only those portions of the gauze which were quite spotless macroscopically, demonstrating the danger to be apprehended from "drop-infection." Recognizing the many difficulties attempts to introduce the universal employment of masks will encounter, the author has sought to devise some less objectionable substitute, but unsuccessfully, and advises the use of the masks in all cases in which the patient is forced to live in the same room with the healthy without their being separated by a distance of more than three feet.

The Inheritance of the Locus Minoris Resistentiæ in Pulmonary Tuberculosis.—Turban says that the extreme rarity of direct hereditary transmission of tuberculous infection is universally recognized, as also the fact that a tuberculous family history does not necessarily increase the gravity of the prognosis when the disease is contracted. The question of hereditary predisposition, however, is still a mooted one, though the statistics collected by the author would seem to give pretty positive evidence in favor of the theory. Out of fifty-five families, in eighty per cent. children or brothers or sisters were found who were suffering from tuberculosis as well as heads of the families, and a significant fact is that in most of these the lesion was situated in corresponding points of the lungs. The evidence is apparently greatly in favor of an inherited point of lessened resistance, and according to the investigations of Birch-Hirschfeld this would seem likely to be due to a failure in development, which he has found most frequently to involve the region supplied by the posterior apical bronchus.

Respiratory Exercises in the Treatment of Pulmonary Tuberculosis.—Schultzen says that the value of voluntary respiratory gymnastics (as opposed to inhalations of compressed air, the pneumatic cabinet, etc.) in the treatment of pulmonary tuberculosis is still contested by many eminent authorities. He advises it in from sixty-five to seventy-five per cent. of the usual class of cases, and finds that both the general condition of the patient and the diseased focus are favorably affected. The most suitable and satisfactory method consists in carefully graduated and regulated mountain climbing, but this is often not feasible owing to the patient's debilitated condition, and may advantageously be replaced by full, deep, slow inspiration immediately followed by somewhat forcible expiration. This is to be kept up all day long, at first every half-hour two to six times in succession, later at intervals of fifteen minutes.

The Agglutination of Koch's Bacillus; its Application to the Serum Diagnosis of Tuberculosis.—Arloing and Courmont, after a careful series of observations and experiments with different methods of technique, conclude as follows: (1) It is possible to obtain pure cultures of Koch's bacillus from glycerin bouillon and to grow successive generations by careful technique. (2) Using these, it is possible to get a definite serum reaction; in the healthy the blood serum occasionally agglutinates at a proportion of 1 : 5; in the tuberculous usually at a strength of 1 : 5 to 1 : 20. (3) This reaction may serve to diagnosticate ordinary cases and detect latent cases in those apparently healthy. (4) In spite of the technical difficulties to be overcome, the reaction by reason of its harmlessness and its rapidity deserves extended application.

The Curability of Tuberculosis.—Schrötter, without in any way discrediting the value of prolonged sojourn in warmer regions, such as the Riviera, in the treatment of phthisis, warmly recommends that each country should make the most of its own climatic and other advantages, and affirms that by carefully conducted sanatoria erected in well-selected regions it is possible to give the poor at home the same chance for restoration to health that the rich are able to procure by travelling. That even when taken in the later stages the disease may be arrested in cases that seem hopeless, is evidenced by a history quoted in full, but ordinarily the sanatorium cases should be those still in a less advanced state.

The Value of Meat in the Preventive and Curative Treatment of Pulmonary Tuberculosis.—F. Parkes Weber directs attention to the infrequency with which tuberculosis and gouty diseases are found in the same individual, and suggests that there may be some substance circulating in the blood of gouty subjects, in minute quantities, yet sufficient to have an antagonistic action toward the growth of tubercle, and that this is likewise the case in persons taking an unusual amount of food. In accordance with this view he advocates the use of a preponderatingly proteid rather than carbohydrate diet in tuberculous individuals, laying stress on the necessity for seconding the treatment by abundant out-of-door exercise.

The Significance of Tuberculosis as a Cause of Premature Death among the Adult Population of Germany.—Rahts presents a review of statistics showing that of those dying of known causes in Germany between the ages of fifteen and sixty years in 1893, thirty-three per cent. succumbed to tuberculosis; in 1896, 33.4 per cent.; and in 1897, 33.5 per cent., evidence that the proportion of deaths due to this cause is by no means on the decrease.

Zeitsch. für klin. Medicin, Bd. 40, Hft. i. and ii., 1900.

The Relation of Charcot-Leyden Crystals to the Eosinophile Cells.—Benno Lewy states that the Charcot-Leyden crystals are found in leukæmia (all structures), in the expectoration of numerous thoracic diseases, in nasal polypi, in various tumors, in the fæces (helminthiasis), and in normal bone marrow. It is shown that as soon as the eosinophile cells appear in very few numbers no Charcot-Leyden crystals are excreted, but when eosinophile cells appear in abundance, the crystals can always be found. Wherever crystals occur eosinophile cells are in abundance; where no crystals exist the eosinophile cells are few or altogether wanting.

A Case of Pernicious Anæmia with Yellow Bone Marrow in the Epiphyses.—C. S. Engel describes the above case and considers it an instance of the aplastic form of pernicious anæmia. Contrary to the usual forms of pernicious anæmia, no red bone marrow was found in the diaphyses, but yellow marrow in these, as well as in the epiphyses. The ribs contained a dirty gray, watery fluid which, microscopically, was utterly devoid of cells. The fluid consisted of numerous immobile bacilli which were easily stained with Loeffler's methylene blue; in addition to these detritus and fat particles could be demonstrated.

The Pathological Changes in the Digestive Tract in Pernicious Anæmia and the So-Called Intestinal Atrophy.—Knud Faber and C. E. Bloch state that it may be generally accepted that in pernicious anæmia, idiopathic as well as that due to bothriocephalus latus, atrophic inflammatory processes are found in the stomach and intestinal tract. Histories of several cases, microphotographs, and an extensive literature accompany the article.

Diplogonoporus Grandis (R. Blanchard).—Tomei Kurimoto describes a particular kind of bothriocephalus, found for the first time in the human intestinal tract.

A Simple Method for the Direct Estimation of the Color of the Blood.—By T. W. Tallquist.

The Mobility of the Heart upon Change of Position (Cardioptosis).—By H. Determann.

Clinical-Chemical Studies.—By C. V. Stejskal and F. Erben.

Observations upon the Mechanism of Circulation.—By O. Rosenbach.

A Case of European Chyluria.—By W. E. Predtetschensky.

MEDICAL COUNCIL—CLINICAL SOCIETY—GASTRO-ENTEROSTOMY FOLLOWED BY PYLORECTOMY—ANTISTREPTOCOCCUS IN SEPTICÆMIA—GRAVES' DISEASE—THE ANTIS ON MR. PAGET'S BOOK—THE INTERNATIONAL MEDICAL CONGRESS.

LONDON, June 1, 1900.

THE General Medical Council continued its sittings up to last night. On Friday penal cases were resumed, and they occupied Saturday also. Several names were ordered to be erased from the register. The council is not a body well adapted for judicial inquiries, but it manages to get through this duty with fairness, though its processes are very slow. Entering its second week of work, the first subject on Monday was the prevention of personation. This is an offence which has been actually committed, and one would therefore imagine obvious precautions should be enforced. But these learned councillors seemed to have doubts. Some of them thought it would be a serious departure from routine to require applicants for registration to fill up and sign a form in their own handwriting. The registrar of the Scotch branch has always done this, but the English registrar thinks it would impose a heavy responsibility on him. It is hard to see why the registrar should have been asked for his opinion. He said the difficulty was there being three offices. But a common-sense precaution which has always been taken in Scotland as a matter of course could impose hardships on no one. So if "the man in the street" picked up a lost diploma he might go into the office and register himself in the name it bore—and if it bore the signature of the man to whom it was granted, as many diplomas do, he would not be asked to sign his name to the application, and the registrar might object to the trouble of comparing them. Could you imagine a clearer exemplification of "how not to do it"?

Another important question related to reciprocity of practice between this country and Italy. The council has shilly-shallied so much over this that the Privy Council has intimated its intention to act in the matter. There was much talk on this communication, and at last it was agreed to represent to the Privy Council that the Italian project did not make reciprocity equal between the two countries. Medical aid associations were also talked over, and a deputation was received. There was a report, too, of the committee, but the matter is to come up at a future session. As much may be said for some other reports and questions.

Thanks were voted to the pharmacopœia committee, and other usual votes passed.

On Friday Mr. Barker read at the Clinical Society notes of a case of gastro-enterostomy followed by pylorectomy. The patient was a woman aged fifty-five years, with a tumor to the left of the left rectus under the border of the ribs, and partial intestinal obstruction. It was thought to be a growth of the splenic flexure of the colon, and the abdomen was opened. Then it was found to be a carcinoma of the pylorus. Consequently retro-colic gastro-enterostomy was at once done. Recovery was rapid, and five weeks later the whole of the pyloric end of the stomach was removed. The resulting openings in it and the duodenum were closed. The patient recovered, gained flesh, and was soon eating ordinary food; but recurrence took place, and she died a year later. The first operation was done under local eucain analgesia, the second under chloroform. Murphy's button was employed and came away on the twelfth day. Mr. Barker thought the operation was facilitated by doing it in two stages, but it should never be done except for malignant disease.

Mr. Bidwell said he had operated in the same manner and approved of doing it in two stages. In one case done in one stage the patient died in ten days from adhesions of the jejunum resulting in a kink, to prevent which he suggested that the loop attached to the stomach should not be too close to the duodenum. If it were, regurgitation of bile into the stomach might occur. He liked Halsted's method of suturing, and thought about eighteen days between the two stages a suitable interval.

Dr. Victor Bonny read a paper on a case of septicæmia treated by anti-streptococcus serum and later by nuclein. Of the former, forty-two injections, amounting to 420 c.c., were given in seventeen days. Of the latter, 30 c.c. of a one-per-cent. solution was injected in the course of eight days, during which the temperature fell and convalescence began. There was a suspicion of a gonococcus in one of the examinations of the blood, but confirmation was prevented by an accident. So, though Dr. Bonny thought it improbable, the case proves nothing, for cases of gonorrhœal pyæmia may go on to an extreme degree and yet recovery take place in a remarkable way.

Dr. Pasteur communicated the sequel to a case of Graves' disease shown in April, 1898. A widow, aged sixty-seven years, had the disease for twenty years with tachycardia. The thyroid dwindled, and gradually bradycardia supervened. Whether this last was due to degenerative lesions of the heart or to myxœdema coming on was a question. The latter was the general opinion. A degree of thyroid atrophy in the wake of Graves' disease is interesting. The heart lesions found at the post-mortem did not seem to account for the course of the disease, and the nervous system had not been investigated.

Mr. Stephen Paget's book on "Experimentation on Animals" having been published on your side of the Atlantic as well as this, your readers can easily satisfy themselves as to the moderation of his statements. The anti-vivisectionists here are terribly disconcerted and have put up Mr. Stephen Coleridge as their advocate. He is a counsel and, perhaps naturally, adopts the professional methods of the special pleader without realizing how inappropriate they are to discussions of scientific matters. He would be wiser if he were to cultivate the judicial frame of mind, and certainly more worthy of his distinguished father. But, as I said, he is advocate for the anti-vivisectionists. I do not know whether they pay him for his efforts, but lawyers are not much given to gratuitous work. He has been working the press as well as he could. On Monday I received from the editor of *The Morning Post* a copy containing a letter of his to Mr. Paget complaining of an inaccurate quotation of one of the official certificates, and Mr. Paget's reply that he had quoted the early form instead of the revised one and thanking him for pointing it out. This courteous reply strikingly contrasts with some of Mr. Coleridge's effusions. He seems to take the counsel's liberty of abusing the opposite side to an extent that betrays the emptiness of his case. The journals have treated his one-sided statements as if they were serious arguments, and so we have had long-drawn-out letters leading to nothing. One of your contemporaries has admitted letter after letter of his controverting its review of Mr. Paget's book; but even now Mr. Coleridge is not satisfied. How can a man be who takes up the advocacy of such a craze, and is not qualified by education to discuss medical matters? He has been treated too kindly by the press, perhaps out of respect to the memory of his father, but he ought to know better than to take advantage of this leniency. In one of his letters he whines about Lord Lister not replying to his several challenges to discussion. For my part I think Lord Lister is quite right in maintaining a dignified silence toward a professional advocate whose equipment for scientific debate is so feeble.

On the morning on which the correspondence in *The Post* appeared the newspapers gave information as to some of the barbarous practices of dishonest horse dealers. But these and other cruelties do not seem to attract much attention from anti-vivisectionists and their advocates. Truly the anomalies of human brains seem innumerable.

The International Medical Congress, which will be held in Paris from the 2d to the 9th of August inclusive, has not at present attracted much attention here, but is beginning to be spoken of. Four gentlemen have been appointed to represent the British government officially, viz., two Indian medical officers, one naval, and a local board commissioner (Ireland). Members are asked to send in the titles of their papers before the 10th inst.; if later, they will not appear in the prospectus. Members can join up to July 15th. The fee is 25 francs, and the ticket entitles the holder to a reduction on French railway fares and free entrance to the exhibition. Paris will be full and expenses high.

OUR PARIS LETTER.

(From our Special Correspondent.)

IMPORTANCE OF SANITARY CONDITION IN PARIS DURING THE EXHIBITION—STATISTICS PUBLISHED—CASE OF SMALLPOX—BUBONIC PLAGUE AT PORT SAID—ARTICLES BY LOCHELONGUE AND NETTER—ACCIDENTS AT THE EXHIBITION—AMBULANCE SYSTEM—NECESSITY OF AN AMERICAN HOSPITAL IN PARIS—EXHIBITION OF THE CITY OF PARIS.

PARIS, June 1, 1900.

Now that the exhibition is in full swing, crowds of foreigners and of provincials are flocking to Paris to see the sights, and the health of the city as affected by this rapid influx of visitors is one that merits attention. Any serious outbreak of typhoid fever or smallpox, any hint at the existence of plague in some part of France would be fraught with disastrous consequences. When we consider how many different nations are represented in Paris at this time, and how primitive are the sanitary conditions that obtain among them, it is perhaps to be wondered at that no serious outbreak has as yet occurred. The necessity of vaccination has indeed been insisted on, and to give an example in a humoristic line, Caran d'Ache, the celebrated cartoonist, published recently in the *Figaro* one of his exceedingly clever series of drawings, in which he showed, as a "*clou*" of the exhibition, a procession of medical men, physicians of the hospitals, internes, and aids, all dressed in the garb of the time of Molière, and all prepared to vaccinate the dusky tribes who will furnish amusement at the exhibition. The statistics published so far by the city of Paris are very encouraging, no cases of smallpox being noted in the last weekly report. I must add, however, that last Saturday, on going into one of my former wards at the Beaujon Hospital, I came across a patient just received, who had an eruption resembling that of smallpox. On questioning him, the general history of the case seemed to be that of this infection, with the exception of the pain in the back. The man had just arrived from Lyons, where smallpox would seem to be prevalent. On inquiry I found that the diagnosis of smallpox had already been thought of, and that the man was to be sent to Aubervilliers, a locality close to Paris, where there is a special hospital for such cases.

What is more to be feared than smallpox is the possibility of an epidemic of bubonic plague. The newspapers are daily reporting cases in Port Said, where forty-eight cases have already been declared, with a total of twenty-two deaths. This epidemic was denied at first, and a certain foreign element tried to prevent the health officers from getting to their patients and carrying out the work of disinfection. These obstructionists, as they were called by the newspapers, were, however, overpowered, and it was shown that the French physician who had reported the first case was in the right. A case was reported yesterday at Alexandria, another has been discovered at Smyrna, and a sensation of uneasiness cannot but be felt. Stringent measures have been carried out, however, and it is to be hoped that the disease will not spread.

It may be mentioned in relation with this question that a good article was written recently in the *Presse Médicale* by Dr. Lochelongue, sanitary officer in Egypt, on the bubonic plague and the convention of Venice in 1897. This article showed how the recent knowledge acquired as to the origin and means of propagation of the plague necessitated a change in the regulations concerning quarantine, the old system being quite faulty. Moreover, new lines of traffic, due to the constructing of railways through Asia Minor and Arabia, would naturally completely remove whatever usefulness the Suez Canal may have offered as a sort of filter by which any suspicious cargoes or ships could be arrested. A map accompanied this article, showing the different routes to be followed. A railway, starting from the Indian frontier, has been constructed in Afghanistan as far as Chaman. The Russians are already at Kouchk. The English, the Germans, and the Russians have already mapped out various lines through Asia Minor and Arabia, and these will most likely be constructed in a few years. The classification of merchandise into two distinct categories—on the one hand such articles as rags, old clothes, hair, and leather, on the other anything not comprised in the previous enumeration—is insufficient. Such articles as rice, grain, and breadstuffs can be contaminated by rats, and yet they cannot be prohibited or disinfected. The only way out of this dilemma is to establish, as Dr. Lochelongue said, a species of intermediary quarantine between the ships on one side and the warehouses on the other. Such is the plan that can be carried out in Egypt by the use of "chalands," or large cargo-boats, used to receive cargoes. Dr. Lochelongue demonstrated also in his article that the present regulations concerning ships in quarantine were inadequate. It is not sufficient, for instance, that no death should have happened on board during the voyage, as the hold may be already infected and an outbreak among the passengers may be on the point of showing itself. Then, too, a port is considered safe when ten days have elapsed without a death, and yet the mice and rats may still be suffering from the plague. Dr. Lochelongue ended his article by saying that quarantine, as practised at present, was quite inadequate, and he cited as a proof of this the fact that, railway quarantine being abolished at present, passengers could go direct by rail from Alexandria, which was plague-stricken, to Suez, whereas if they went by sea they had to undergo a quarantine of eight days.

Since the opening of the exhibition two very serious accidents have occurred, due to the haste with which the buildings were put up. A bridge in the Avenue de Suffren, built of wood and what is called "cément armé," gave way and crushed a comparatively large number of persons who were passing below. The bridge had not yet been opened to the use of the public, but the shoring had been removed too soon, it seems. Some scaffolding in the large central hall in the Champ de Mars also gave way, and four men who were working at a great height were killed. Two central ambulance offices have been established inside the exhibition, and there are at all times medical men in attendance ready to render any assistance in case of need. There is getting to be less and less room in the Paris hospitals, on account of the increase in the population, and with the present influx of visitors all the hospitals will be full to overflowing. The result will be that needy foreigners will have some difficulty in finding accommodation when taken seriously ill. The English population of Paris has, of course, its own admirably constructed hospital, the funds for which were given by Sir Richard Wallace, but there does not exist anything of the sort for Americans, and it is more than likely that the need of such an institution will be felt very much during the exhibition. It happens now and then that an American is taken to one of the French hospitals, where, not knowing French, and being surrounded by patients who are not always well disposed toward foreigners, he is certainly not placed in the best conditions for making a rapid recovery. Of all the hospitals in Paris, the one best suited for sending Americans to is that of Boucicaut, as it comes up in its general style and arrangements to what Americans are accustomed to.

I visited this morning a part of the exhibition which is calculated to excite the curiosity of physicians. It is the exhibit made by the Assistance Publique in the pavilion of the City of Paris. If one enters by the Champs-Elysées gate, which is certainly the finest by far and the most impressive, he should go down the right bank of the Seine till he comes to the Pont des Invalides, cross over the temporary wooden bridge, and enter the building which is at the right of the Invalides bridge. The building is in the form of a large hall, with a gallery running around it. In the centre is a reservoir, which is to be filled with water from four different sources: the Seine, the Ourcq, the Vanne, and the Aure. The first two are used only for washing purposes, according to the sign that is put up on each tank. In a room near-by are exhibited cultures of the different microbes to be found in Paris water. Near the door there are some charts showing the mortality from contagious diseases in some of the large towns in France. Special notice should be paid to a chart showing the prevalence of typhoid and scarlet fever in Paris during the last year. In one month there were seven hundred and twenty cases of typhoid fever and in another month seven hundred and eighty cases of scarlet fever. Diphtheria is decreasing, but the mortality during the last three years is about the same. Still further one comes to the veterinary section, where are shown maps indicating how Paris and its environs are divided into a certain number of districts for the inspection of horses and cattle, specimens in wax of curious lesions such as glanders or actinomycosis, and some large intestinal calculi of the horse. Then there are some good drawings in color of different varieties of mushrooms. The exhibit of the Assistance Publique comes next, and is certainly not very extensive. The most curious thing is an old four-poster bedstead, dating from the last century, and coming from the "Hôtel Dieu, confession 80," so reads the sign. This bed is covered with red tapestry and a green baize cloth, and four wax manikins have been figured, three in the bed and a fourth warming himself beside a brazier. This bed was only exceptionally used for four patients. Different pots and pans are also exposed, so as to give one some idea of the way in which people were taken care of in the hospitals at the end of the last century. A drawing is hung on one of the posts, and it represents the Duke of Chartres bleeding a patient, while his tutor is standing by. On the opposite side of the room is a modern bed, such as is used at the Boucicaut hospital. It is constructed wholly in iron, and is flanked by a night table in iron and porcelain. Plans of different hospitals are hung up on the walls, and surgical instruments, such as they were at the time of Dupuytren and as they are nowadays, are also exposed. Further on one can see a model destined to show how the beds are arranged with glass compartments at the isolation pavilions at the Enfants-Malades Hospital. It consists of a high glass case which reaches to the roof of the ward. An extremely curious object is the "tour des enfants assistés," destined to receive foundlings. It is a sort of crib in a large cupboard placed in the wall of the establishment, and which can revolve on itself. When a child was abandoned, it was placed in this crib, the bell was rung, and the guardian inside the hospital turned the cupboard so as to be able to take the child out. In this way the person who left the child could not be recognized by the doorkeeper. This "tour" was used up to 1860, when it was replaced by an open office, where the children were inscribed. In former years most of these poor children died. Dr. Sevestre and, later on, Dr. Hutinel have done much to ameliorate the hygienic conditions of this Hôpital des Enfants Assistés. Interesting statistics as to the mortality of patients in the hospitals are also shown, and there is a chart indicating the number of foreigners of different nationalities who are taken care of in the different hospitals. In 1888 there were 135,000 patients admitted, and 7,782 were foreigners; in 1899 there were 195,000, of which 9,530 were foreigners. Of this number the greater part were Germans, about 3,200, Italians, Swiss, and Belgians coming next, the English numbering only about 180, and the Americans 85 to 90.

SOMETHING ELSE TO DO FOR SEA-SICKNESS.

To the Editor of the Medical Record.

Sir: Great minds think alike. I have read with deep interest Dr. Herman Partsch's article on what to do for seasickness, in the issue of June 9th. To every word he has written I can say "That's right!" I have been there and know it is all true, for experience is a very good instructor. I can truly claim, I believe, the rather dubious honor of being the champion seasick man of the universe. I always go to sea with a bottle of beef tea at one of the head corners of the berth and a bottle of strong tea at the other; and take a dose after each paroxysm. This prevents the desire for being cast overboard. But Dr. Partsch has forgotten the greatest of all alleviations, viz., ice at the nape of the neck and base of the brain. I was informed as to this remedy by a stewardess on the old Guion Line many years ago. I never knew her name and I don't remember how she looked; but I love her still. On this particular trip I was taking my bride abroad on a wedding-trip (as a rule this is not a recommendable thing to do), and I was so sick that I did not care whether I vomited on my bride from my upper berth or not. After observing me profoundly for two days this good stewardess spoke to me as follows: "You are the sickest man I ever see." Then she went and got the ice, and I lay on it with perfect comfort for the rest of the voyage. I would recommend all those inclined to this terrible evil of the sea to provide themselves with a small rubber bag for an ice-water pillow for the week. Those who have never had this agony may laugh; but not those who have been so stricken.

J. M. W. Kitchener, M.D.

East Orange, N. J.

Poisoning by Hydrogen Arsenide.—An aeronaut was recently poisoned by hydrogen arsenide which escaped from the balloon. This shows the necessity of purifying the hydrogen arsenide used for balloon purposes. The balloon was filled in the ordinary way and nothing peculiar in the odor of the gas was noticed. A few hours afterward persons who had assisted in the operation were taken seriously ill.—*Scientific American.*

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Fifty-First Annual Meeting, Held in Atlantic City, N. J., on June 5, 6, 7, and 8, 1900.

(Concluded from page 1069.)

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

Fourth Day—Friday, June 8.

Post-Operative Treatment of Abdominal Section in Women.—Dr. Walter B. Chase, of Brooklyn, read this paper. He said that, other things being equal, the best after-results in these cases followed proper preparation of the patient and good hygiene. In closing the abdominal incision he recommended the use of chromicized catgut for layer suturing, and silkworm gut when the through-and-through method was followed, the suture not being tied too tightly. He condemned buried unabsorbable sutures, since they remained as foreign bodies liable to cause pain and ulceration. Removal of the through-and-through sutures was recommended after from eight to twenty days, the alternate sutures being removed and the others allowed to remain a few days more. He recommended greater latitude of position after laparotomy than had usually been permitted. In the treatment of shock he advised before the close of the operation the administration of a high rectal enema of a pint of hot salt solution and an ounce of whiskey, together with proper cardiac stimulation. Hemorrhage could be immediately arrested by compression or ligation of bleeding vessels; when practicable the operation should be performed with the patient in bed. Flatulence, nausea, and vomiting, if due to ether narcosis, would subside spontaneously. In nausea he advocated hot water in drachm doses frequently repeated; if vomiting persisted, he gave high rectal enemas of water containing two or three drachms of a saturated solution of sulphate of magnesium at intervals of about two hours until the bowels were opened. If nausea was not present twelve hours after the operation, teaspoonful quantities of hot water or chicken broth at intervals of an hour were given. The quantity might be increased if it was well borne, and it might be followed by beefsteak, lime-water, and milk. The quantity and quality of the urinary secretion should be watched. Evidence of injury to the urinary tract and diminished or suppressed renal secretion, partial or entire, called for prompt and energetic measures, such as saline laxatives, pure water by the mouth, and salt solution by rectal enemas, diaphoresis, and if the arterial pressure was diminished digitalis and persistent dry cupping.

Dr. I. S. Stone, of Washington, agreed with Dr. Chase that morphine was rarely necessary, but there were cases in which patients were apparently saved by morphine. He cited a case in which a patient with symptoms of impending death was remarkably revived by gr. $\frac{1}{8}$ of morphine with gr. $\frac{1}{200}$ of atropine. He had for a number of years used the layer suture in closing the abdomen, but had now discarded it. He emphasized the importance of not using too much medication, finding that better results followed the opposite treatment.

Dr. Reed, of West Virginia, recommended the use of a running stitch of silkworm gut in bringing the fascia together in closure of the abdomen, anchoring the suture at either end. The fascia was thus perfectly apposed, and at the end of ten days or two weeks, by cutting away one end of the shot the strand of silkworm gut came away with ease.

Dr. W. E. B. Webb, of Birmingham, demonstrated the use of a silver wire in the closure of the abdominal incision. The method took the place of the through-and-through suture and did away with the objection to the buried suture.

Dr. Goelet thought that the after-treatment of laparotomy began before the operation, in putting the patient in the best possible general condition. He secured a thorough regulation of the liver and of the excretory organs. When a patient was suffering from shock it was the physician's duty to give morphine; and he had never found any objection to giving it combined with atropine. In closing the abdominal wound he objected to the layer suture because there were apt to be knots in the suture. With deep sutures he tried to avoid the pain by putting on several layers of gauze and tying the sutures over them. In cases of pain and intestinal distention he had seen good results follow the use of asafœtida.

Dr. Ricketts said that anæsthetics had made too many slow operators. He thought digitalis was an over-estimated remedy and that nitroglycerin was overlauded. The best remedy he considered to be the old-fashioned strychnine.

Dr. F. F. Lawrence, of Ohio, stated that good results in abdominal section were secured by short incisions, little manipulations, and short anæsthesias. He thought the effects of the suturing depended more upon the mode of tying than upon the material. If morphine was depended on, it should be given before the patient recovered from the anæsthesia.

Dr. Bonifield said that the thirst after abdominal section was very much increased if the preparatory purgation had been done with salts. This should be accomplished with compound glycyrrhiza. He also urged patients to drink freely of water two or three times before the operation. For the relief of pain he injected phosphite of codeine and chloral into the rectum. The codeine relieved pain and the chloral was given for its quieting effect on the nervous system. The combination acted better than the drugs alone. He thought a patient did not necessarily need stimulants after operation. The treatment should be on the same principle as that of the general practitioners: if the patient required it, a stimulant should be given; if not, it should be withheld, because, if given before it was required, when it was needed there was nothing to depend on. Regarding sutures he thought it a strange statement that there was catgut to be depended upon; and he believed rather that the trouble came from not using enough sutures and there being some capillary hemorrhage.

Dr. Harris said that lest there might be suppuration he rarely allowed the first dressing to remain on more than six or seven days without examination of the wound; also he made it a practice to examine every second day after the sixth or seventh.

Dr. C. C. Thayer, of Clifton Springs, suggested the danger of ileus from handling of the intestines.

Dr. J. C. Biddle thought digitalis, nitroglycerin, and strychnine each had its field. The peritoneum in all cases of laparotomy should be brought closely together; how it should be done was, in his opinion, a matter for each particular operator to decide for himself.

Dr. Engelmann called attention to a suture with which he had no practical experience, but which was advocated by a brilliant young surgeon of Europe—a metallic tier suture which helped to hold the wall in position.

Dr. Chase said, in closing, that he thought our individual experience had much bearing on the rule by which we should work. If doubtful about his own mind, a physician was not in a safe position to work for patients; he must be guided by his convictions, and in so doing he would retain all that was best in his own methods and be able to adopt the good methods of others.

Ovulation and Menstruation Not Independent Functions.—Dr. C. C. Thayer, of Clifton Springs, said that if it was true that ovulation and menstruation were not interdependent, we might regard conception without menstruation as possible. The author quoted instances on record of pregnancy after the climacteric; cases were also quoted of pregnancy occurring before the establishment of the menses, this being a frequent occurrence among the Hindoos. It would seem, then, from literature that menstruation was not an unfailing attendant of ovulation.

Contribution to the Study of Dysmenorrhœa.—Dr. George Tucker Harrison, of New York, drew attention to the importance of this subject to the general practitioner, as well as to the gynæcologist. He showed that light had been thrown on symptoms by recent investigations regarding the innervation of the uterus and ovaries.

The Treatment of Menorrhagia (Dysmenorrhœa) of Pelvic Origin by Electricity.—Dr. G. Betton Massey read a paper with this title. Menstrual pain, he said, was not due to obstruction, but to the attempt of nature to perform a cyclic function with organs that were underdeveloped or diseased. The obstruction theory had been disproven by Schultz, by the speaker, and others, who found no accumulation, and a canal amply capable of drainage. In the obstinate cases, that had been proved to be rebellious to medicinal treatment of the neurotic elements, he found catarrhal endometritis usually present, and obtained cures by the use of the galvanic pole, preferably mercurialized, within the uterine cavity. Dilatation was condemned as unnecessary and at times harmful. The treatment should not be intrauterine unless a persistent discharge was present.

The papers of Drs. Thayer, Harrison, and Massey were discussed jointly.

Dr. Zinke said that he had ceased to use electricity for at least eight years in the treatment of any gynæcological cases. In all cases amenable to treatment he believed a cure could be obtained without the use of electricity. He thought the most difficult cases were those occurring in young girls, since it was often impossible to make a positive diagnosis without examination.

Dr. Herzog, of Chicago, called attention to two types of dysmenorrhœa—one dependent upon inflammatory changes of the uterine mucosa, the other due to inflammatory changes in the ovary. He also named syphilis as a cause of dysmenorrhœa. He observed that the mucous membrane was not thrown off at the time of the menstrual flow.

Dr. Engelmann said he was much interested in the subject, and had studied the menstrual conditions in school-girls. He believed a great number of irregularities were due to nervous conditions. He had gone over nearly five thousand cases, not of hospital patients, but the so-called well women in educational institutions and in business. Of these seventy per cent. suffered more or less pain at the time of menstruation; thirty per cent. suffered severe pain, which increased with the amount of study, diminishing and ceasing during vacation times. He thought the possible nervous cause should impress upon the profession the importance of general management of the case in young girls without examination in order to see what could be attained. He knew that a great many able men said in regard to electricity exactly what Dr. Zinke had said; but his own experience was distinctly at variance with that. He liked the effect of electricity, but he would be unwilling to rely upon it. He would say that, as one of the means of treatment, in its proper place it was as potent and reliable as any remedy we had. It must be used at the proper time, precisely as a drug was given under certain indications. This was also true in regard to inoperable tumors. He was sorry to hear a man whose word was so authoritative as Dr. Zinke's expressing himself as he had.

Dr. Bonifield was surprised at the statement that a large accumulation of fluid in the uterus at the time of menstrual flow caused no pain. It had been his experience that such patients suffered the most pain. Dr. Herzog's observation that the mucous membrane was not thrown off largely at the time of the menstrual epoch, he stated was the very latest observation on that subject. He granted that Dr. Massey might get the results he claimed, but believed that other men claimed just as good results in other ways less objectionable and less troublesome. His method was to pack the uterus with a gauze tampon and produce a miniature labor.

Dr. Laurence said that painful menstruation was not a disease but a symptom; and he believed dysmenorrhœa should be eliminated as a disease from gynæcological nomenclature. He thought the fact should be borne in mind that there were pelvic and uterine and tubo-uterine affections which belonged to the constitutional disorders as did chlorosis and anæmia.

Dr. Zinke did not wish to convey the impression that he had absolutely a distaste for electricity; but there was no case on record in which the use of electricity produced a cure of any diseased condition of the internal genitalia. It might give relief, but personally he had seen no cases in which this was so.

Dr. Thayer was greatly in favor of electricity in dysmenorrhœa. He had used it for twenty years, and was more in favor of it to-day than ever before. Aside from the anatomical malformations, he would say that the more important cause of dysmenorrhœa was a neurotic one. Electricity entered along the line of hygienic and constitutional treatment.

Dr. Massey said, in closing, that he did not want to be behind Dr. Harrison in his homage to Marion Sims, but the thought occurred to him recently that the day of authority in medicine had passed away sometime after he had graduated; that more harm had been done by the blind following of authority in medicine than could be computed. Facts, and not the personality of the man bringing them forward, were wanted. Sometimes great personality led to great error. He referred to the incurable kind of cases and the kind supposed to come to the surgeon. He could not too strongly corroborate the remarks of others, that needless examinations should not be made.

SECTION ON PEDIATRICS.

Third Day—Thursday, June 7th.

Diabetes Mellitus in Children.—Dr. Leopold F. Haas, of New York City, presented this paper, which was read by the secretary. The etiology was said to be still very obscure. Dr. Heinrich Stern, of New York, had collected the histories of one hundred and seventeen cases. These cases were published a few years ago. Phthisis and gout predisposed to this disease. In most of the speaker's cases a family history of one or the other of these diseases was present. The clinical histories of two cases of diabetes were given, in which both patients had what was known as "adenoid habitus." The first case was that of a girl nine years of age, who gave a rheumatic history. She was taken with some fever, pains in the joints, and palpitation of the heart. A rash appeared around the joints affected, with a burning sensation. It was noted that the rash was not itching in character. The child had enlarged tonsils and frequently wet the bed. The usual drugs, such as codeine, etc., were tried with slight improvement. The second case occurred in a boy as the result of being run over by a bicycle. The urine was 1.044 specific gravity, and contained ten per cent. of sugar. He was placed upon restricted diet. Three months later the patient had an attack of measles, and the sugar in the urine was reduced to four per cent. Dr. Haas concluded that diabetes in children was much more common than was generally supposed. He thought that a family history of tuberculosis predisposed to diabetes, and drew attention to the possible connection of this disease with peliosis rheumatica.

Dr. Heinrich Stern, of New York, said that diabetes in children occurred most frequently between the fifth and ninth years, and that he thought this disease was one of development, with some nervous disturbance, probably located in the medulla. He did not think it was due to any physiologico-chemical substance.

Dr. Louis J. Lautenbach, of Philadelphia, spoke of adenoids in this disease. He said that they expressed some deep-seated condition that as yet was not absolutely determined. It was the rule, however, to remove them.

Dr. Louis Fischer, of New York, said that, judging from his German clinic, he thought that cases with a tuberculous family history represented the type of this disease. In one case that he had, there was none of the cardinal symptoms, but there was one per cent. of sugar in the urine. He said that it was his rule to examine the throats of all children coming under observation.

Purpura Hæmorrhagica, or Scorbutus.—Dr. Henry E. Tuley, of Louisville, presented this paper. He spoke of the great difficulty met with in isolated cases, in differentiating between scorbutus and purpura hæmorrhagica. He thought that purpura was an acute infection having its origin in the gastro-intestinal tract. He also gave the classical symptoms of scorbutus, and added cachexia. He said that it was caused by error in diet associated with unhygienic surroundings. He then reviewed the history of a case, that of a young child fed on corn. Symptoms of diarrhœa developed with bloody stools. Spots appeared on the knees, and the lips and teeth were covered with dried blood. The gums bled easily.

Dr. J. P. Crozer Griffith, of Philadelphia, said that there were many diseases in which purpura occurred, and that the eruptions shaded into one another. He said that the purpura in rachitis was around the swollen joints, while that in urticaria was not so marked. In angio-neurotic œdema there were certain eruptions. The name "purpura," like "jaundice," had several meanings.

Dr. Cotton, of Chicago, said that spongy gums did not necssarily mean that the case was one of scorbutus. He thought that it was an accidental condition in a good many cases. It was also found in purpura as well.

Dr. Burnes, of Arkansas, said that scorbutus was common where he lived. He mentioned two cases, one following a fall, the other a case of malaria with severe chills. The patient refused to remain in bed. Purpura developed. It was of a bluish cast. Dr. Burnes thought that malaria might be a factor in causing the purpura, as it was a great blood destroyer.

Dr. Tuley closed the discussion. He said that the term "purpura hæmorrhagica" should not be used and that the disease should be classified as scorbutus.

The Value of Blood Examinations for Diagnostic Purposes.—Dr. J. Brandeis, of New York, read this paper. He dwelt on the importance of blood examinations, and spoke of accurate diagnosis in chlorosis, pernicious anæmia, leukæmia, malaria, filaria sanguinis hominis, and relapsing fever. He then spoke of the importance of such an examination in aiding one to make a differential diagnosis, *i.e.*, chlorosis from pernicious anæmia, typhoid from malaria, malignant disease of the liver from other liver diseases. In this way certain doubtful cases were cleared up. He mentioned several clinical cases and gave their histories.

Differential Diagnosis between Abdominal Typhoid and Appendicitis, by Means of the Iodine Reaction.—Dr. S. Weiss, of Vienna, contributed this paper. It was read by the secretary. If a drop of blood taken from the ear or finger, under antiseptic precautions, was treated with iodine, the red corpuscle in healthy persons became yellow, and the white cells were unaffected. In disease, however, the multinuclear cells were stained, and it was of interest to note that the eosinophiles were never affected. This iodine reaction always showed the presence of pus. Cases of appendicitis and perityphlitis could, by this reaction, be differentiated from typhoid fever.

Dr. J. L. Morse, of Boston, said that a few years ago we did not expect anything from the examination of the blood. Now we expected too much. Blood examinations in children differed markedly from those in adults. He thought the so-called pernicious anæmias in children were not such, but were secondary anæmias. The blood of children reverted to the fœtal type. The presence of leucocytosis was very important. In his own experience he had found no leucocytosis in serous pleurisy.

Hydrencephalocele.—Dr. Carl Beck, of New York, read this paper. He reported several cases, one of which gave a history of a fall of the mother during the first month of pregnancy, at which time she broke three ribs. The cases were illustrated by *x*-ray and other photographs. Several cases were operated upon, and brain substance with cerebro-spinal fluid were found to be contained in the tumors. One patient was alive and doing well after operation.

Symmetrical Development; or, Does Our Present School System Develop the Highest Powers of the Child?—Dr. Stuver, of Fort Collins, Colo., presented this paper. What was the best kind of education, was a very important question. It was necessary to develop all the powers of the child, physically, intellectually, morally, and symmetrically. He said that the predominance of physical development over that of the mind was shown in the modern prize-fighter. Children were born with instincts, not with knowledge, and the child passed through all the stages of intellectual evolution. Teachers should have a clear conception of the phylogenetic development of the child. As an aid in this, they should understand the physiology of the brain as well as general hygiene. In speaking of some of the evils of our school system, Dr. Stuver said that the children in the kindergarten were given too much work to do, thus having a tendency to eye-strain. He thought that too little attention was given to the general health of school-children. They needed open-air exercises. The school sessions, together with the recitations, were generally too long. More time should be given to the so-called manual training. The custom known as "cramming" for examinations was a vicious one. The calls of nature were not properly attended to.

School Break-Downs.—Dr. J. Henry Bartlett, of Philadelphia, presented this paper. He mentioned an article that appeared in the *Ladies' Home Journal* which referred to sixteen hundred children between the ages of eight and fourteen years, who were total physical wrecks. The speaker refused to make any statement for fear of hurting some friend's feelings.

He said that break-downs were rarely caused by overstudy, but that such cases usually occurred during periods of development, such as teething and puberty. This condition was more common in girls than in boys, in the proportion of forty-three to seven. He spoke of the important part that the gastro-intestinal tract played in this condition. Eating in haste had become a national habit.

The Care of the Ear in School-Children.—Dr. Louis J. Lautenbach, of Philadelphia, read this paper. He said that the word "deaf" was too often synonymous with "dumb." The frequency of ear disease among school-children was shown by the statement that seven per cent. were deaf in both ears, and twelve per cent. to twenty-five per cent. were deaf in one ear. He quoted Dr. Knapp as saying that one-half of all ear diseases occurred in children before the tenth year. It was necessary, he thought, to submit the children to regular periodical examinations. The relation of nose and throat trouble to middle-ear disease was very important, for the Eustachian tube in children was always open. When a nasal douche was given, some of the fluid would irrigate the Eustachian tube.

Antecedents of Valvular Heart Disease in Children.—Dr. Frederick A. Packard, of Philadelphia, read this paper. In analyzing a number of cases in children who had suffered from previous illness, he thought that endocarditis was secondary to some form of kidney disease. In adults this affection was due to an infection. Angina resulted from endocarditis. Dr. Packard had collected seventy-five cases from his hospital records, and found that rheumatism was a most important factor in cardiac disease, as was also scarlet fever. Measles, chicken-pox, pertussis, and diphtheria had little effect upon the heart.

Dr. Wahrer said that the examination of children's eyes and ears in the rural districts was impossible. In regard to overwork of children, he said that he did not favor the kindergarten system. We sent our children to school too early, and we gave them too much work to do. The child should be examined by the family physician before it was allowed to go to school.

Dr. E. E. Graham spoke of the changes that took place during development, and how they might be modified by overwork. The system of competitive examinations for higher standing in our public schools was a bad one. He spoke of the "played-out" physical condition of medical students, who were adults, and then asked what it must be with children after examinations. The school hours were too long. At the present season all of our medical colleges were closed, but the children must work until the first of July.

Dr. Sutherland, of Nebraska, said that our public-school system, as it stood, was very faulty. In the first place, he thought that the restrictions placed upon the teachers were greater than they should be. The teachers should have more latitude in giving instruction. Secondly, there was too much politics in the school board. Much of the work done was useless. It was quality of work that was wanted, not quantity. The children should study about the birds, rocks, etc.

Dr. Hyatt, of Pittsburg, said that there was no question so important as this one of the schools. He thought that the children should be classified according to their play as well as their studies. Excesses must be avoided. Physiological exercise of the mind and body was necessary. Dr. Hyatt said that the teachers were overworked.

Dr. Frank Allport, of Chicago, said that he was very much interested in the study of the eyes and ears of school-children. Teachers said that they could not tell what was the matter with the children. It was not desired that they should make a diagnosis, but by using a simple letter chart they could tell whether a child had one weak eye or not. He had arranged a series of ten questions relating to headaches, cross-eyes, and whether the child failed to read any or all of the letters of the chart, etc. These questions were not objectionable, and would not cause the child any discomfort. Dr. Allport said that thirty-three per cent. of the children had some eye or ear disease, and twenty per cent. had some nose trouble.

Therapeutic Value of Liquid Air, with a Practical Demonstration.—Dr. A. Campbell White, of New York, read this paper. He said that he had received letters from all parts of the United States and Mexico, asking him for sample packages, and whether it was given hypodermatically or for abscess of the liver. Among experiments shown by him, Dr. White froze a rubber ball, which became brittle; also a peach, a strawberry, a tomato, mercury, and alcohol. To illustrate the force of liquid air, he worked an engine and a pop-gun with it. The composition of liquid air was the same as that of the atmosphere. The nitrogen was the first gas to evaporate, and thus pure oxygen was left. In medicine, liquid air was used in the form of a spray for local anæsthetic effect and as a cautery. Bacteria were not killed by it, but their activity was suspended for some time. The pain and bad odor of carcinoma were destroyed by it. The most promising effect of liquid air in medicine was upon nævi.

Just before closing the following resolution was adopted:

"*Resolved*, That for the benefit of the physical condition and the mental development of American school-children, the American Medical Association recommends the annual and systematic examination of the sight and hearing of all school-children."

Fourth Day—Friday, June 8th.

Athrepsia Infantum: its Diagnosis and Treatment.—Dr. Louis Fischer, of New York, read this paper. He said that if an infant a few weeks old suffered from vomiting and diarrhœa, and this condition was allowed to become chronic, colic and flatus supervened, and a chronic gastro-intestinal catarrh resulted. The neglect of this condition meant a development of the condition known as "athrepsia." Parrot was the first one to describe this disease, and he divided it into three stages. In the first stage the stools were liquid, curdy, and green, and contained an excess of mucus. The abdomen was distended with gas, the tongue was coated; stomatitis was present, and wasting began. In the second stage all these symptoms were intensified. Wasting became marked, and undigested food appeared in the stools. The stools occasionally appeared dark brown, the color being due probably to the presence of altered bile pigment. The child did not sleep, and the mouth became the site of a parasitic stomatitis. The skin was harsh and dry. Small boils or a rash might appear. The temperature was subnormal. In the third stage the child became moribund. Muscular twitchings were present; little or no nourishment was taken, and finally death occurred, preceded by marked convulsions. The greatest number of cases occurred in bottle-fed children, although some were breast-fed. These latter cases were probably caused by the mother's milk being lacking in some chemical constituent. The percentage of proteid was the one most frequently deficient. The treatment, he said, was to remove the cause if possible, with good hygiene and diet. The so-called "cream mixture" was often of service. This consisted of cream ℥ i., barley water ℥ iii., and sugar ʒ i. He then spoke of the different methods of modifying cow's milk. In France, the law forbade the giving of solid food of any kind to a child under one year of age, without the authority of the family physician. Dr. Fischer said that no matter how beneficial boiling or sterilization or pasteurization of milk might be, one could not transform cow's milk into woman's milk; and further, it was a great mistake to believe that modified cow's milk was a full substitute for woman's milk. In closing, he mentioned the process of hydration of milk with hydrochloric acid, and referred briefly to the small percentage of proteid in condensed milk.

Intubation in Private Practice, and its Perfection.—This paper, by Dr. Joseph Trumpp, of Munich, was read by the secretary. There was a tendency in Europe not to use intubation in private practice. One should not attempt to do it without first having practised on the cadaver of animals. In regard to the serum treatment of diphtheria there were seventy-seven per cent. of recoveries. After describing the technique of the operation, the paper gave a critical discussion of the value of rubber tubes in intubation. The author had not seen any ill effects from their use, and stated further that obstruction, excoriation, etc., occurred less often with rubber than with metal tubes.

The Injuries Resulting from Extubation.—The paper, by Dr. Janos Bokay, of Budapest, was read by the secretary. The author referred to certain injuries which were most likely to occur, such as ulceration of the trachea, etc., and considered the best means of their prevention and treatment.

Dr. William M. Welch, of Philadelphia, said that he felt that there was greater danger connected with intubation in private practice than in the hospital. He related a hospital case that ended fatally before the house physician could reach the patient. If this was liable to occur in a hospital, it was evident that the danger would be even greater in private practice. The safest place for such cases was the hospital. In regard to the size of the tube, Dr. Welch said that one selected according to the age of the patient was often too small. He had had one patient who coughed up the tube half a dozen times in one night. The kind of tube chosen was important. He favored the use of rubber tubes, for they were cleaner than metal ones. In a hospital it made no difference. He said that it would naturally be thought that the rubber tube, being lighter, would be coughed up more easily, but in fact the weight of the tube made little if any difference. He mentioned a case in which the exudate was so extensive that the cast of the trachea and bronchi had been thrown off. Making a false passage was only possible in the hands of an inexperienced operator. The tube occasionally fell down into the trachea. Dr. Welch had had one case of this kind in which he did a tracheotomy. In another case on which he was about to operate the patient coughed it up. Ulceration generally occurred about the bulge of the tube and its lower extremity. He thought that the use of antitoxin in intubation cases had been somewhat disappointing. He said that the comparison of cases of intubation before the days of antitoxin with the cases of the present time was unfair.

Dr. Rigg, of Pittsburg, said that he agreed with Dr. Welch as to the hospital care of intubation cases. His own experience had not been so satisfactory as that some other physicians had reported. In regard to antitoxin, he said that its early use was most important. In many cases it was given too late.

Dr. A. Campbell White, of New York, said that before the days of antitoxin fifty per cent. of the cases of croup were saved and only a small percentage were intubated. In the hospital, intubation had been advised only as a last resort. Now that antitoxin was in use, intubation was performed at once, and in such cases the results had been most successful. Dr. White mentioned a case occurring before the time of antitoxin, the patient being brought to the hospital in a moribund condition. Intubation was done immediately, with artificial respiration, and in a few minutes the child was sitting up. It died, however, in a day or two. In such cases now life might be saved by the use of antitoxin. Those cases in which the membrane extended downward were benefited by intubation, though they generally resulted fatally. He mentioned a case in which the tube fell below the vocal cords.

Dr. Louis Fischer, of New York, in speaking of antitoxin, said that it was his rule to give 3,000 units for an initial dose, and, if no abatement of the symptoms took place in twenty-four hours, to repeat it. He said that antitoxin was the best remedy, combined with calomel and rhubarb. He condemned the forcible extraction of the tube after intubation, and said that it resulted only in injury to the parts. He often gave apomorphine in emetic doses to bring off the pseudo-membrane.

Dr. Rosenthal, of Philadelphia, said that unquestionably intubation was oftener done by the general practitioner than ever before. Every case in which he used the rubber tubes had ended fatally, and he thought that Dr. O'Dwyer was right in using the metal tubes. When a tube was expelled, the one next in the scale should be used. He said that it was not diphtheria that killed, but a septic pneumonia. He mentioned cases of heart failure that occurred six weeks after the disease.

Dr. Welch closed the discussion by saying that croup complicated with measles was invariably fatal. He said that the stenosis was due to the intense congestion of the mucous membrane.

Surgical Circumcision; its Technique; Prevention of Infection; its Legal Control.—This paper was read by Dr. Ferd. C. Valentine, of New York. After referring to the flattering compliment paid to him by being allowed to read a surgical paper before the section on pediatrics, Dr. Valentine recited the local indications for circumcision, and the general conditions in which the operation was required even in the absence of local disturbance. He described the technique of a very simple circumcision, and illustrated it by means of pictures taken from his book on "The Irrigation Treatment of Gonorrhœa: its Local Complications and Sequelæ." Insisting that circumcision was a surgical operation, he averred that it should be performed only by medical men and in a surgical manner. He mentioned the fact that tuberculosis, syphilis, and other diseases were frequently communicated to infants by ritual circumcisers. The infants so infected became menaces to public health. If physicians were guilty of such acts, they would certainly become defendants in courts of law. Dr. Valentine advocated the legal prohibition of circumcision unless it was performed by physicians, and urged that devout Jews, who wished to follow the religious rite, could very well avail themselves of Jewish physicians appointed as ritual circumcisers in order to satisfy the requirements of their religion. These physicians could perform the religious ceremonies without violating asepsis and correct surgical technique. The speaker mentioned that those persons circumcised in youth seemed to be less liable to acquire syphilis than others.

Dr. Louis Fischer asked what was the after-treatment, especially in secondary hemorrhage.

Dr. Valentine said that he thought he would be inclined to use suprarenal extract. It was an historical fact that hæmophilia was more common among the

Jews than in any other race. He said that there was only one accident that could occur during this simple operation, and that was a hæmatoma following the cutting of a vein. This would often give rise to systemic disturbances.

Dr. Rosenthal asked what Dr. Valentine would do in the case of a child only a few days old with an impervious foreskin?

Dr. Valentine replied that there was only one thing to do, namely, to slit the foreskin.

The following papers were read by title: "Tuberculosis of the Knee and Hip Joints in Children; its Diagnosis and Treatment," by Edward A. Tracy, of South Boston, Mass; "Floating Kidney in Children," by Isaac A. Abt, of Chicago; "The Symptomatology of Appendicular Inflammation in Children," by Thomas H. Manley, of New York.

SECTION ON MATERIA MEDICA AND THERAPEUTICS.

Third Day—Thursday, June 7th.

Election of Officers.—Dr. N. S. Davis, Jr., of Chicago, was elected chairman and Dr. J. N. Upshur, of Richmond, Va., secretary for the ensuing year.

Therapeutics of Croupous Pneumonia.—This paper was read by Dr. I. M. Allen, of Liberty, Mo. The various forms of treatment of this disease during the past century were outlined. He divided the therapeutic cycles into three periods. During the first epoch blood-letting and emetics were the remedies employed; in the second epoch blistering and expectorants were relied on; in the third or last period a tonic treatment had come into vogue. To Dr. Johnson, of Kansas City, belonged the honor of first classifying pneumonia as an acute infectious disease. It was the practice of the speaker to administer a purgative at the inception of the disease. Digitalis and strychnine were given early in small doses and increased gradually. Alcohol was entirely prohibited. In the later stage of the disease nitroglycerin was given. For specific medication he employed sodium salicylate in doses of gr. xv. every four hours. This was best administered in milk of magnesia. He continued this agent for five or six days. Its value was due to its antiseptic effect on the pneumococcus. The number of pneumococci in the blood and sputa was markedly diminished during its administration. Binz thought that the salicylate was converted into salicylic acid and thus acted as an antiseptic. The antipyretic influence of the drug was also very marked. After the sixth day iodide of potassium and tr. ferri chloridi were to be employed. Oxygen was very valuable. He had obtained positive results in cases of mixed infection from the use of anti-streptococcus serum. He did not restrict the diet unless jaundice was present.

Dr. Boise, of Philadelphia, pointed out the resemblance that existed between the products of the diphtheria bacillus and the pneumococcus of Fränkel. He employed local applications of heat or cold for their effect on pain. Injections of decinormal saline solution were of signal service in many cases. A hospital mortality of twenty-five per cent. corresponded to a mortality of ten per cent. in private practice. Serum therapy offered the best hope for the future.

Dr. Mitchell, of Cincinnati, believed that pneumonia was not an inflammation, but a true toxæmia. He employed hot plunge baths with cold to the head and spine, especially when dyspnœa was marked. This was very valuable in the pneumonias of children. Digitalin and strychnine were given in all cases.

Dr. Hill, of Milwaukee, called attention to the modifying influence of the influenza bacillus on pneumonia. Death resulted (1) from heart failure; (2) from pulmonary obstruction. In all cases he used digitalis during the first two stages and strychnine in the last stage. He believed in external applications for their dilating effect on the capillaries of the surface.

Dr. Melvin, of Saguache, Col., said that the country physicians throughout the West believed that prompt administration of veratrum viride caused the crisis to appear earlier than usual. It certainly modified the course of the disease. Aconite in his practice had been most useful. His cases seldom had a crisis later than the fifth day. Later on digitalis should be employed. The mortality was very much lower than with other plans of treatment.

Therapeutics of Vertigo.—Dr. J. Leonard Corning, of New York, read this paper. He said that vertigo could not be regarded as a derangement induced by morbid forces acting upon the semicircular canals. Considering the multifarious origin of this affection, an action of this kind was physiologically unthinkable. By investigating the condition of the mind during vertigo, and by determining the modification of the reaction time, the writer was able to demonstrate an impairment of the higher mental faculties. To carry out these researches he invented and employed a very ingenious apparatus consisting of a revolving chair of unique construction and a recording apparatus with appropriate electrical connections. From these researches he concluded that vertigo, however produced, must be regarded as a cortical difficulty. Also it was found that the reaction time was very much lengthened by the use of narcotic and sedative drugs, notably the bromides and ether. In this manner he proved what had long been observed, namely, that these drugs inhibited vertigo. His conclusions were that—(1) this derangement of the cortical centres was always accompanied by some impairment of consciousness. (2) This impairment was disclosed by the greater length of the reaction time, and by (3) introspection. (4) Vertigo might, however, be engendered by direct impairment of the functional efficiency of the centres of perception without the interference of the afferent nerves. The vertigo associated with auto-intoxication and that due to intracranial disease was to be thus accounted for. (5) However originated, all forms of vertigo had this in common, that they interfered directly or indirectly with normal cortical action. (6) Rotary vertigo of the milder sort might be inhibited by intense sensory impressions, particularly by those of sound. (7) The impairment of consciousness was in direct ratio to the intensity of the vertigo.

The paper was discussed by Drs. Benedict, of Buffalo, and Hill, of Milwaukee.

Increasing the Value of Cod-Liver Oil by the Addition of Free Iodine and Free Phosphorus.—This paper was read by Dr. Louis J. Lautenbach, of Philadelphia. He described the different methods of preparation of cod-liver oil. He said that the ready absorption and good effects were due principally to the free iodine and phosphorus contained therein. The old method of preparing the oil by a process of expression preserved these principles and many other putrefactive alkaloids. The new method consisted in securing the oil by passing superheated steam through the livers. This oil was far more agreeable to the palate and stomach, but was less valuable. He believed that this defect could be remedied by the addition of free iodine and phosphorus to the ordinary cod-liver oil of commerce. Gr. $\frac{1}{100}$ of pure phosphorus and gr. $\frac{1}{6}$ of free iodine in a tablespoonful, to be taken at bedtime, was the usual dose employed.

Protest against the Use of Proprietary Remedies.—Dr. Daniel Brower, of Chicago, read this paper. He said that the profession was being overwhelmed by proprietary remedies. The manufacturers who projected them copyrighted the name, and patented the process and the resulting product, so that these remedies remained a monopoly for all time. More than twenty-five hundred such new remedies had been introduced within the past few years. An examination of one thousand prescriptions of three leading Chicago druggists revealed that from twenty-one to twenty-six per cent. of those prescriptions contained these remedies. These drugs cost from three to four times as much as they did in other countries. The Code of Ethics expressly said that it was equally derogatory to professional character for a physician to hold a patent for any surgical instrument or medicine, or to dispense a secret nostrum, whether it was the composition or exclusive property of himself or others. It was also reprehensible for physicians to give certificates attesting the efficacy of patent or secret medicines or in any way to promote the use of them. By the use of these drugs the profession became perpetually at the mercy of monopolists who could fix the price, vary the composition or purity as fancy might dictate. There was no objection to a manufacturing chemist patenting a process. There should, however, not be a monopoly on any product. To those who wished to use combinations the "National Formulary" furnished all of the formulæ of the best combinations that were in general use, at one-third of the price of the corresponding proprietary preparation.

Dr. N. S. Davis, of Chicago, said that we must divide these drugs into two classes: (1) those whose contents or process of manufacture was secret; (2) elegant preparations of well-known drugs in fixed proportion.

Dr. Allen protested against the physician dispensing his own drugs. No one should use any fixed routine combination of remedies for any disease.

Dr. Tompkins, of West Virginia, said that religious newspapers and clergymen were responsible for much of the circulation of these proprietary remedies.

Dr. Lochboehler pointed out the danger of these remedies, in that they put dangerous unknown drugs in the hands of the laity, and he cited several instances in which death resulted from this indiscriminate use of these synthetic drugs by the layman.

Dr. Brower, in closing, stated that there had been a very marked increase in the number of cases of impotence in late years due to the general use by the public of these unknown synthetics. The physicians were responsible because they praised and prescribed the articles, and the public came to know of it through the advertising agents.

Irrigation of the Colon as a Therapeutic Measure.—Dr. George J. Lochboehler, of Washington, D. C., read this paper. He said that for this purpose from two to four quarts of decinormal salt solution should be employed. The tube should have the opening on the end and not on the side. The tube devised by Dr. F. Turck was preferable, in order to prevent the coiling so common with a soft tube. Such large quantities of fluid acted mechanically and were of especial value in strangulated hernia. Irrigation had been used very successfully in a large number of cases of gastro-duodenitis. The speaker reported one desperate case of typhoid fever and two cases of appendicitis, in which a cure was effected by this means. The only contraindication to its use in typhoid fever was during the stage of necrosis, when it should not be employed.

Dr. Brower pointed out the beneficial effect that these irrigations had on the kidneys, and urged their more frequent employment.

Dr. Osborn, of New Haven, spoke of the value of such injections following surgical operations. Many of the disagreeable sequelæ such as thirst, anuria, etc., were thus prevented.

Dr. Culbertson, of Cincinnati, said that as a means of reducing temperature in acute infectious diseases a quart of ice-water thrown into the lower bowel was one of the best. It reduced the temperature at once from a degree to a degree and a half.

Dr. Bernheim stated that as a result of his physiological investigations he found that the reverse peristalsis that was set up in the bowel following such injections carried the salt solution as far as the stomach.

Treatment of Addison's Disease, with Case.—Dr. John V. Shoemaker, of Philadelphia, read this paper. This was a case of Addison's disease in a young man. The administration of suprarenal extract had no effect on the disease. The patient died in a short time of general tuberculosis. The suprarenal glands were markedly involved. A general review of the literature was appended.

The Therapeutic Application of the Organic Extracts.—This paper was read by Dr. O. T. Osborn, of New Haven. He outlined the history of thyroid experimentation. Among other things it was noticed by Kocher that symptoms of myxœdema did not appear when the thyroid was removed in old age. The adult thyroid contained 4 mgm. of iodine, and this was the only tissue of the body that contained that element. It produced diuresis when taken internally. It seemed that the thyroid was necessary for the proper equilibrium of the central nervous system; to regulate the proper quantity of mucin that should appear in the tissues; to regulate the proper amount of connective tissue, especially of the skin; to the proper organization of phosphoric acid for assimilation into bone salts; and, by its vasodilator power, to regulate properly the peripheral circulation, thus regulating the heat loss at least and the normal insensible perspiration, which if disturbed showed on the one hand in the drying of the skin in myxœdema, and on the other in the increased sweating in Graves' thyroid disease. It also seemed to have some power in regulating the rapidity of the cardiac contractions. When large doses of this gland were given to a healthy adult, nausea, vertigo, and other alarming symptoms resulted. Exophthalmic goitre was due to hypersecretion, and therefore the use of the thyroid extract was contraindicated during the continuance of active symptoms. All of these were increased if it was administered. If the gland underwent atrophic changes, as it very often did, later on the reverse condition might occur, viz., the first stage of myxœdema, then it could be given. It was probable that every case of overweight, especially after forty years of age, could be reduced by larger or smaller doses of thyroid extract daily, provided there were no ill effects from its use. After the first two weeks the patient would lose from two to five pounds per week. At the beginning gr. iii. should be given twice a day. This was gradually increased. The disagreeable symptoms were the same as the early symptoms of exophthalmic goitre. The diet needed no modification. Thyroid extract was of value in the treatment of certain skin diseases, such as dry, scaly eczema and psoriasis. It had not been successful in the past because too large doses had been given. The speaker had found it of especial value in dull, heavy-featured children of a strumous diathesis. Enlarged glands in the neck had become normal under its use. Melancholia was occasionally benefited by it. Eighty per cent. of all cases of exophthalmic goitre occurred in women, and it was reasonable to suppose that it bore a close relation to the menstrual function. Thyroid had been successfully employed in some women at the menopause.

Thymus.—He said that intravenous injections of this substance lowered the blood pressure. It had been demonstrated that it did not contain any iodine. It contained a large amount of nuclein and phosphorus. In some cases of exophthalmic goitre it was of service. Its use as yet was entirely empirical.

Pituitary Body.—This gland was divided into two parts; the anterior was glandular and resembled thyroid tissue; the posterior was largely made up of nervous elements. An extract of this latter part, when injected into a vein, raised the blood pressure. When this gland was removed in animals, they died of symptoms like those in human beings from whom the thyroid had been removed. This gland was always diseased in acromegaly. Giantism was due to an increase in the secretion of this body. Acromegaly was due to a perverted secretion. If disease of this gland existed, the thyroid was enlarged, and the reverse also held true. Two successful cases of feeding of the pituitary body in acromegaly were reported.

Suprarenal Extract.—The active principles of this drug did not produce their constitutional effects when administered by the stomach. There was one principle present in the drug which, when administered intravenously, raised the blood pressure more than any other known agent. Degeneration of the adrenals was only one of the many causes of Addison's disease. The general consensus of opinion as to its value in eye and nose diseases was that it was invaluable. For local use ten grains to the ounce was the usual strength. The speaker had had much success in aborting follicular tonsillitis by cleansing the tonsils with a saline solution, swabbing with hydrogen peroxide, and then spraying with suprarenal extract. This was to be repeated in twelve hours. The congestive stage of urethritis was also benefited by injections of this agent. It should be employed locally in all forms of capillary hemorrhage. If used in a cavity of the body, it should be washed out, because it underwent putrefactive changes after a few hours.

Psychic Therapeutics.—Dr. J. C. Culbertson, of Cincinnati, read this paper. He believed that the principal requisites for success were: (1) ability to diagnose; (2) a strong personal influence. Other therapeutic agents were only valuable adjuncts. He would dispense this personal influence just as he would dispense a nervine or an anodyne. Confidence was a potent remedial agent. There was a psychic element present in all disease. This often overshadowed the pathological state. This was especially marked in educated people. A discriminating course of positive injunctions or orders, with placebos, were often of greater value than drugs. One should never be vacillating, but positive at all times. Fear or joy might cause either a cure or a disturbance of the organism, and the personal influence of the physician might save life.

The paper was discussed by Drs. Reamy, Wheatly, and Bernheim.

Dr. Culbertson, in closing, said that a diagnosis should always be made on the first visit, and, no matter whether right or not, the name of the disease should be the same to the patient throughout the whole sickness. Positive men were the successful men.

Fourth Day—Friday, June 8th.

Pharmacological Assay of Drugs and its Importance in Therapeutics.—Dr. E. M. Houghton, of Detroit, who read this paper, said that many of the most important drugs could not be standardized by chemical assay. For this reason animal experimentation was essential. The best theory that had been offered to explain the reactions between the elements of the animal body and drugs was that of chemical affinity. The normal function of a given organ was altered in degree by the union occurring between the protoplasm of its cells and the given drug. This action was quantitative. Other conditions being equal, animals of the same size and weight would respond equally when the same dose of a given drug was administered. In the speaker's experiments, when the conditions were similar, there was not more than two per cent. variance between the results of two observers. He stated the following to illustrate the uncertainty of the present system: He purchased three specimens of tincture of strophanthus. As far as could be determined they were alike, yet upon injecting them into animals the results differed as much as five hundred per cent. The strength of the suprarenal extract might likewise be determined only in this way.

Dr. Lyons, of Detroit, said that in the chemical assay of drugs there was very often a variance of from ten to twenty per cent. between different observers.

The paper was further discussed by Drs. Allen and McClintock.

The United States Pharmacopœia for 1900.—Dr. Joseph Remington, of Philadelphia, presented this paper. He said that the United States Pharmacopœia occupied a unique position among the pharmacopœias of the world. Its authority was established throughout the country mainly through the voluntary assent of doctors and pharmacists of the United States. In other countries the governmental authority was behind it. Among the most important changes to be made in the new pharmacopœia would be the introduction of any product of nature of known origin; also any synthetized product of definite composition which was in common use by the medical profession, the identity, purity, or strength of which could be determined. No compound or mixture would be introduced if the composition or mode of manufacture thereof was kept secret or if it was controlled by unlimited proprietary or patent rights. The average approximate dose of each drug would be inserted. The book would appear about 1903. No restriction would be placed upon the text of the book.

A resolution was adopted condemning the admission of unethical preparations to the exhibition hall of the association in the future. An unethical paper that was presented to the section was returned to its author.

AMERICAN ORTHOPEDIC ASSOCIATION.

Fourteenth Annual Meeting, Held in Washington, D. C., May 1, 2, and 3, 1900.

Harry M. Sherman, M.D., of San Francisco,
President.

(Concluded from page 1072.)

Second Day—Wednesday, May 2d.

Forcible Correction of Spinal Curvature followed by Paralysis.—Dr. H. Augustus Wilson reported a case in which the kyphosis had been noted only a few weeks before he had seen it. There was a family history of tuberculosis. In addition to the statements of the parents, who were careful observers, there was other evidence of the recent development of the deformity. Under profound anæsthesia the patient had been subjected to full extension in the horizontal posture while he had made forcible correction with the hands from above downward. A very decided and audible snap had occurred, such as is present in osteoclasis, but there had been little improvement in the deformity. A second attempt had yielded the same result. A plaster-of-Paris jacket had been applied, the jacket being fenestrated at the kyphosis. The patient was placed in bed with counter-extension. The temperature rose to 101.4° F. on the second day, and remained at this point for about twelve days. It then declined for a short time, but rose again slightly, and remained above the normal for about eight weeks. In a short time sloughing of the soft parts occurred above at the head, and subsequently also over the site of the kyphosis. The latter was so marked that the spinous processes were exposed. There had been no pressure over these points. When discharged at the end of nine weeks the patient was able to move around feebly, but there was no distinct paralysis. In forty days he had been readmitted with a spastic paraplegia, which was almost complete. Apparently the membranes of the cord had become involved in a tuberculous process. Under treatment directed toward immobilization of the spine and improved nutrition, the patient had improved slowly.

Dr. A. M. Phelps was inclined to believe that the forcible correction of the spine had had nothing to do with the subsequent paralysis. The case seemed to him a typical one of pressure myelitis resulting from the invasion of the cord and thickening of the membranes of the canal.

Dr. Ridlon took the same view of this case.

Dr. Lovett said that Dr. Dane's brace was interesting because its aim was to produce torsion. His own studies in lateral curvature had impressed upon him the importance of throwing the weight of the spine backward on the articular processes, not necessarily producing lordosis of the lumbar region, however. The weight should be thrown upon the articular processes a little before the erect position was assumed.

Dr. Phelps asserted that it was only when the spine had been bent backward considerably that any pressure was made on the articular processes.

Dr. Lovett replied that this statement was not in accord with the results of experiment, which showed that these processes came in contact at a point about 15° in front of the erect position.

A Case of Scorbutic Spine.—Dr. John Ridlon reported a case of this kind occurring in an infant of twelve months, and coming on so suddenly that it was difficult to resist the inference that the symptoms were the result of some traumatism to the knee. The child was large and fat, and it had a rough and muddy skin. The legs were held slightly flexed at the knee, and the hands were moved carefully. The range of motion at the ankles, knees, and hips was normal. The spine was arched forward, and held rigidly. The gums were dusky. He ordered the child fed on unsterilized milk, raw meat, and orange juice, and in two weeks the bow was well. In making the diagnosis it should be remembered that acute articular rheumatism was rare in infants, and was accompanied by fever, and that infantile paralysis and rickets must also be excluded. In rickets the onset was gradual, and there were other evidences of the disease besides the spine.

Dr. R. H. Sayre said that his plan of treating such cases had been to put the child on a pillow, made rigid by inserting a short board inside of it, and then changing the diet. Most of his cases had occurred in children who had been fed on sterilized milk or on patent infant foods. One child had had an extremely tender spine and also complete paralysis of the lower extremities.

Dr. Phil. Hoffmann reported one case, occurring in an infant of four months, who had been referred to him as a case of Pott's disease. The kyphosis was sharper than usual in the rachitic spine. The child had made a good recovery.

Dr. Henry Ling Taylor said that he had reported to this association one of the earliest cases of this kind published in this country. In the cases that he had seen there had not been a true paralysis, only a disinclination to use the limbs because of the extreme pain caused by motion. He had not found it necessary to resort to any special mechanical treatment.

Dr. Stewart L. McCurdy, of Pittsburg, said that he had reported two or three cases several years ago. These cases presented a gradual posterior curve rather than a true kyphosis. In some cases there was an almost complete pseudo-paralysis. In none of his cases had there been bleeding from the gums. The absence of pain, fever, and fretfulness enabled one to differentiate between scorbutus and rachitis.

Knee-Joint Surgery for Other than Tuberculous Processes.—Dr. Joel E. Goldthwait, of Boston, presented a paper on this subject. The ages of his patients had varied from four years to sixty-five. He personally believed there was no more danger of opening the knee joint than the peritoneum. If there was any legitimate doubt as to the diagnosis there should be no hesitation in opening the joint and determining the true condition by actual exploration. The importance of doing so was evident when one considered how much more could be accomplished by making an early diagnosis of tuberculosis. The difficulty of making the diagnosis was increased in adults, in whom non-tuberculous lesions of the joints were in the majority. After opening the joint experience had shown that the surgeon must rely less upon the gross appearance than upon the results of microscopical examinations. The present paper was based on a study of twenty-seven patients and thirty-three operations. In five cases both knees had been operated upon. Of the thirty-three operations one was for the removal of loose pieces of cartilage in a woman aged sixty-five years. Three pieces as large as hickory nuts had been removed. In one case the exploratory incision showed a beginning osteo-sarcoma. In eight of the cases the operation had been demanded because of the presence of loose cartilages. The patients were all young men, and in quite a number of them there was a relaxed condition of the joint which had favored the crushing or tearing of the inner edge of the cartilage. The point of contusion seemed to be usually the inner thin edge. Sutures of any kind, because of the structure of the cartilage, cut out almost immediately; hence, the best treatment was removal of the cartilage. Under the latter treatment the joint could be removed in one week, and the after-treatment ended in three weeks. After the first week the dressings should be removed one a day and the joint flexed so as to prevent the formation of adhesions. A flannel bandage was used for the third week. He felt that there was danger of over-treatment in these cases. Apparently the patient suffered no inconvenience from the absence of the cartilage. Of course the mild cases could be relieved by massage and bathing. When there were marked fringes, these should be removed by operation. In the majority of cases the fringes acted as foreign bodies and became locked under the patella during motion just as in the case of the loose cartilage, although the results were not so severe. The frequent resulting attacks of synovitis were followed by coagulation of the synovia, thus forming large coagula in the joint.

Discussion: The Treatment of Vertebral Tuberculosis with Reference to the Forcible Correction of the Deformity.—Dr. John Ridlon opened the discussion. He said that in the past three years he had operated upon eight lateral curvatures under ether and thirty-five cases of Pott's disease. In the worse cases he had gained at first one and one-quarter inches in height, and at the second attempt three-fourths of an inch, but in almost all the cases of lateral curvature this gain had been subsequently lost. He did not think it was worth while now to straighten a lateral curvature case under ether. He had operated on both old and recent cases of Pott's disease. There had been two fatal cases. The first one was really due to the prior existence of tuberculosis, the operation having been done without having kept the patient sufficiently long under observation. In the other fatal case, everything had gone along well for six months or more, and then several abscesses had developed, and the prolonged suppuration had finally resulted in death from exhaustion. In many of the cases he had used almost no pressure with his hands; in others he had used very considerable force. There was almost always some crunching of the bones. None of his patients had subsequently developed paralysis, but he had operated on several cases when paraplegia existed at the time. In the longest case the patient had been in bed about one year, and in the shortest for four weeks, but he had aimed to keep them from six to eight months in bed, allowing them to lie on the face, back, or side. He had had a few cases in which there had been no return of the deformity, and about half a dozen in which the patients had gone for a year without any support or any return of the deformity, although the straightening had been as much as one-half to three-fourths of an inch. In the majority of cases he had succeeded in keeping the deformity reduced to about half of what it had been before the operation.

Dr. Goldthwait said that at the Children's Hospital the usual treatment during the past two or three years had been the application of apparatus in the hyperextended position. He exhibited a series of tracings taken during this period. They showed that the deformity had not increased, or only very slightly. From a consideration of these and the general results obtained, he would hesitate to correct forcibly any spinal deformity resulting from tuberculosis of the spine unless it was associated with an obstinate paraplegia. He was not aware that the method of forcible correction had materially increased the mortality.

Dr. W. R. Townsend said that the method had never appealed to him, and he predicted that the deformity would recur in the large majority of cases.

Dr. De Forrest Willard, of Philadelphia, said that he had looked upon the method as illogical and unsurgical, and accordingly he had employed it only in one desperate case of total paralysis. Here, contrary to his expectations, the operation had been beneficial, and it was only in this class that he would think of resorting to it.

Dr. R. H. Sayre said he believed many cases of severe lateral curvature could be greatly benefited by the application of great force under anæsthesia. The amount of force applied usually to the scoliotic spine was altogether insufficient. By longitudinal traction and torsion, under anæsthesia, he believed much could be accomplished.

Dr. T. Halsted Myers, of New York, said that in all of the four cases in which he had tried forcible correction the result had been unfortunate.

Dr. Galloway said that he had never performed this operation, having always regarded it as unscientific, but he was ready to try it in the first case of Pott's paraplegia presenting itself that was incurable by other methods. So far, he had not met with such a case.

Dr. Weigel thought the reports presented forced one to conclude that the mechanical support used after forcible correction had been inefficient.

Dr. R. Tunstall Taylor, of Baltimore, thought the older mechanical methods were safer and more accurate, and did not introduce the errors incident to the use of a method that involved manipulations by several individuals. This last point seemed to him a matter of considerable importance.

Dr. Phil. Hoffmann expressed some surprise that so much stress had been laid upon the use of forcible correction in cases of paralysis, for he had never seen a case of Pott's paralysis that had not resulted in recovery.

Dr. John L. Porter, of Chicago, said that from his observations of a large number of Dr. Ridlon's cases he felt sure that more than fifty per cent. of these patients were straighter now than when operated upon under anæsthesia.

Dr. Ridlon said he would not attempt to break up a spine that seemed to him to have been entirely cured. In very recent cases in which the weakness, pain, and disability were considerable, he would be disposed to choose Goldthwait's method without anæsthesia. It was the middle class of cases, those with a slowly increasing deformity, that were especially suitable for forcible straightening under an anæsthetic. Dr. Goldthwait's disappointing results, and the discussion just closing, had impressed him more than ever before with the great value of using an anæsthetic.

Dr. Goldthwait said that he had purposely refrained from bringing tracings of cases that he had treated under anæsthesia, because they were no better than those already exhibited by him. He had not observed much difference in cases which had relapsed whether they had been kept in bed or had been allowed up in a short time. Hubbard had shown that, as a rule, Pott's paraplegia was recovered from in from six to nine months, the time depending upon the location of the disease, and provided the patient was kept recumbent. Forcible correction greatly reduced this period of recumbency, and certainly this was a great gain. He would not attempt forcible correction unless paraplegia was present, and he would never use traction or much force to bring about the correction.

Third Day—Thursday, May 3d.

Brace for Lateral Curvature of the Spine.—Dr. Gwilym Davis, of Philadelphia, presented a brace that he had devised for lateral curvature. This brace had a hip band and both an anterior and a posterior upright. A shoulder-piece encircled the high shoulder. From the posterior upright a band passed over the lump and underneath the arm of the affected side. The two points of support were on the arm above and the hip below.

Dr. R. H. Sayre said that if pressure was made on the large side, as it would be with this brace, the peak of this arch would become more and more arched. The force should be directed so as to transfer the leverage in such a way as to turn the vertebræ around on their axes. All forms of apparatus which made pressure on the bulging part simply served to increase this bulging.

Dr. Weigel thought the apparatus exhibited did not afford the necessary fixed point of support. Simply keeping the high shoulder down could not have any special corrective influence on the deformity.

Dr. Davis replied that, in his opinion, the brace did not exert merely a direct pressure, but a twisting force. The question of support was merely a matter of adjustment.

Retardation of Growth as a Cause of Shortening after Coxitis.—Dr. Henry Ling Taylor, of New York, read a paper with this title. He said that his attention had been strongly directed to this subject by a case in which he had had the mortification to find an increase of shortening of four and a half inches in a period of about four years. Further investigation had shown that it was quite common for a shortening of half an inch to take place in the tibia, and an equal amount, or even more, in the femur. In twenty-one cases the shaft of the femur on the affected side had been from one-fourth of an inch to two and a half inches shorter, with an average difference of five-eighths of an inch. In thirty cases, the average shortening on the affected side had been three-fourths of an inch. The patella of the affected side was nearly always smaller and narrower. In twenty-six cases there was a difference of from one-eighth to half an inch in the transverse diameter. In only one measured case had there been no difference, and this patient had never worn a brace. The foot was shorter in a number of cases. The shortening of the various bones was found to be proportionate to the duration. Those cases which had received the least treatment seemed to have less than the average amount of shortening, but there was apt to be more displacement. A comparison of ten cases of old unilateral poliomyelitis, with a similar group of hip cases, showed about the same amount of bone shortening. Further observation seemed to show that the absence of locomotion apparently favored the occurrence of such shortening. Retardation of growth was found in those affections of childhood which disabled one limb, and somewhat in proportion to the amount and duration of the disability and restraint imposed.

Developmental Shortening in Tuberculous Bone Disease.—Dr. Stewart L. McCurdy, of Pittsburg, presented in this paper several illustrative cases corroborating some of the statements made by Dr. Taylor in the foregoing paper.

Dr. R. H. Sayre said that the records of college gymnasiums showed that the average increase of height after the age of nineteen or twenty years was quite surprising. He had noticed in cases in which apparatus had been discarded from one limb a considerable time before the other, when both were affected, an increase in the limb first liberated. All of the small bones of the foot, as well as those more directly connected with the diseased area, were affected in this way.

Dr. Goldthwait said that in a series of cases of hip disease that he had measured some years ago, in practically all a shortening had taken place below the knee. Skiagraphs from these cases showed a perfectly regular atrophy or lack of development of the upper end of the tibia or of the femur, and the epiphysis, instead of being square in front, was wedge-shaped. There was also a marked depression of the epiphyseal line. It was possible that the strap about the calf might have been a factor in producing the atrophy as a result of pressure.

Dr. Weigel said that there was no doubt in his mind that weight-bearing was a very important factor.

Dr. Gibney said that it seemed to him that there should be an elongation of the femur in hip disease as well as in disease of the knee. Most of the investigations that had been made showed that in tuberculous disease of the knee the limb actually lengthened. According to his experience, in some of those dry cases which went on so well at first, an alarming degree of shortening often showed itself after a few years.

Dr. H. Augustus Wilson referred to the recent observations of Dr. Hurd in China regarding the changes taking place in the feet of Chinese women. She observed that after the use of the muscles had been partially restored there was evidence of increase in the diameter and length of the bones. If these observations were accurate, it would appear that very much of the shortening observed in cases of joint inflammation was due to the bandaging and consequent interference with the circulation rather than to the joint inflammation.

Dr. A. M. Phelps said that he had come to the conclusion that the shrinkage of the muscles was largely the result of a neurotic influence—a true degeneration of the muscles due to the reflexes. The circulation in the bone was carried on by the pressure of the muscles, which forced the blood into the bone; hence, if the limb was placed at rest the circulation would be impaired, and the bone would undergo atrophy.

Dr. Galloway observed that one reason for the lengthening of the limb in knee-joint disease was that two epiphyses were subjected to stimulation—the lower end of the femur and the upper end of the tibia.

Dr. Shaffer said he had found that in the cases in which the nervous phenomena had been most marked—especially in the dry cases—the shortening had been proportionately larger than in those even in which suppuration had been present. This fact had often guided him in making a prognosis.

Dr. Ridlon cited a case to illustrate the fact that muscular shrinkage was not always associated with intense reflex spasm.

Dr. H. L. Taylor said that careful measurements from the anterior spine to the knee joint would probably show lengthening in certain of the early cases. The principal thought in the paper was, that the shortening in all of the bones of the lower extremity following hip disease of many years' standing was almost exactly the same as the shortening which followed infantile paralysis of the same duration. This to him was a very striking and surprising fact. He fully agreed with those who attributed this retardation of growth and lack of development to circulatory disturbances. These came in part through nervous influences, and in part from mechanical compression.

Report of Some Studies upon the Articulations of the Foot.—Dr. John Dane, of Boston, presented this paper, which was based on one hundred and seventy-six dissections. He found that adventitious bones were most common at the joint made by the scaphoid and cuboid in front of the os calcis and the head of the astragalus. This bone might coalesce with the cuboid, changing its normal square shape. This and other anomalies of the articulations were pointed out and exhibited, and attention was called to their important influence on the statics of the foot.

Observations on Certain Painful Affections of the Feet.—Dr. L. A. Weigel, of Rochester, made some remarks on this subject, illustrating them freely with skiagraphs from many cases.

Investigations as to the Treatment of Flat Foot.—Dr. E. H. Bradford, of Boston, sent a communication on this subject, which comprised a study of the mechanics of the foot, particularly as regards the various arches of which the foot was composed, and the effect upon these arches of changes of position and of weight-bearing. He stated that when pressure was made behind the scaphoid there was no difficulty in pronating the foot, and the conclusion was reached that there was a point on the foot at which if pressure was applied the pronation could be checked, and at this point it was easy to do this. The foot-plate should, therefore, be constructed with the "lift" at this point.

A Case of Congenital Dislocation of the Wrist.—Dr. Phil. Hoffmann, of St. Louis, reported a case of this kind, and Dr. Gibney followed with another case, in the person of one of the physicians present at the meeting.

A Case of Congenital Dislocation of the Shoulder.—Dr. John L. Porter, of Chicago, present by invitation, reported this case. He said that out of ninety-eight cases of congenital dislocations of various kinds collected by one author, only five were congenital dislocations of the shoulder. The large majority of these dislocations were subspinous. A photograph was exhibited, which he believed to be the only one extant, showing the condition present. In his case delivery had been effected with the aid of forceps, although the labor had not been attended by any special difficulty. When seen by him two months later, the right arm had been abducted slightly and flexed and pronated. The humerus moved voluntarily very little, though the hand had apparently as strong a grasp as the other. Supination was impossible except to a very slight degree. The humerus could be abducted, but not carried across the chest. Examination by a neurologist subsequently showed no evidence of paralysis. He had been able to find twenty-eight cases of this dislocation on record. His conclusions were: (1) It was of the greatest importance to distinguish between traumatic and developmental cases; (2) a successful method of treatment had not yet been established; (3) in cases determined to be developmental by the history and measurements, an early operation before the humeral head had formed a new articular facet, and had itself become deformed, offered the best chances of success.

Dr. A. M. Phelps said that he had had eight cases of congenital dislocation of the shoulder, and had operated on four of them. In all the operative cases he had found fracture of the posterior border of the glenoid cavity. He believed the dislocation was always traumatic—never congenital.

Dr. Gibney said that he had reason to believe many of these cases were treated at neurological clinics as examples of Erb's paralysis, the true condition not being recognized.

Dr. Porter contended that if the condition was always the result of traumatism inflicted at birth, then measurements made within a few months after birth should not give, as they did in some instances, such differences in the development of the extremities.

Rapid Osteoclasis for the Correction of Rachitic Deformities of the Legs.—Dr. Wallace Blanchard, of Chicago, read this paper. By rapid osteoclasis he meant osteoclasis performed in a period not exceeding eight seconds. When operating so rapidly, the circulation of the part was not impaired, and certain unpleasant consequences were thereby averted. By osteoclasis the length of the limb would be slightly increased, whereas by a Macewen supracondyloid osteotomy the limb would be shortened. After osteoclasis it was his custom to make exaggerated correction of the curve. The same plan was adopted for bow-legs. Bending instead of breaking the femur was often sufficient. After eight years' use of the Grattan osteoclast he felt that it had not received its just due. The lighter modifications of this instrument were decidedly inferior to the original instrument. By rapid osteoclasis no injury was inflicted on the soft parts; the instrument did not slip nor did it cause any splintering. Speedy union was the rule, so that all retentive appliances might often be dispensed with after four or five weeks.

Dr. R. H. Davis expressed surprise at Dr. Blanchard's being willing to leave off such appliances so soon, as certainly at this time the callus was not sufficiently hard to admit of this being done without inviting relapse.

Dr. T. Halsted Myers said that he used osteoclasis freely in his service at the New York Foundling Hospital. If the pressure bar was applied on the inner side, the bone could be fractured much more readily than when applied on the outer side.

An Operation for Ununited Intracapsular Fracture of the Hip.—Dr. Gwilym G. Davis, of Philadelphia, read this paper. In two cases treated by him the incision had been made anteriorly, and by blunt dissection the capsule had been exposed and opened. The edges of the fracture had then been freshened and a second incision made on the outer surface of the greater trochanter, and the compact tissue in this part having been perforated two ivory pegs were inserted to hold the fragments together. In the first case steel pegs had been used, and had been allowed to project externally, but they had excited suppuration. For this reason he had discarded the plan of bringing these pins to the surface. Both patients had been between thirty-five and forty years of age.

Officers Elected.—The following officers were elected for the ensuing year: *President*, Dr. Arthur J. Gillette, of St. Paul; *First Vice-President*, Dr. B. McKenzie, of Toronto; *Second Vice-President*, Dr. Henry Ling Taylor, of New York; *Treasurer*, Dr. E. G. Brackett, of Boston; *Secretary*, Dr. John Ridlon, of Chicago.

The next meeting will be at Niagara Falls in May, 1901.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Tuesday, May 15, 1900.

John H. Huddleston, M.D., Chairman.

Pernicious Anæmia.—Dr. Charles E. Nammack presented a patient forty-eight years of age, who was born in Ireland and who had spent thirty years of his life as a stoker and fireman on board a tropical steamer. For these thirty years he had been in absolutely good health, not sick in bed a single day. His first symptoms consisted of gradually increasing weakness followed by severe vomiting in which there were some blood flecks. He then had his attention called to the fact that his skin was becoming yellow. When he came to the hospital his pulse was 98, his temperature 100° F., and his respirations 22 to 24. He was not very emaciated, but the subcutaneous layer of fat, which is often so well preserved in pernicious anæmia, was not present. He denied all venereal history, though he admits that he has incurred the risk of infection a great number of times. He drank some, but usually not to excess. He had never been what might be called a steady drinker. His teeth were examined very carefully after his admission to the hospital. Some time ago, in the London *Lancet* Hunter described a series of cases of pernicious anæmia in which carious teeth were found. Hunter attributed the blood disorder to the swallowing of septic material from the mouth and its subsequent absorption in the stomach. None of this patient's teeth, however, was carious. The gums were somewhat retracted, but the twenty-three teeth present were in a reasonably good condition. His heart was found to be normal, his liver slightly enlarged, his spleen little if at all enlarged, and his lungs were perfectly normal. There was a scar in his right iliac region, not due to operation for appendicitis, but to the opening of an old abscess. Examination of his stomach contents showed the presence of hydrochloric acid in about the normal quantity. Lactic acid was also present, but only in small amount. The blood count showed 500,000 red blood cells to the cubic millimetre and about the normal amount of white blood cells. There was no leucocytosis, though blood examinations were repeatedly made to ascertain this point. There was twenty per cent. of hæmoglobin, *i.e.*, each of the red cells contained about twice the normal amount of hæmoglobin. The red cells were very varied in character and size and form, *i.e.*, there was marked poikilocytosis. A large number of megaloblasts were present. The diagnosis, pernicious anæmia, seemed clear. It was necessary only to exclude gastric carcinoma. The examination of the stomach contents seemed to assure the absence of cancer in the stomach. Besides, there was no leucocytosis. This would almost surely occur if gastric carcinoma had existed long enough to cause such symptoms as were present in the case. The patient's color was the characteristic lemon yellow of pernicious anæmia, not the muddy yellow of cancerous cachexia.

Frequency of Pernicious Anæmia.—There was no doubt that this disease occurred much more frequently than had been imagined. In this country particularly the old school of practitioners had been inclined to think it very rare. A few years ago Dr. Cabot, of Boston, reported sixty-six cases of the disease before the Association of American Physicians at Washington. At the recent session of that body he increased the number of cases in his report to one hundred and ten. It seemed clear then that those who looked for the disease carefully would find it much oftener than might be expected from the tone of the text-books and the usual authorities on the subject.

Treatment.—The prognosis of the disease still remained as before, absolutely fatal. A ray of hope had recently been thrown on the therapeutics of the disease by Hunter's studies in England. On the theory that the disease was due to the absorption of toxins from the gastro-intestinal tract, these occurring because of the presence of foci of suppuration in carious teeth in the mouth, Hunter advised thorough antisepsis of the gastro-intestinal tract and the use of some serum injected subcutaneously to neutralize as far as possible the septic material which had already found its way into the circulation. An English physician had reported one case successfully treated by this method. The patient used mild antiseptic mouth washes, bismuth and salol and beta-naphthol internally, and was given injections of anti-streptococcus serum. Improvement began at once and was almost marvellous in its rapidity. In forty-five days the blood was perfectly normal. It remained, of course, doubtful as yet whether this rapid recovery was due to the treatment or to one of the well-known remissions of the disease which occurred so frequently. Such remissions seldom produced so rapid an improvement as was reported in this case, and practically never caused a complete return to normal health. The method of treatment was, at least, encouraging.

Scurvy.—Dr. Nammack presented a patient aged forty years, an Austrian by birth, suffering from scorbutic symptoms. He had contracted the disease from the use of unsuitable food in New York. The patient confessed that he drank beer rather freely, used tobacco to excess, and took four cups of coffee a day. During the fifteen years he had been in this country he had never been ill before. He was a carpenter by occupation, worked hard, and lived with extreme frugality. His meals had consisted of coffee and bread, with some sausage, canned and preserved meats of various kinds, with smoked and salt fish and other articles that he could obtain very cheaply. He did not mind the quality of his food, provided he could get it cheaply. He had evidently been living on half-spoiled victuals most of the time. His first symptom was tingling and prickling, with pain in the legs. He then noticed that his gums were tender and bled easily when touched, or when he chewed rough food. Black spots, some of them as large as a silver dollar, occurred on his legs. When he came to the hospital he was found to be poorly nourished, of a dusky yellow color, in marked contrast to the light lemon yellow of the patient suffering from pernicious anæmia, and with large areas of subcutaneous hemorrhage, especially on the backs of his thighs and calves. His mucous membranes were intensely pale and the conjunctivæ especially lacked color. His gums were purple and œdematous. They hung down over the teeth in fungoid masses and bled at the slightest touch. There were petechiæ on his body, but not many on the arms. There were no hemorrhages into the retina. Blood examination gave 2,200,000 red blood cells to the cubic millimetre, and 7,000 leucocytes. The hæmoglobin value was sixty per cent. No megaloblasts were present, and the poikilocytosis was not marked. There was no leucocytosis at any time during the affection. The man was evidently suffering from secondary anæmia due to his scorbutic condition.

Etiology of Scurvy.—This case would seem to be a striking confirmation of the explanation of the origin of scurvy which had been advanced very recently at Ann Arbor. It was not considered to be due to an exclusive diet of any kind, especially not to exclusive animal food, but rather to the absorption of ptomains from decomposing or badly preserved food. It was well known that scurvy did not occur among the Esquimaux, though their diet consisted for most of the year of nothing else than animal food. It did not occur among the negroes in Central Africa, though they lived almost wholly on the plantain. It was infrequent in India and in China, though a great many of the people ate nothing else than rice. Cases of scurvy that had occurred aboard ship from the use of salt meat could be very well explained on the theory of poor preservation of the meat, allowing the production of toxic ptomains in it. It seemed interesting to note, Dr. Nammack said, that none of the soldiers of the late war returned from Cuba or the camps, who came under his observation, showed any signs of scurvy. A great deal of notoriety was given by the newspapers to the embalmed-beef scandal, yet none of the soldiers seemed to have suffered severely from anything like ptomain poisoning as the result of poorly preserved meat. Numbers of them had severe secondary anæmia, as the result of malaria, typhoid fever, and dysentery, but no scurvy was reported.

Bradycardia; Pulse of Thirty-Six.—Dr. James J. Walsh presented a patient, a woman aged thirty-one years, whose pulse was normally about 36 and under excitement went up to 40. There was nothing in her family history that threw much light on the condition. Her mother and five brothers and sisters were living and well. As a child this patient suffered from most of the ordinary diseases of childhood, and there was a tradition in the family that if there was any disease about she would catch it. She played, ran, and skipped rope quite as other children did. Though seen a number of times by doctors they never called attention to the fact that her pulse was slower than normal. About ten years ago she had the grippe, and while convalescing from that her physician called her attention to the fact that her pulse did not rise above 40. Since then she had been apparently in perfect health. For a while she was a dancer on the stage and in private drawing-rooms. She did not notice that she seemed more exhausted than others after severe exertion. Of late she had been suffering somewhat from digestive symptoms, and it was for these that she had come under treatment. Her gastric symptoms had practically disappeared under simple tonic treatment, and now she considered herself in good health once more. The question arose whether the bradycardia was congenital or acquired. It seemed to exist in no other members of the family, and the fact that physicians did not call attention to it when she was young seemed to indicate that her bradycardia was a sequela of influenza.

Cicatricial Stenosis of the Pylorus.—Dr. Freeman Ward presented a patient forty years of age, a man who had been suffering from gastric symptoms for some eight years. He first noticed severe vomiting, in which streaks of blood occurred with pain shortly after eating. This continued for some time and then disappeared, and for years he had very few gastric symptoms. Two years ago he began to have a dull pain in the epigastrium. After a while this became severe, and would wake him up between 2 and 3 o'clock in the morning and compel him to get up and walk about for a while. Frequently spells of vomiting came on during the pain, and then marked relief followed. He noticed that the vomited material often contained particles of food that he had eaten some time before, sometimes as long as twenty-four or forty-eight hours. He was given a Boas test meal, and his stomach contents were removed for examination. Altogether nearly 1,400 c.c. was withdrawn. The total acidity of this was much higher than normal, and hydrochloric acid especially was in excess. All the digestive ferments were present, and starch digestion was particularly good. The patient's stomach was washed out every evening for some days with marked relief. The pain did not recur during the night. He was then put on regular evening lavage. If this lavage was omitted duringt he first two weeks the pain always recurred. Gradually, however, it became possible to lengthen the interval between the lavages. He now could go for thirty-six and sometimes forty-eight hours without inconvenience. His appetite was much better, and he had no discomfort in the epigastrium. He had gained three pounds in weight. Before the regular washing out of his stomach was begun a certain amount of gastric dilatation could be demonstrated. The fundus of the stomach was three fingers' breadth below the umbilicus. It was now in its normal position above the umbilicus. The diagnosis of the case was post-ulcerative stenosis of the pyloric region. The contracted scar tissue of the healed ulcer had materially lessened the lumen of the pylorus and so prevented exit of food. It seemed doubtful whether the present treatment would continue to relieve his symptoms.

Pyloric Stenosis and Loss of Weight.—Dr. Ward also presented a patient aged twenty years who in twelve months had lost seventy-two pounds in weight. His first symptom some three years ago was vomiting, in which there was some blood and a feeling of discomfort amounting almost to pain after the taking of food. There was a distinct area of tenderness in the pyloric region, but no thickening could be felt. The test meal showed the stomach contents and secretions to be perfectly normal. Inflation of the stomach with carbonic acid gas showed that it was not dilated. The state of malnutrition that had developed was so serious that as no medical means seemed of any avail surgical intervention was advised. The operation was done by Dr. Farquhar Curtis, who found the pylorus closed. It had been thought that perhaps a hypertrophic stenosis of the pylorus existed, but the condition was found to be stenosis from the scar of an old ulcer. The patient weighted one hundred and six pounds at the time of the operation. He now weighed one hundred and eighty-two pounds.

Stomach Distention and Diagnosis.—Dr. Ward called attention to the fact that in this case every possible means had been taken to diagnose the presence or absence of dilatation of the stomach. Among other means the introduction of water into the stomach in order to find how much it would hold was tried. At the General Memorial Hospital a resident physician succeeded in introducing ninety-eight ounces of water. At the operation, however, no dilatation of the stomach was found. The amount of water, then, which could be introduced served to show not the actual presence of dilatation of the stomach, but the distensibility of the stomach walls.

Specific Tumor of the Stomach.—Dr. Ward's third patient was a man aged thirty-eight years, who began to suffer with gastric symptoms some eight years ago. His first symptoms were pain shortly after eating, and frequent vomiting in which there was some blood. The pain was increased by acid or irritating foods. The patient went to Carlsbad and was treated by a distinguished stomach specialist, whose diagnosis was gastric ulcer. His symptoms, however, were not allayed by the usual treatment for ulcer of the stomach. The giving of liquid food alone did not cause improvement, and while rectal feeding did away with gastric pains for the two weeks during which it was kept up, just as soon as feeding by the mouth was resumed the pain recurred. Even an absolute milk diet did not prevent the recurrence of pain. Occasionally in the vomited material there were streaks of fresh blood. Once or twice the hemorrhage was rather severe. At times the vomited material contained a substance of dark coffee-grounds appearance. No tumor could be felt anywhere in the gastric region, and there were no special areas of tenderness. As the abdominal muscles were very tense an anæsthetic was given in order to make a more complete palpation for the tumor. No tumor was found. The patient had become very emaciated, and weighed less than one hundred pounds, and it became evident that unless something was done a fatal termination from inanition could be looked for. An operation was performed, when it was found that the pylorus was completely closed by a tumor the size of a tangerine orange. The patient's condition was so poor that it was clear that an operation for the removal of the tumor at this time would almost surely result fatally. A gastro-enterostomy was done in the hope of bringing about an improvement in his condition, and with the idea of doing a secondary operation for the removal of the tumor as soon as the patient's condition justified it. The tumor was considered to be an adenoma of the stomach wall. Without any hope really of doing the patient good, potassium iodide was given in order to be assured that the tumor was not specific. In a few weeks the man gained rapidly in weight. In about six weeks the abdomen was opened a second time, when it was found that the tumor had completely disappeared. The patient had had no trouble since, and now weighed one hundred and forty pounds, having gained over forty pounds in six months.

Specific Treatment for Tumors.—In the discussion of the last case, Dr. James J. Walsh said that it emphasized the necessity for the administration of specific treatment whenever internal tumors existed, even though there might be no specific history. Within the last few months, he had seen a case in which a large tumor of the splenic flexure of the colon led a prominent surgeon to diagnose a rapidly growing sarcoma. The patient was told to prepare for operation, and was told very frankly that the tumor was so large that there was very little hope that the operation would be radically successful. The patient came to New York with the idea of taking the mixed toxin treatment for sarcoma. The man had been a most careful liver, and there seemed no reason at all to doubt his story of the absence of venereal infection. He was put on mixed treatment, however, and in two weeks marked improvement set in. At the end of two months the tumor had practically disappeared.

Dr. Alfred Meyer said that specific tumors might simulate not only any form of neoplasm, but also aneurisms. Within the last few weeks he had seen a case presented before the German Medical Society in which what seemed to be a pulsating tumor occurred at the sterno-clavicular junction. With the idea rather of relieving the pain than of effecting any improvement in what was presumed to be an aneurism, the man was put on rather large doses of potassium iodide. Improvement occurred not only as regards the symptoms, but the tumor became greatly lessened in size. After a few months it completely disappeared.

Relation of Gastric and Urinary Acidity.—Dr. Alfred Meyer called attention to the fact that there seemed to be an inverse ratio between the acidity of the urine and the acidity of the stomach. When the gastric contents were strongly acid the urine was reduced in acidity. This seemed to account for the formation of certain calculi. Dr. Meyer had had under his care two patients in whom there was an excess of gastric acidity and a corresponding deficiency of urinary acidity. In both calculi developed. In one of the patients a phosphatic calculus of the pelvis of the kidney led to a pyelitis which necessitated the removal of the kidney. In the other a simple phosphatic calculus was passed to the bladder. The possible connection of excessive gastric acidity and the formation of urinary calculi was well worth studying. The etiology of calculi was a vexed question. Prophylaxis was now the order of the day in all affections, and if we could ward off the formation of calculi in predisposed individuals it would certainly be a great triumph.

Dr. Nammack said that the lessening in size of tumors and the disappearance of symptoms from them under the administration of specific treatment did not entirely justify the conclusion that the tumors were syphilitic. Sarcomata particularly were often influenced by the administration of potassium iodide. Brain sarcomata and even other brain tumors were often greatly improved by a course of the iodides. It seemed unfortunate that more attention had not been directed generally to the possible good that might be accomplished by the absorptive power of the iodides in these embryonic tumors and in granulation tissue generally.

Absent Knee Jerk with Ankle Clonus.—Dr. Leszynsky said that when Dr. Mills, of Philadelphia, presented some years ago a patient with absent knee jerks yet marked ankle clonus, the condition was considered a rare one. He had seen several such cases, and had one to present this evening. The patient, a man twenty years of age, suffered from Pott's disease when one year old. Later he had a tuberculous osteitis of the knee joint. His right leg was considerably smaller than the left, and his right foot dropped a little in walking. In neither knee could there now be demonstrated any knee jerk even with most careful reinforcement. Well-marked ankle clonus existed on both sides. There were other interesting symptoms. There were some numbness and insensibility of the outer part of the right leg, and some anæsthetic patches in the left ankle. There was also some disturbance of the temperature sense. It was probable then that there was a syringomyelia and that the cavity in the cord occurred only in the lumbar region in the third and fourth segments of the lumbar cord. The centre for the knee jerk was situated here, and it was obliterated by the pathological process of the syringomyelia. It was only when there existed an actual lesion of the lumbar cord as well as some other pathological condition above it, yet with the centre for ankle reflexes left untouched, that there was ankle clonus without exaggerated knee jerks.

Lateral Sclerosis.—Dr. Leszynsky presented a patient who was sent to him some time ago for diagnosis. Two years ago she lost more or less the use of her limbs. Afterward there seemed to have been some improvement, but never a return to the normal. Now she had completely lost the use of both legs. They continued to be well nourished, and no trophic conditions had developed anywhere. It was suspected at first that the case was one of hysterical paraplegia. Against this, however, were the slow and gradual onset, the total absence of pain, the failure to find any symptoms of hysteria in the previous history, and the absence of any cause like emotion, or family or monetary trouble, to bring on the hysterical palsy. Besides, none of the stigmata of major hysteria existed. There were no patches of anæsthesia and no hyperæsthesia. There was a good pharyngeal reflex and the visual fields were not narrowed. There were exaggerated knee jerks and ankle clonus. These last two symptoms, it was formerly thought, assuredly stamped an affection in which they were present as not functional. This was known now not to be true, for both exaggerated knee jerks and ankle clonus had been noted in purely hysterical cases. The long persistence of both these exaggerated reflexes and the amount of exaggeration, however, spoke strongly against hysteria. It seemed probable, then, that the case was one of chronic myelitis of the pyramidal tracts—the so-called lateral sclerosis.

Babinsky Great-Toe Reflex.—There was present in the case the symptom pointed out some time ago by Babinsky in Paris, which had been thought to be of differential diagnostic significance between functional and organic spinal disease. Ordinarily when the sole of the foot was tickled or touched, dorsal flexion took place. If there was disease of the spinal cord itself, especially of the pyramidal tracts, this flexion was limited to the great toe, which immediately after the irritation of the sole was strongly raised toward the dorsum of the foot. This could be seen very readily in this case. Some doubt remained as to the diagnosis of lateral sclerosis, because of the absence of the scissors gait, and the fact that the bowels were not much affected and the bladder was not at all. In women, however, we did not see the development of the scissors gait until late in the disease. Mechanical factors in the muscles of the female leg and the farther separation of the heads of the femora accounted for this. There was some incontinence of fæces, *i.e.*, when the call to go to stool came it must be obeyed at once, or the sphincter was not able to control the intestinal contents. In women incontinence of urine in these cases was not nearly so common as in men. Of late the affection seemed to have made more rapid progress than before. It was probable that if the woman could be kept under observation for some time, it would be possible to decide with certainty that lateral sclerosis was present.

Significance of Babinsky's Reflex.—The presence of the Babinsky contraction of the big toe seemed always to indicate the presence of a pathological condition of the spinal cord. It was not pathognomonic of degeneration of the pyramidal tracts, but it at least indicated some interference with their function. Siller had recently observed it in two cases of cerebral hemorrhage in which the knee jerks were absent. He was inclined to attribute to it an ominous significance in these cases, because both of his patients died.

In the discussion Dr. Nammack said that the presence of the exaggerated reflexes so persistently seemed to him to stamp the affection as organic, not functional. As Patrick, of Chicago, once said, a single objective symptom meant more against the diagnosis of hysteria than any number of theoretical considerations.

Angina Pectoris.—In the attack, rest and fresh air are of use, with morphine hypodermically. Nitrite of amyl up to twenty drops on a handkerchief should be inhaled. Between the attacks, iodide of potassium, gr. v.-xv., should be given daily for months or years. During fifteen days of each month nitroglycerin aids in nutrition of the heart. Ignipuncture or tincture of iodine over the heart region may be of service. Moderation at table should be observed, with suppression of alcohol and tobacco, avoidance of emotion and fatigue.—Paris Correspondent in *Medical Press*, January 17th.

CONCERNING THE PERITONEUM AND THE TREATMENT OF EXUDATIVE PERITONITIS.*

BY ALBERT A. BERG, M.D.,

ADJUNCT SURGEON TO MOUNT SINAI HOSPITAL, NEW YORK CITY.

THE rapid and extensive progress made in surgery during the last two decades of the nineteenth century has left few unexplored regions, and but little fertile soil to cultivate. It has been said that the new era in surgery will devote itself to the perfection of our present diagnostic knowledge, to the more sharp definition of the indications for or against operative attack, and to the attempt to establish on a rational and sound basis the present therapeutic procedures, thus eradicating all that is useless and cumbersome. In accordance with this view I have prepared this paper; not because I have any new method of treatment to propose for diffuse exudative peritonitis, but rather because I would wish with your aid in discussion to bring some order out of the chaos in which the therapeusis of this disease is involved, and because I would seek to establish a rational basis on which to rest our operative measures. It seems most important at the very outset of these remarks to consider the two cardinal points which underlie the entire subject-matter of peritonitis. These are: (*a*) Is the presence of bacteria alone sufficient to produce an exudative peritonitis, and if not, what else must be added to aid the bacteria in their work? (*b*) What protects the peritoneum from becoming the seat of such an inflammation in the presence of bacteria?

It has been well enough established, both experimentally and clinically, that bacteria alone are not capable of producing an exudative peritonitis. Without entering too deeply into the experiments of Wegner,[1] Grawitz,[2] Waterhouse,[3] and Orth,[4] I may be permitted to quote the conclusions which the above investigators have unanimously arrived at:

1. That the introduction of bacteria, even of the pyogenic types, into the normal peritoneal cavity produces no evil results, provided they are not mixed with caustic or irritating substances.

2. The introduction of non-pyogenic organisms into the normal peritoneal cavity produces different results, depending on whether the organisms injected cause decomposition of albumin, or not. In the latter case even considerable amounts of bacteria and fluid are absorbed, without evil consequences, while in the former general sepsis, but not purulent peritonitis, results.

Opposed to the conclusions I have just mentioned are the results of the investigations of Pawlowsky,[5] Alexander Fränkel,[6] and others, who found that injections of even very small doses of the staphylococcus aureus, or of the streptococcus, produce an exudative peritonitis. We must infer, and even Pawlowsky has conceded this, that there were other factors associated with the bacteria in their experiments, which resulted in the production of the peritonitis established by their injections. Clinically we are very often confronted with evidences that the presence of bacteria alone in the healthy peritoneum is not sufficient to establish an exudative peritonitis. It has fallen to the lot of every one of us to soil the peritoneum with the pus of some very infectious abscesses, and yet in very many cases no peritonitis has developed. The patients have recovered, and exhibited at no time any signs leading us to suppose the coexistence of an exudative peritonitis. In this connection the observations of Bönnecken[7] on the bacteria of incarcerated hernial sacs may be briefly mentioned. He found: (1) In the fluid of incarcerated hernial sacs there are already in an early stage of the incarceration, long before necrosis of the bowels has occurred, micro-organisms. (2) These are both cocci and bacilli, and wander out from the bowel into the hernial sac. (3) Death is due in these cases to peritoneal sepsis, usually without purulent peritonitis.

Again, Tavel and Lanz[8] say concerning this point, that the presence of bacteria which have wandered out into the peritoneum is not sufficient to produce a peritonitis, as long as the other parts of the serosa are normal, and retro-absorption can take place. This is shown by the rarity of peritonitis through wandering of bacteria into the peritoneum. Instances of bacterial peritonitis following such out-wandering of bacteria, in which only this factor is present, have been shown neither experimentally nor clinically.

To what is this protection from the deleterious action of the bacteria due? Several theories have been advanced to account for it. First, the peritoneal serum was supposed to exert a bactericidal action on the organisms which had been introduced (Schnitzler and Ewald[9]). Then again it was advanced that the leucocytes which had wandered out into the peritoneal cavity had overcome and destroyed the bacteria. The peritoneal cells were also said to have bactericidal power. Of all the explanations, the most rational is that which ascribes the protective attribute of the healthy peritoneum against bacterial infection to its rapid absorptive power. The experiments of Grawitz[10] bear out this view; for he found that when the peritoneum is injured by caustics, or when a wound of the peritoneum favors the sedimentation of the bacteria, so that a phlegmon results, then bacterial peritonitis ensues.

This brings us to the consideration of absorption in the healthy and diseased peritoneal cavity—a question that has bothered the ablest physiologists, and one which is even to-day not certainly decided. As an absorbing organ we may consider the peritoneum as being made up of endothelial cells and stroma, the latter supporting a rich supply of vascular and lymphatic vessels. It must be remembered that the peritoneum has an enormous surface exposed for absorption, almost as extensive as the area of the skin. In viewing the question of absorption from this surface, we must consider by what routes, and by what method, absorption takes place.

As to the channels by which absorption takes place, it has been fairly conclusively shown through the labors of Hamburger,[11] Orlow,[12] Adler, and Meltzer,[13] that the chief route is by way of the blood-vessels; the lymphatics, if they enter at all, play but a subsidiary rôle in the path by which absorption occurs in the healthy peritoneum. This helps us to understand the gravity of an absorption of pathogenic organisms by the peritoneum, provided the tissues are not able to cope with them after absorption. For it must be remembered that every absorption of bacteria into the blood is not necessarily followed by a proliferation of these organisms, and furthermore, even when the bacterial resorption is very considerable, bacteriæmia is very rare, at least in human beings. Were the lymphatics more concerned in the absorption from the peritoneal surface, there would be an additional protection in the lymphatic glands against an entrance of the pathogenic organisms into the blood, and the picture of peritoneal septicæmia would probably be a less frequent one.

---

* Read in abstract before the Surgical Section of the New York Academy of Medicine, May 14, 1900.

The method of absorption from the peritoneal cavity is still not positively decided. The one school, which includes such able investigators as Hamburger,[14] Cohnstein,[15] and others, argue that they have distinctly proven that resorption from the peritoneal or pleural surfaces follows the physical laws of osmosis and filtration; whereas another school, including equally competent investigators, such as Orlow,[16] Starling, and Tubby,[17] urge that absorption is a distinctly active process, the peritoneal cells being the active factor in the absorption.

Hamburger, the leading exponent of what I may term the physical method of absorption, believes resorption to be due to these factors: (*a*) Imbibition, both molecular and capillary; (*b*) osmosis; (*c*) hydrostatic pressure. He urges, in support of the first of these factors, that all tissues, living as well as dead, can imbibe fluids, and, owing to this property of imbibition, that fluids will pass from the peritoneum to the blood-vessels. But in reference to this the following objection is to be noted: Why should the property of imbibition carry fluids from the peritoneal cavity into the blood and lymphatic vessels? Is this imbibing of fluids and yielding them up to the blood and lymphatic system in itself not a manifestation of cellular activity? Thus when the latter is suspended, as for example after death, imbibition takes place until the tissues have become saturated, and then resorption ceases. This imbibition accounts for the absorption that has been noticed in experiments undertaken after the death of animals. But in the normal living tissues, the cells yield up their imbibed fluids to the blood and lymphatic vessels, and so resorption goes on indefinitely. Hamburger, who attempted to disprove the cellular activity in causing absorption, laid stress upon the results of those of his experiments which showed that even after severe injury to the peritoneum by chemical (NaFl) or thermal means, absorption and the equalization of the osmotic coefficient took place, and that these also occurred in animals dead from a few minutes to twenty-four hours. He apparently overlooked the fact that his chemicals or thermics did not destroy the property of imbibition, owing to which a certain amount of fluid disappeared from the peritoneal cavity, and which he attributed to resorption; and also overlooked the fact that osmosis, a purely physical phenomenon, will occur through any animal membrane living or dead. As regards imbibition, therefore, I might say that it is owing to this property of imbibing fluids that the peritoneal tissues are enabled to accommodate the fluids they have absorbed from the peritoneal cavity, while they are transporting them to the blood and lymphatic vessels. For were they not able to imbibe, it is very evident that no absorption by means of a membrane unprovided with openings could take place.

In reference to his second law of absorption, viz., osmosis, we must remember that when fluids containing diffusible substances in solution are separated by an animal membrane, these diffusible substances will pass through this membrane from the side on which the osmotic tension of that particular diffusible substance is greater, to that on which it is less: thus if hypotonic NaCl solutions are put into the peritoneal cavity, NaCl will osmose from the blood-vessels until the osmotic tension of NaCl is equalized on both sides of the peritoneum; and vice versa, if hypertonic NaCl is placed into the peritoneal cavity, the NaCl will osmose from the peritoneal cavity into the vessels until the osmotic tension is again equalized. The laws of osmosis will explain the passage of diffusible materials through the peritoneal membrane, but as regards the absorption of fluids from the peritoneal cavity, in accordance with the physical laws of osmosis, the proof is not convincing; for were resorption due entirely to osmosis we would expect it to be as rapid after death as during life, and we would not expect the markedly retarded absorption that has been observed by Orlow, while animals were kept under continuous chloroform anæsthesia; so that while osmosis may account for some of the absorption, it must be conceded, as Orlow has expressed it, that the peritoneum is an active membrane in that it modifies the physical laws of osmosis, just as does the intestinal mucosa.

As regards now the third factor, which was described by Hamburger as being concerned in absorption, viz., hydrostatic pressure, I can only remark that this can at the best play but a subsidiary rôle in the mechanism of resorption, inasmuch as the intra-abdominal pressure is never a constant one, but fluctuates with inspiration and exspiration, with the degree of intestinal distention, and with the contraction of the abdominal muscles. The three factors concerned in peritoneal resorption, as formulated by Hamburger, do not sufficiently explain the mechanism of absorption from the peritoneum. Imbibition, both molecular and capillary, enables the cells to carry the fluids only from the absorbing surface to their place of delivery; osmosis will account for the passage of diffusible substances through the animal membrane, and such diffusion takes place from the blood-vessels into the peritoneum, as well as from the peritoneum into the vessels; whereas hydrostatic pressure, being a variable factor, cannot account for the steady, continuous absorption which takes place from serous membranes. This brings me to the consideration of the other theory as to the mechanism of peritoneal resorption, viz., that this is an active cellular process. If resorption is such an active process, then if we can in any way interfere with this cellular activity resorption should be diminished. We know that when chloroform is administered there ensues a temporary paralysis of the cerebral cells, and also of the leucocytes (as shown by Massart), which lose their irritability and their chemotactic function. It would be wrong to suppose that this action of the chloroform is limited only to the cerebral cells and the leucocytes; much more rational is it to suppose that the cells of the entire organism are temporarily paralyzed, and their function consequently impaired. If this were so, we would expect a retardation of absorption while an animal was under the influence of chloroform. This does actually occur, and is beautifully illustrated by the experiments of Orlow.[16] He found that if the serum is taken from an animal and injected into the peritoneal cavity of another animal of the same species it is absorbed, but in less amount in the same period of time when the animal is kept under continuous chloroform anæsthesia than would be the case were the animal not kept under this anæsthetic. Furthermore, we find that bacteria alone (Grawitz and others), when injected into the healthy peritoneum in amounts not too excessive to be absorbed, do not produce peritonitis, but if the peritoneal cells are poisoned at the same time as the injection is made, as for example by the chemical toxins resulting from bacterial life, thus paralyzing their resorptive power, then peritonitis results; or if these cells are destroyed by the action of caustics, then peritonitis results. Now were resorption a purely physical process it would not be retarded by a local disturbance of the peritoneum, such as is produced by caustics or toxins, and the bacteria being at once absorbed, peritonitis would not result. Inasmuch, however, as resorption is an active process, if this activity is in any way interfered with or suspended, then the bacteria can grow and multiply, and produce their deleterious results. I may be permitted in this connection to cite the opinions of some of the investigators on the mechanism of absorption from serous membranes. Thus Starling and Tubby say: "The cells between the blood and the pleural fluid seem to exert a pull on the latter; in fact there is an active absorption going on. The cells must perform a considerable amount of work in this absorption; so that we must look upon them as being actively concerned in the absorption of fluids, such as one-per-cent. saline solution." Quoting again from the same authors: "There is evidence to show that with certain solutions an active absorption from the cavity may take place, whether by the blood-vessels or pleural endothelium we are at present unable to determine." Says Orlow: "These experiments go to prove positively that the peritoneum is not merely a passive membrane, through which fluids simply diffuse, as through animal membranes outside of the body, but that it is an active membrane, in that it modifies the physical laws of absorption, just like the intestinal mucosa."

The arguments thus far advanced, I think, show conclusively that resorption from serous membranes is an active process; and I would beg that this be kept strongly in mind when I come to discuss the treatment of exudative peritonitis, and have to consider the best method of dealing with the exudate.

So far I have considered only the absorption from the healthy peritoneal surface. Let me now take up the question of resorption from the peritoneum when it has become diseased. If the question of absorption in the healthy state is a difficult one to decide, how much more so is it when we consider absorption from the diseased membrane. For here we have to consider not only the changes which have occurred in the peritoneal cells, but also the changes in the blood-vessels, in the blood current, and in the nerve supply. The first question that comes up for discussion is: Is there any absorption from the diseased peritoneum? This can be answered positively in the affirmative. The next point to consider is: What is the rate of absorption as compared with the healthy peritoneum? Here again we have positive evidences in the results of the experimental investigations of Schnitzler and Ewald,[19] who have shown that in rabbits in which a purulent peritonitis exists, the rate of absorption is somewhat slower. In this connection it might be well to state that these investigators have also demonstrated that an increase of peristalsis hastens the rapidity of absorption up to a certain point, beyond which no further increase in the rate of absorption is possible; and vice versa, a slowing of the peristalsis lessens the rapidity of absorption. The final question, By what channels does absorption take place in the diseased condition of the peritoneum? is difficult to determine; it certainly is partly by the lymphatics, for the lymphatic glands are found enlarged in inflammatory conditions of the serous membranes; it probably also occurs by the blood-vascular system, although no experiments have as yet been reported in this connection.* I beg of you to bear in mind, then, that there is quite a rapid absorption from the peritoneal surface, even when it is the seat of a severe purulent inflammation; for I will have cause again to refer to this when I consider the question of drainage of the peritoneal cavity when it is the seat of an exudative inflammation.

I have gone thus into the details of the routes and mechanism of peritoneal resorption, because it is owing to its very rapid absorbing-power that the peritoneum owes its protection against the action of bacteria. This brings me to the final question I proposed at the beginning of this paper, viz., If bacteria alone are not sufficient to produce an exudative peritonitis, what else must be present to aid the bacteria in their work? Briefly stated it may be said that any agent which interferes with the peritoneal protective attribute, viz., the rapid resorptive power, is sufficient to enable the bacteria to produce their deleterious effects. The earliest investigations of Grawitz proved this; for he found that when the peritoneum was injured, *e.g.*, by caustics, or when it was completely destroyed at a local area, the bacteria would sediment at that particular site of injury or destruction, and establish a peritonitis. This protective attribute may be lessened or abolished by (*a*) chemical agents, which cause either a death of the cells, or injury more or less marked, or a disturbance in their physiological function, so that the latter is either temporarily or permanently suspended; (*b*) by mechanical agents, such as gauze, tubes, etc., which act in the same way as the above. This helps us to understand the apparently conflicting results of the experiments instituted by Pawlowsky,[20] on the ability of the healthy peritoneum to withstand the presence of bacteria; for he injected not only bacteria but also their chemical toxins, which latter paralyzed the absorptive power of the peritoneal cells, and so favored the local sedimentation and further action of the bacteria.

To quote from Tavel and Lanz,[21] page 143: "In order that bacteria should develop on the peritoneum, and produce a bacterial peritonitis, there must be already a mechanical or chemical peritonitis. A primary bacterial peritonitis is not a possibility, because the normal serosa, by its resorptive property, absorbs the implanted bacteria, or else it does not respond by inflammation to these bacteria."

To recapitulate from the data I have furnished thus far, it is evident:

1. That bacteria alone, except when in very large quantity, are not sufficient to produce an exudative peritonitis.

2. That this immunity on the part of the healthy peritoneum to the deleterious action of bacteria is due to its very rapid resorptive power.

3. That this resorption under normal conditions is mainly by way of the blood-vessels.

4. That peritoneal resorption is an active cellular process, and not a passive one. This cellular activity is manifested in the diseased as well as in the healthy condition, but to a somewhat lessened degree. The more marked the disease the greater is the interference with this activity, it being least when the peritoneal endothelium has been considerably altered, and ceasing altogether with the destruction of these cells, resorption by much modified peritoneum being similar to resorption by other types of cellular tissue. This conclusion is of the utmost importance in connection with the question of drainage of the peritoneal cavity, and will be referred to again in the latter part of this paper.

---

* The writer has commenced a series of experiments with the object of determining the channels by which absorption takes place in the diseased peritoneum and will report the results at a subsequent time.

5. In virtue of its rapid resorptive power primary bacterial peritonitis is not a possibility, unless the bacteria are present in such large numbers as to paralyze the peritoneal cells, and so hinder their rapid resorption. There must primarily be a factor which by interfering with the cellular activity of the peritoneal cells favors a sedimentation of the bacteria, with their consequent further growth and development. Such factors may be either mechanical, *e.g.*, gauze packings, drainage tubes, etc., or chemical, either organic or inorganic in character.

These facts should govern our methods of procedure with the local conditions found in exudative peritonitis, and reference will be made to them again. Before proceeding to the subject of the treatment of such inflammations of the peritoneum, I would wish to direct attention to the rather common fallacy of associating the term "septic" with the purulent types of peritonitis, and to the error of estimating the virulence of the inflammation by the character of the exudate. I have shown in my previous remarks that peritonitis is primarily either a mechanical or chemical process, to which may be added the further element of bacterial life and development, with the toxin production that necessarily accompanies them.

A mechanical or chemical peritonitis may be either dry, *i.e.*, adhesive, resulting in the formation of adhesions between the viscera, or exudative, *i.e.*, with the presence of an exudate in the peritoneal cavity. The character of this exudate varies, it being hemorrhagic, or serous, or sero-purulent, or purulent. Such a mechanical or chemical peritonitis is usually of a benign character; the patients exhibit the classical signs of an inflammation of the peritoneum, but in the vast majority of cases the disease goes on to a spontaneous cure, the exudate being absorbed, or the adhesions becoming organized. If bacteria are added to such a mechanical or chemical peritonitis, the inflammatory process is not altered in character, although it may be in degree; in that the exudate becomes more distinctly purulent, or even fetid, from the products of bacterial life. But there is superadded the element of poisoning from the absorption into the system of the toxins produced by the bacteria. The severity of the case depends on the degree of this intoxication. Some of the worst cases of poisoning from peritoneal absorption of toxins and bacteria occur in patients whose peritonea show absolutely no signs either micro- or macroscopically of a peritonitis. We have designated such pathological conditions as peritoneal septicæmia. Vice versa, many of the purulent types of exudative peritonitis are not at all septic. The bacterial element of a peritonitis then does not modify the inflammation in character, but merely adds another factor in the resorption of either toxins or bacteria, or both, to the local manifestations. How irrational, then, to base our estimate of a peritonitis on the character of the exudate! Thus Pawlowsky[22] has shown that the purulent and fibrino-purulent peritonitides belong to the less intense and virulent forms, whereas the hemorrhagic types, and those in which no macroscopical changes of the peritoneum are evident, are the most virulent and fatal. This toxic factor is the one that determines the prognosis in every individual case, and it bears no relation to the character or amount of the exudate.

The toxæmia and bacteriæmia which are found in septic cases of peritonitis are due, however, not only to resorption from the peritoneal membrane, but in very many cases they are equally due to the resorption by the intestinal mucosa of the toxins and bacteria which are present in the intestinal canal. As we know, the intestine is the habitat of numerous varieties of cocci and bacilli, and these, owing to the stasis of the intestinal contents from the paresis of the muscularis, a result of the peritonitis, take on increased virulence and elaborate products of much higher toxic coefficients. This intestinal resorption must not be considered as playing a secondary rôle in importance to the peritoneal resorption, for often it is the chief factor in causing the toxæmia and bacteriæmia. Furthermore it must be distinctly remembered that patients can die from this intestinal intoxication alone.

How then are we to treat rationally this toxæmia and bacteriæmia? As regards the former the ideal remedies would be antitoxins to neutralize the deleterious influences of the toxins. Such antitoxins we do not possess, hence we must rely on such therapeutic measures as will, in the first place, aid the patients to eliminate the toxic elements from the circulation and tissues, and which will support the patients until they have rid themselves of these toxic substances. The chief excretory channels are the kidneys. It should be our earnest endeavor to promote free diuresis. This is accomplished best by frequent infusions of saline materials into the circulatory system. I am accustomed to infuse either subcutaneously or intravenously, or per rectum, small quantities of hot normal salt solution, about 100 gm. every hour. These infusions both stimulate the circulation and by increasing arterial pressure promote free and copious diuresis. It is very important to make these infusions frequently, and not to inject too much at any one time; for such large infusions merely overload the right heart, thus retarding its action and upsetting the circulation, and so producing congestion of the kidneys and internal viscera with consequent depression of their especial functions. In addition to such frequent infusions I give the patients a nourishing diet, and stimulation as required. When the toxæmia is intestinal in origin, we find these viscera paretic, distended, and congested, for it is this pathological condition of the bowel that has caused the intestinal bacteria to take on increased virulence, and their products consequently to have an increased toxic value. When this condition of the intestine is present it is met most satisfactorily by drawing a distended coil of intestine into the wound, and, after due protection with hot pads, to open it on its convexity, allow the contents to escape, and then insert a long rectal tube into the lumen of the intestine, washing the latter out thoroughly, both distally and proximally to the opening. When the intestinal irrigation is finished, the opening in the bowel is closed by a few Lembert sutures. If the muscular coat of the bowel has become absolutely paralyzed, as is evident by absence of all peristaltic movement and the lack of tone of the fibres, I do not sew up this opening in the bowel at all, but leave a large-sized rectal tube in the proximal end of the intestine, and irrigate the bowel through this with saline solution several times a day, thus favoring free intestinal drainage and elimination of toxic materials.

If bacteriæmia as well as toxæmia exists, I am sorry to say that our present therapeutic procedures will avail us but little. It would appear rational to employ the bactericidal sera in these cases; but after an extended use of these remedies I cannot say very much in their favor. I have attributed the failure of the sera to produce an effect in these cases to the fact that when bacteria have invaded the general circulation, and have not been overcome by the normal resisting-power of the human tissues, by the time clinical symptoms of their invasion of the general system are manifested they have gained so much headway that these therapeutic measures no longer exert any marked influence upon their development and life history.

This brings us to the consideration of the treatment of the exudative peritonitis *per se*. As we practically recognize to-day no idiopathic type of exudative peritonitis, the first thing to consider in this connection is the removal of the cause of the inflammation. This cause may be either a local or a general one—local, in the form of an inflammatory process of some viscus situated within the peritoneal cavity, or contiguous to it; or general, the peritonitis in the latter case being merely a manifestation of a systemic disease, *e.g.*, a bacteriæmia or general toxæmia. When the peritonitis is merely such a concomitant inflammation, the treatment is not to be directed to it, but to the general systemic disease of which it is a manifestation, and such a peritonitis regularly tends to spontaneous cure when the general systemic disturbance is relieved. When, however, the peritonitis is the direct result of a local disease process of a viscus situated within the cavity of the peritoneum or contiguous to it, this acting cause must be removed before we can consider the diseased peritoneum at all. Thus an inflamed appendix must be taken out, a ruptured or perforated intestine must be repaired, an abscess cavity must be drained by proper incisions, etc. Besides removing the cause of the existing peritonitis, we can do but little for the inflamed serous membrane. But in treating exudative inflammations surgically, we must consider two other points, viz., How are we best to remove the products of exudation, and how are we to prevent their re-accumulation? As to the best method of removing the exudate surgeons are at variance. Some prefer to mop out the products of exudation with sponges or compresses of gauze, whereas others consider it best to sluice the peritoneal cavity with large quantities of normal saline solution until the fluid returns from the cavity clear of all exudate, and still others prefer to eviscerate and wash out the peritoneal cavity. There does not seem to be any better reason for the use of the one or the other of these methods beyond the personal predilection of the particular surgeon, and yet it seems that there are special indications calling for the employment of the one or the other of these procedures.

Our chief aim in dealing with any inflamed organ is to injure its structure and nervous mechanism as little as possible by our manipulations. On this basis evisceration, with the traumatism to the nervous apparatus of the intestine and peritoneum that necessarily accompanies this procedure, can hardly be considered a proper and rational mode of cleansing the peritoneal cavity, even though it is the most thorough. Its baneful effects much more than counterbalance its good qualities. As regards simple irrigation without evisceration, Riedel and Kümmel [23] have shown, by experiments on animals, that irrigation of the peritoneal cavity in cases of purulent peritonitis worked unfavorably and harmfully; moreover, that even healthy animals subjected to irrigation of their peritoneal cavity became asphyxiated during the procedure, and that the peritoneum of such animals after death showed ecchymoses and like irritative phenomena on the intestine. No such like effects can be attributed to the introduction of soft mops into the peritoneal cavity for the purpose of removing the exudate, and this is consequently the best method to be pursued. There are, however, cases in which washing of the peritoneal cavity with saline solutions is preferable to drying it out with mops. These are as follows: (*a*) when large masses of fibrin are present in the cavity, these may be dislodged and carried away with the current; (*b*) when the exudate is of a thick, creamy consistency and is spread out among the intestinal coils in all directions. In such cases the exudate can be more rapidly removed and with less traumatism to the peritoneum than by the method of mopping. It is my custom in removing the exudate to take very soft sea-sponges, attach them to long sponge-holders, and carefully pass these into all the fossæ and spaces of the peritoneal cavity. This procedure takes but a very few minutes, and I have several times convinced myself that the peritoneal cavity can in this way be made entirely dry.

As regards the second point in the consideration of the exudate—viz., How are we to prevent the re-accumulation of the products of inflammation?—this necessarily implies the question, Are we to drain the peritoneal cavity, or not? Before entering into this consideration, let me repeat a few of the facts I have brought out in the first portion of this paper; these are, that the peritoneum is an actively absorbing organ; it absorbs almost as rapidly in the diseased as in the healthy state; but wherever it has been modified or destroyed, or removed, there active resorption does not occur, and stagnation with the deleterious action of the bacteria, if they are present, results. As long, therefore, as the peritoneal surface maintains its integrity, drainage of its cavity is superfluous, for it can easily and readily take care of the products of exudation that result from its inflammation. There are, moreover, besides its superfluity several objections to drainage of this serous membrane. These are: (*a*) The danger of secondary infection through the medium of drains. (*b*) All drains are foreign materials to the peritoneum, whose presence is resented by it, and if they are introduced an additional burden is put upon the reactive power of the peritoneal cells, in order to make such materials extraperitoneal. (*c*) The presence of such foreign materials, be they gauze or tubes, by retarding the absorption favors the local sedimentation of bacteria around them, and an augmentation of the existing inflammation. This can easily be shown by injecting organisms into the healthy peritoneal cavity, and into a similar peritoneal cavity into which a piece of gauze or tubing has been placed. In the former case no peritonitis results; in the latter a purulent peritonitis is set up. (*d*) Danger of secondary intestinal obstruction from the adhesions resulting from the use of drains. (*e*) That drainage of the general cavity is not possible for more than a few hours at the utmost, for at the end of this time all such foreign materials have been walled off from the general cavity.

It follows that, as long as the peritoneum is peritoneum, so to speak, drainage is superfluous and objectionable. When, however, a region has been denuded of its peritoneal covering, this area must be drained, for these parts no longer possess their rapid absorbing power, and hence their protective attribute; or when the peritoneum, though intact, has lost its identity as peritoneum, either on account of inflammation or traumatism, then all such affected parts must be drained, even though it necessitates the employment of a complicated system of drainage.

One further point demands our attention in the consideration of the treatment of peritonitis, viz., When is catharsis to be established? The results which are achieved by early free evacuation of the bowels are: (*a*) the prevention of stasis of the intestinal contents, and the increased virulence of the bacteria that goes with such stagnation, and consequently the less absorption into the vascular system of the products of fermentation and bacterial life; (*b*) the increased rapidity of absorption from the peritoneum, on account of the increased peristalsis (Schnitzler and Ewald). As baneful effects resulting from early catharsis may be especially mentioned the goading on to work of an infiltrated and inflamed muscularis, which can certainly result only in increasing the loss of tone, or even in causing paralysis of the muscular tunic of the bowel. When the pros and cons for early catharsis are weighed, it is easily seen that there is more immediate danger from the intestinal absorption of the toxins due to stagnation than from the loss of tone or paralysis which may result from early catharsis. So that when indications of intestinal distention are manifested, free catharsis should be established as soon as possible. When, however, no distention is present, there is certainly no indication for early evacuation of the bowel; in fact, such a procedure is entirely contraindicated. It has been my custom to be guided entirely by this sign as to when to move the bowels: if no distention is manifested, I never hesitate to wait three or four days before resorting to catharsis.

Let me rapidly rehearse, then, the method of treatment of exudative peritonitis that has yielded the best results in my hands: Cœliotomy, the site of the incision depending on the cause of the peritonitis; removal of the acting cause; if the intestine is very much distended, incision of one of the most distended coils and evacuation of its contents; suture of the bowel if its muscular wall is not paralyzed, otherwise drainage of the proximal end of the bowel; removal of the exudate from the free peritoneal cavity by moist sponges; protection of all raw spaces or modified peritoneal surfaces by gauze; closure of the rest of the abdominal wound; in addition the general systemic treatment for the toxæmia and bacteriæmia, as I have outlined in the paper.

I have taken from the records of the Mount Sinai Hospital all the cases of diffuse exudative peritonitis, following upon appendicitis, which have been operated upon during the past three years of 1897, 1898, and 1899. In all there were seventy-three cases, of which nineteen resulted in recovery, or twenty-six per cent. In considering these statistics it should be taken into account that many of these cases were in a most desperate condition on their admission to the hospital, and operation would have been declined by many surgeons. Inasmuch, however, as some of these most desperate cases have resulted in recovery, we have in the hospital adopted the same rule as applies in strangulated hernia, *i.e.*, never to decline to operate unless the patient is actually moribund.

The first table is a very important one, as showing the relation that exists between the mortality and the duration of the peritonitis. Thus:

TABLE I.

Duration of the Disease.	Total Number of Cases.	Cures.	Percentage of Cures.
One day	9	5	55
Two days	14	6	42
Three "	20	5	25
Four "	10	0	0
Five "	5	2	40
Six "	2	0	0
Seven "	6	1	16
Eight "	1	0	0
Nine* "	—	—	—
Ten "	5	0	0

* In one case the duration of the peritonitis was not ascertained.

Thus it is seen that the percentage of recoveries diminishes considerably as the duration of the disease increases. Two apparent exceptions occur in the above table, in that two patients recovered in whom the disease had lasted five days, and one in whom it had been of seven days' duration. This can be explained either on the basis that the history as given by the patient was faulty, or that the peritonitis was not of a very septic type; but as a rule it can be said that the prognosis becomes proportionally bad as the duration of the disease increases.

It is considered by many that children recover more frequently from peritonitis than do adults. But if we compare the percentage of cures in children with that in adults, taking into consideration also the duration of the peritonitis, it will be seen that there is not much difference in the various ages as regards the percentage of recoveries. It is not the age of the patient, but rather the duration of the peritonitis before it has been subjected to treatment, that influences the subsequent course of the disease. (See Table II.)

In the third table which I have prepared I have arranged the cases according to the treatment they have received; in each class I have considered whether the appendix when it was found was perforated or not, for the coexistence of a perforation with the peritonitis materially alters the prognosis for the worse, thus: Appendix was—

Found perforated in 45 cases, of which 11 recovered = 24 per cent.
Found non-perforated in 5 cases, of which 2 recovered = 40 per cent.
Not found at all in 23 cases, of which 6 recovered = 26 per cent.

As regards the treatment four different methods were followed: (*a*) Simple packing of the outer wound, and extensive drainage of the peritoneum with no attempt to remove the exudate; (*b*) mopping out the exudate with soft sponges, combined with more or less extensive drainage; (*c*) irrigation of the peritoneal cavity until all the exudate was removed, combined with drainage; (*d*) evisceration with irrigation, with more or less extensive drainage.

Combined with either one of the procedures enterotomy or enterostomy was performed whenever the intestinal distention was marked enough to demand it. I have not compiled the statistics of the cases in which this procedure was carried out, but we have always found it to benefit materially the septic condition of the patient, and, by relieving the intestinal distention, to favor better and more easy respiration and circulation, and to help to restore the tone of the muscular tunic of the bowel. (See Table III.)

From the above tables it will be seen that the percentage of recoveries was highest in those cases in which evisceration combined with irrigation was practised. It is hardly fair, however, to compare this group of only three patients with the other groups which comprised many more. Comparing the other groups, we see that the percentage of recoveries was highest when the exudate was simply sponged away, being thirty per cent. in these cases, as against twenty-five per cent. when irrigation of the peritoneum was employed, and

TABLE II.

Ages.	DURATION.																			
	1 Day.		2 Days.		3 Days.		4 Days.		5 Days.		6 Days.		7 Days.		8 Days.		9 Days.		10 Days.	
	Cases.	Cures.	Cases.	Cures.	Cases.	Cures.	Cases.	Cures.	Cases.	Cures.	Cases.	Cures.	Cases.	Cures.	Cases.	Cures.	Cases.	Cures.	Cases.	Cures.
Under ten years	3	2	2	1	..	..	..	..	1	0										
Between ten and twenty years	1	0	9	3	6	1	5	0	..	..	..	..	2	1	..	..	..	..	3	0
Between twenty and thirty years	1	1	1	1	5	2	1	0	3	1	1	0	2	0	1	0				
Between thirty and forty years	3	2	1	0	6	1	3	0	..	..	1	0	1	0	..	..	..	..	1	0
Over forty years	1	0	1	0	3	1	1	0	1	1	0	0	1	0	..	..	..	..	1	0

as against fifteen per cent. when the exudate was not removed, the peritoneal cavity being simply drained. Furthermore it will be seen that the duration of the disease had been comparatively twice as long in those cases of recovery in which sponging was employed as in those cases in which the other procedures were carried out; and we have noticed above that this duration of the process was a most important factor in determining the prognosis. Leaving out, then, the cases in which evisceration and irrigation were performed—and the number is entirely too small to draw any conclusions—it would appear that by removing the exudate by sponging the highest number of cures would be obtained. With the removal of the exudate in this manner, as with all the other procedures, some drainage was also provided. But latterly I have not attempted in any way to drain the general peritoneal cavity. If there were any raw spaces I have protected these with gauze wicks, and closed the rest of the abdominal wound. This I consider by far the best procedure. I have followed it thus far in three cases with entirely satisfactory results, all these cases terminating in recovery. The duration of the disease had been two days on an average; the exudate was sero-purulent in character, was diffusely spread over the peritoneal cavity, and the appendix was perforated in all three. After removal of the appendix, the exudate was rapidly sponged out by soft sponges on holders, and the raw surface of the appendix protected by a narrow wick of gauze, which was led out of one angle of the abdominal wound, the latter being closed throughout the rest of its extent. The gauze was removed after twenty-four hours. It was extremely gratifying to compare the convalescence of these patients with that in whom irrigation or packing and drainage had been practised. In the former the pulse and temperature had approached the normal within thirty-six hours, and there was after this comparatively little disturbance; whereas in the latter the temperature and pulse remained high for from four to seven days, and during this period the patients suffered from the traumatism which had been inflicted, or from a local peritonitis, which was taking place around the packings or tubes. From either of these the patients often seemed to succumb, even after the primary inflammation had shown indications of regression.

TABLE III.

Method of Treatment.		Total Number of Cases.	Cures.	Per Cent.
A Simple packing and drainage; no attempt to remove the exudate.	Appendix not found ...	10	3	30
	Appendix perforated	9	0	0
	Appendix non-perforated	0	0	0
	Totals.............	19	3*	15
B. Exudate removed by sponging; drainage.	Appendix not found...	6	2	33
	Appendix perforated ...	16	4	25
	Appendix non-perforated	1	1	100
	Totals.............	23	7†	30
C. Exudate removed by irrigation; drainage.	Appendix not found....	7	1	14
	Appendix perforated ...	18	6	33
	Appendix non-perforated	3	0	0
	Totals.............	28	7‡	25
D. Evisceration combined with irrigation to remove the exudate; drainage.	Appendix not found....	0	0	
	Appendix perforated....	2	1	50
	Appendix non perforated	1	1	100
	Totals.............	3	2§	66

* Of these 3 cases, the duration of the peritonitis had been 3 days in each.

† Of these 7 cases, the duration of the peritonitis had been 5, 2, 2, 3, 7, 1, 2 days respectively.

‡ Of these 7 cases, the duration of the peritonitis had been 1, 2, 1, 2, 1, 3, 2 days respectively.

§ Of these 2 cases, the duration of the peritonitis had been 1, 2 days respectively.

I cannot close these remarks on the peritoneum without again pronouncing against what has been our too active handling of this most sensitive tissue. The pendulum of our activity is gradually swinging the other way, and we are commencing to recognize that gauze packings, irrigation, evisceration not only injure the delicate nervous mechanism of the peritoneum, but also favor, by interfering with the activity of the cellular process, the local sedimentation of bacteria with their consequent local development and deleterious effects. The peritoneum has been endowed with its own protective attribute, which is not heightened by manipulation or the introduction of foreign material. If we supplement the internist's treatment of peritonitis, as formulated by that great master Alonzo Clark, by a removal of the cause of the inflammation, and cease to abuse and injure this delicate membrane, we will meet with more gratifying results.

Vitiligo in a Baby Three Days Old.—Yukovski says that vitiligo in children is very rare. Most of the cases observed have been among negroes. The child observed by the author was the offspring of white parents presenting no specific history. The child had exophthalmos, myxœdematous skin on the neck and face, a guttural voice, and icterus. The vitiligo was noticed only on the third day. The question arises, whether or not those spots were present at birth. The author accepts the theory of the neurotic origin of the disease. Under the influence of some neurotic influence we have either a local dilatation of the blood-vessels, decomposition of red blood corpuscles, and emigration of melanocites, followed by deep local pigmentation, or local spasm of the blood-vessels, obliteration of the arteries, and secondary pigment atrophy.—*Meditsinskoe Obozrenie*, April, 1900.

THE TREATMENT OF TYPHOID FEVER.

By D. E. ENGLISH, M.D.,

MILLBURN, N. J

In the treatment of typhoid fever we should ever bear in mind the nature and probable cause of the disease, for treatment directed to the relief of the symptoms only is not so uniformly successful as a combined symptomatic and specific treatment.

We are told by investigators that the disease known as typhoid fever is due to the presence in the intestine of a microbe, the bacillus typhosus, which may be helped in its work by one or more other microbes; that these minute forms of life give rise to certain poisonous matters in the intestine, which, besides acting as local irritants, find their way into the blood and are diffused throughout the body. Thus we have a local inflammation and ulceration of the intestine; a direct poisoning of the great nervous centres, and an infiltration and enlargement of the lymphatic system of vessels and glands due to a specific poison; as well as the prostration, emaciation, and parenchymatous degeneration of various organs due to long-continued high fever. From this the indication for treatment would seem to be as follows:

I. To empty the gut of all infected matters as soon as possible.

II. To render the gut as nearly as possible uninhabitable by the microbes.

III. To prevent so far as possible the further absorption of the poison.

IV. To neutralize or expel the poison already absorbed.

V. To keep the temperature within safe bounds.

VI. To prevent so far as possible overaction of organs already damaged, *i.e.*, to promote physiological rest, and avert rupture of the intestine.

VII. To support the strength of the patient, and guard against sudden collapse.

I. When a case of typhoid fever is seen early, it is rarely possible to make a positive diagnosis at the first visit. The disease for which it is most often mistaken is malarial fever. In case of doubt it is best to order quinine sulphate gr. iii. every three hours. If, after thirty-six hours, the temperature has continued on a curve typical of typhoid fever, simple malarial fever may be excluded. This initial course of quinine need not prevent the fulfilling of the first indication as outlined above. My favorite purge for this contingency is calomel, because calomel empties the gall bladder, and the bile is nature's own intestinal antiseptic. From ten to thirty grains may be given, according to circumstances. If there has not been free catharsis within six hours, it is well to give magnesium sulphate ʒ i. in a glass of boiled water, every hour until the intestines seem to be well cleaned out.

II. To render the gut uninhabitable by the pathogenic microbes it is necessary to keep it as nearly empty as possible, and as nearly aseptic as possible. How can we keep the intestine empty and at the same time give it physiological rest? While intestinal rest is highly desirable, experience seems to teach that the bowels may be moved once, or even twice, each twenty-four hours without unduly straining them, even in typhoid fever. To accomplish this a small dose of podophyllin, perhaps assisted by a little aloin, may be given morning and night: podophyllin gr. $\frac{1}{8}$ to $\frac{1}{4}$, aloin gr. $\frac{1}{8}$ to $\frac{1}{4}$. Podophyllin is a valuable drug in these cases because it increases the secretion of bile and so promotes intestinal asepsis. While a large dose of calomel will empty the gall bladder, it is probably true that small continued doses do not increase the secretion of bile, and as the local antiseptic properties of calomel in the intestines are feeble, it is not wise to rely on it as an intestinal antiseptic after the initial dose.

III. It is probably not possible to keep the intestine aseptic, although scores of preparations are offered to the profession for that purpose, their promoters claiming unequalled advantages for each. My favorite intestinal antiseptic is carbolated camphor.[1] This preparation I have used in many conditions which seemed to depend on putrefactive changes in the contents of the stomach or bowels, as well as in typhoid fever. It relieves flatulence, renders the fæces nearly odorless, and lowers the temperature decidedly without any apparent weakening of the heart. The camphor, besides being an antiseptic of considerable power, has a good effect on the general nervous system, and acts as a direct tonic and stimulant to the great sympathetic nerve centres in the abdomen. Although this preparation is said not to be a chemical combination, and therefore one would expect to get the individual effects of both of the ingredients, still much larger doses of carbolic acid can be given in this way than when it is administered alone. Ten to twelve drops, representing gtt. iii. to iv. of the acid, may be given every two hours for forty-eight hours before there will be any change in the color or odor of the urine. When this occurs, the dose should be decreased somewhat, or the interval between doses lengthened, but the remedy should not be entirely discontinued until the patient is well advanced in convalescence. The carbolated camphor need not be stopped for slight albuminuria; the albuminuria is caused by the disease, not by the medicine, and I have seen it disappear while the patient was still taking good-sized doses of this remedy. If one ounce of carbolic acid crystals and three ounces of camphor gum are put together in a glass vessel and allowed to stand a short time, the result will be a smooth, transparent, oily liquid, almost colorless when first made, changing with age to a light pink as carbolic acid does; having the odor of camphor, a burning taste when put upon the tongue, and a specific gravity of about 0.990. If kept in an air-tight glass vessel, it remains unchanged for an indefinite time, but when exposed to the air the camphor evaporates faster than the carbolic acid, and the preparation becomes stronger with the acid. To guard against this it is best to keep an excess of camphor in the vessel at all times. An elegant way in which to accomplish this is to fuse about one drachm of camphor in the bottom of an ounce vial, and when it has solidified fill the vial with carbolated camphor. If the acid is not entirely saturated with the camphor the preparation is irritating, or even caustic, to the mucous membranes; but when fully saturated it can be taken pure on the tongue without harm. This preparation mixes freely with fixed oils, vaseline, alcohol, collodion, and ichthyol, and dissolves iodoform in the proportion of one to twelve, completely disguising the odor of the iodoform. It will not mix with water or glycerin. It is best given by dropping the dose into a No. 2 capsule just before it is administered. It will dissolve the capsule if allowed to remain in it long. This preparation will probably keep the intestine as nearly aseptic as it is possible to do with any drug given by the mouth. To empty the intestine and to keep it as nearly as possible empty and aseptic will prevent further absorption of the specific poison, and so fulfil indication No. III.

IV. The best agent for neutralizing the absorbed poison and for expelling it from the body is water. Large and frequent draughts of sterile water will act as a diluent, a diuretic, and a diaphoretic; will relieve in this way, or in these ways, the congestion and irritation of the kidneys and the albuminuria, and will carry the poison out of the system.

---

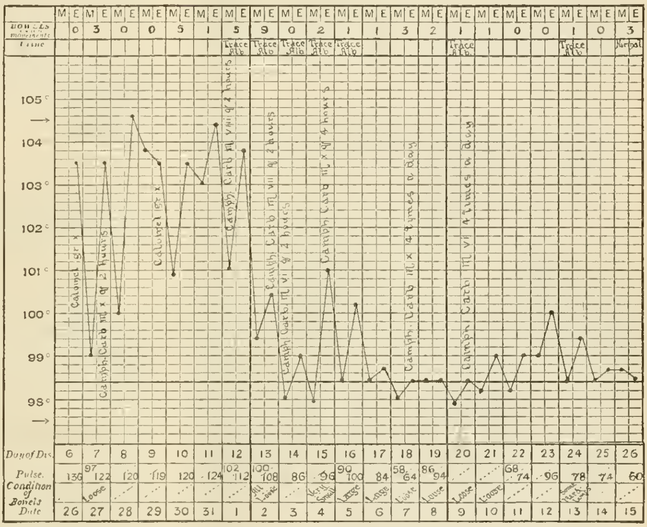
[1] "Camphorated Carbolic Acid." Medical Record, September 30, 1893, vol. xliv., No. 14, p. 426.

V. After the second day of treatment by carbolated camphor the temperature of typhoid fever rarely goes above 103° F., and more often keeps below 102° F. On the third day of treatment there is generally a decided fall, and the temperature does not become high again except by accident, such as constipation, error in diet, or too sudden stopping of the specific treatment. The prostration, typical tongue, iliac gurgling, and perhaps some tympanites, may continue with a nearly normal temperature, but the patient is evidently much better, and finds it difficult to restrain his appetite, and irksome to keep his bed.

In the occasional cases in which I have used means to reduce the temperature, the following tablet, given every one to two hours for five or six doses, has answered the purpose satisfactorily:

℞ Acetanilid.................................. gr. iij.
Camphoræ monobrom.,
Caffeinæ citrat...........................āā gr. ss.
M.

VI. The two organs most liable to damage from overaction in typhoid fever are the intestine and the heart. It is best to have the bowels move once or twice a day; if the patient is taking much milk, four or even five movements a day seem to do no harm. So that about the only way in which we can promote intestinal rest is to keep the patient quiet, not to overfeed him, and to guard against tympanites. The carbolated camphor generally prevents tympanites, but a little turpentine or compound tincture of cardamom will do no harm if another remedy seems indicated. Or a turpentine stupe may be used on the abdomen; but it should not be forgotten that turpentine is a renal irritant and may cause albuminuria, strangury, or nephritis, if used too long or in too large a dose. When it becomes necessary to check the bowels, which is seldom the case, I use small doses, gr. iiss. of Dover's powder, and give as few of them as possible. To prevent cardiac fatigue the most important measure is to keep the patient absolutely quiet. He should lie on the back with the head rather low; the lower extremities should be kept warm, and everything should be done to promote easy circulation of the blood. When the pulse is rapid and soft, small doses of tincture of digitalis (about ♏ v.) in whiskey (about ʒ i.) may be given tentatively about every four hours. The whiskey will tend to prevent the contraction of the arterioles by the digitalis. But these two remedies must be used with care in the early stages, and with the object of resting, not stimulating, the heart. The patient should use a bed-pan and urinal, and should be cautioned against moving a muscle unnecessarily.



VII. To support the strength of the patient adequately without overloading the stomach or fatiguing the intestine demands careful judgment. For the first week no food should be given that will pass through the stomach or leave any débris. For the first two weeks I rely entirely on dissolved beef made after Weir Mitchell's formula, as follows:

℞ Acidi hydrochlor. c. p........................ ʒ i.
Aq. destillat.................................ad ℥ i.
M. S. One teaspoonful to a pint of water for making beef tea.

Put one pint of boiled water, a good pinch of salt, and a teaspoonful of the above prescription in a one-quart glass fruit jar, and shake well. Then add one pound of finely chopped beef, and shake again. Close the jar air-tight and set it in a cool place like the cellar floor, but not on ice, for twelve hours. Then put the jar into water and keep it warm, about 110° F. to 120° F., for four or five hours. Be careful not to let it get too hot. The contents of the jar should be strained through a cloth, and all the liquid squeezed out; the residue will be about the size of a hen's egg and nearly white. This essence may be seasoned with pepper and salt and given warm in ounce doses every hour for the first week, and in two to three ounce doses every hour or two hours during the second week. If the essence is properly made, the residue will be found to consist almost entirely of white fibrous matter, the red muscular fibres having dissolved out.

During the third week one pint of milk may be given every twenty-four hours, but it should be given in divided doses, and largely diluted with sterile water, and with the addition of as much salt as will be palatable. This is better given at about the temperature of the stomach if the patient can take it so. Also in the third week the white of one egg in water, and one entire egg beaten with the juice of one lemon, may be given each twenty-four hours. In making "egg-lemon" the juice of one lemon should first be rubbed with a little sugar, the well-beaten yolk then stirred in, and last the white beaten to a froth spread over the surface. This makes a delicious and beneficial food for the third and fourth weeks. Whether or not the diet should be changed during the fourth week depends largely on the condition of the patient, and must be left to the judgment of the physician in charge, but even in the later stages of typhoid fever it is much safer to give too little food than too much.

In cases seen early and treated in this way there will be very few, if any, embarrassing complications or sequelæ. While the duration of the disease is not greatly shortened the patients get well without excessive prostration or emaciation, and the period of convalescence is shorter than under expectant or simply symptomatic treatment. I have not lost any cases treated in this way, nor have I seen any hemorrhage or perforation. Carbolated camphor may be given in

♏ vi. doses, four times a day, indefinitely, without harm, and it is wisest to continue giving it until the patient is entirely well. The accompanying temperature chart shows about the usual curve under this treatment. This patient travelled over fifty miles from a boarding-school to her home on January 1, 1898, and I first saw her that evening. She continued taking ♏ vi. of carbolated camphor four times a day for a week longer than the chart shows, and the albuminuria disappeared while she was still taking the remedy. She also took podophyllin gr. $\frac{1}{8}$ and aloin gr. $\frac{1}{8}$ once or twice a day nearly every day throughout her sickness. Once or twice in her case, as in a number of others, when the heart seemed to need a stimulant I gave a few doses of the following:

℞ Tr. nucis vomicæ,
Tr. digitalis............................āā ʒ ii.
Spts. vini gal ....ad ℥ iij.
M. S. A teaspoonful, in water, every one to three hours when needed.

Success in the treatment of this disease depends largely on careful watching of the patient, and giving nature a little aid at just the right moment; and on strict sanitation of the bed and room of the patient. This, combined with the specific treatment spoken of above, will save nearly every case of typhoid fever.

THE USELESSNESS OF THE PITUITARY BODY AS A THERAPEUTIC AGENT.[1]

By WILLIAM M. LESZYNSKY, M.D.,
NEW YORK,
CONSULTING NEUROLOGIST TO THE MANHATTAN EYE AND EAR HOSPITAL; NEUROLOGIST TO THE DEMILT DISPENSARY, ETC.

In 1886 Marie in his original description of acromegaly suggested that the pituitary gland (hypophysis cerebri) played an essential rôle in this disease, and many subsequent observers are still inclined to accept this theory. Pituitary substance has therefore been suggested as a remedy for acromegaly, this being the only pathological condition in which it has been administered for therapeutic purposes. Pituitary tablets are on the market, each three-grain tablet containing one grain of the desiccated pituitary body of the sheep, equivalent to eight grains of fresh gland substance.

The reports thus far published regarding the physiological effects of the injection of the extract of the pituitary body are so contradictory that they are of no scientific value. Andriezen has demonstrated that in the lowermost vertebrates the secretion from the anterior lobe of the gland (prehypophysis) is carried through the central nervous system, and he believes that this secretion possesses either a trophic influence on the nervous tissues, or is in some way concerned in the metabolism of nerve tissue. There is no evidence, however, which would lead us to assume that these studies in comparative anatomy and physiology are applicable to man. While some of the published reports as to the efficacy of the preparations of the sheep's gland have seemed quite encouraging, in so far as the relief of headache and of paræsthesia of the hands is concerned, it is the general consensus of opinion that it in no way influences the progress of this disease, which at best is rarely recognized until well advanced in its course. In all of these cases, other therapeutic measures have been employed at the same time, to which much of the symptomatic improvement may be attributed.

In two patients with acromegaly recently under the writer's observation, the daily administration of the pituitary tablets was continued for several months, but the symptoms were not ameliorated by its use. In both of these patients bitemporal hemianopsia was present as the result of pressure upon the optic chiasm by the enlarged prehypophysis. In one, the remaining half-fields diminished. In the other, one eye has become blind from optic atrophy. This progressive loss of vision would indicate that the hypophysis had continued to enlarge, thus destroying the remaining fasciculus of the nerve.

If we accept the theory recently enunciated by Dr. Harlow Brooks, "that the increased secretion of the prehypophysis in acromegaly acts as a direct stimulus to the connective-tissue cells, and by its persistent action slowly augments their growth," the use of the pituitary-gland preparations would be contraindicated. On the other hand, although extirpation of the gland in dogs has been successfully performed, acromegaly has not followed. It is also a well-established fact, that in man the hypophysis cerebri has been the seat of a destructive process, such as sarcoma, without the presence of any of the pathognomonic symptoms of acromegaly. We must, therefore, conclude that acromegaly is not due to obliteration of the glandular structure of the hypophysis.

It will thus be seen that this alleged remedy for acromegaly has been used only empirically; that it has proved absolutely inefficacious; and that there are neither rational nor logical grounds for its therapeutic administration in the disease for which it has been recommended.

A PRELIMINARY NOTE ON A SIMPLE AND NEW METHOD OF REPEATEDLY STERILIZING SPONGES BY BOILING.

By CHARLES A. ELSBERG, M.D.,
ATTENDING SURGEON MOUNT SINAI HOSPITAL DISPENSARY.

It is generally acknowledged that for the rapid and thorough removal of blood, pus, or other fluids during operations sponges are often indispensable. Their softness, elasticity, and porosity, the ease with which they absorb fluids, and the readiness with which they yield them on pressure, have given to sponges a unique and valuable place in our surgical armamentarium.

Sterilization by boiling—the simplest and most thorough method of disinfection—has been hitherto impossible, because boiling in water, soda solution, or other antiseptic solutions causes a loss of elasticity and a shrinkage of the sponges.

As the result of a series of investigations into the physical and chemical properties of this material, and based on chemical principles identical with those made use of in the sterilization of catgut by the ammonium-sulphate method,[1] I have devised the following method by which sponges can be repeatedly sterilized by boiling. The steps of the procedure are the following:

1. The sponges are freed from calcareous matter by immersion for twenty-four hours in eight-per-cent. muriatic-acid solution, and are then thoroughly washed in water.

2. They are then boiled for fifteen minutes or longer in the following solution: Potassium hydrate, 1 part; tannic acid, 3 parts; water, 100 parts.

3. They are washed in water, carbolic acid, or sublimate solution until all of the potassium hydrate-tannic-acid mixture (which is of a dark-brown color) is removed.

4. The sponges are preserved in five-per-cent. carbolic-acid solution.

Sponges that have been used can be resterilized by washing them in water, and then boiling them once more in the solution, etc. The solution can be used any number of times, as it does not deteriorate by boiling or by age.

---

[1] Read before the New York County Medical Association, May [illegible], 1900, in connection with a discussion on organo-therapy.

[1] Elsberg: "A New and Simple Method of Sterilizing Catgut by Boiling." MEDICAL RECORD, May 5, 1900.

Sponges prepared in this manner are absolutely sterile, and they will be found to have retained all their physical qualities—size, softness, elasticity, power of absorption, etc. The procedure will be described in further detail in a future publication.

105 East Fifty-seventh Street.

A REMINDER FOR THE CARE OF CHILDREN DURING THE SUMMER.

By S. Henry Dessau, M.D.,
New York.

Lest we forget, let us remember that the greatest number of infants and children under three years of age die annually from gastro-intestinal diseases.

Lest we forget, let us remember that, with rare exceptions, the gastro-intestinal diseases of which these children die are of the acute type and occur as diarrhœa.

Lest we forget, let us remember that by far the larger majority of these diarrhœas occur during the summer months. So true is this that they have deserved the general name of summer diarrhœas of infants and children.

Lest we forget, let us remember that, the combined observations and conclusions of eminent men in the profession in all ages until the present time have attributed the underlying cause of these fatal diarrhœas to the excessive heat of the summer months.

Lest we forget, let us remember that, although the advanced knowledge of collateral sciences has demonstrated the important part played by the deleterious action of germs upon infant foods and their immense reproduction under favorable conditions of filth and bad air, without the all-controlling influence of the summer heat no such extensive contamination of the infant's food could occur.

Lest we forget, let us remember that the heat of the summer months is now upon us, and that in our endeavors to protect infants and children against evil attacks of diarrhœas during the season by providing them a suitable and agreeable food, when deprived of nature's own, we should also bear uppermost in our minds and daily thoughts the prime necessity of warning parents to combat the depressing influences of prolonged heat and a humid atmosphere by every conceivable means in their power.

Lest we forget, let us remember that the weak infant has weak physiological functional powers, and for this reason the heat-regulating function is weak and much more easily overcome than in adults. In this way infants and young children manifest a different clinical picture of the bad effects of heat from that of adults, which is recognized as heat-stroke or sunstroke.

Lest we forget, let us remember that one of the first of the evil effects of heat upon the infant is to weaken the digestive function, which is first manifested by a loss of the appetite, and, therefore, above everything else the infant should not be forced or induced to take large quantities of food, nor even the same amounts as usual.

Lest we forget, let us remember that with a combination of germ-impaired food and weakened digestive powers of the stomach under the influence of an excessively heated atmosphere, the very best conditions are presented for an attack of diarrhœa.

Lest we forget, let us remember that under the influence of a greatly lowered vitality of the infant, due directly to the excessive and prolonged heat of the summer months, certain germs, which are always found in the intestinal canal, even during a period of the best of health, are permitted under such altered conditions to exert a poisonous action, and hence even breast-fed babies may and do become the victims of a summer diarrhœa.

Lest we forget, let us therefore remember that, while it is beyond question most imperative to have only the purest food given to babies and young children during the summer season, at the same time it is equally as imperative to impress upon the understanding of mothers and nurses the great importance of keeping the child in as cool a condition in summer as circumstances will permit.

For this purpose the cool country air is best for those whose means can afford it, while for the masses including the poor of large cities other devices must be thought of—such as a liberal use of ice for sucking or eating, bathing in cold water several times in the day if need be, seeking the early morning air, a free ventilation of the sleeping-apartments especially during the night, doing as little cooking in small apartments as possible, using the lightest kind of clothing, in fact letting children imitate little Hottentots; taking short trips on the water to the sea-shore or crossing and recrossing the ferries, visiting the shady parts of the public parks during the heat of the day. All of these need not by any manner of means preclude a strict observance of domestic cleanliness, which produces at least a mental effect of apparent coolness and comfort, nor the general cleanliness of city streets and a free use of flushing, which not only in fact cools the air of the streets, but in addition insures a purer breathing-air freed from decomposing matter.

Seeking the shade of trees is undoubtedly one of the best plans for obtaining cool air in summer. Dr. Chapin has recently called attention to the fact that the foliage of trees has the property of reducing and regulating atmospheric temperature in their immediate vicinity.

Nothing here has been said regarding the infant's food, as the purpose of this simple rubric is to direct attention to the general care of the child.

Bacteriological Study of Meningitis Cerebro-Spinalis Epidemica.—After a very exhaustive study of the literature of this subject, and based upon his own observation of an epidemic of cerebro-spinal meningitis, Khtegloff comes to the following conclusions: (1) The disease is caused by Weichselbaum's intracellular meningococcus; (2) that the meningococcus is a coccus *sui generis*, not to be confounded with other diplococci; (3) that its vitality in agar cultures is especially characteristic; (4) its presence in the nasal secretion of a patient suffering with meningitis is of diagnostic value.—*Meditsinskoe Obozrenie*, April, 1900.

The Relationship of Diabetes Mellitus to Epilepsy.—W. Ebstein says that diabetes or even glycosuria is a very rare complication of epilepsy. There are three possible relationships between diabetes mellitus and epilepsy; the glycosuria may be either the cause or the effect of the epilepsy, or both conditions may arise independently of each other, though due to a common cause. So far as the author can find from the literature on the subject, no proof has yet been furnished of epilepsy determining diabetes or even serving as a predisposing cause. Epilepsy frequently alternates with diabetes and mental disorders in neuropathic families. Also, in a subject free from any neuropathic taint, there may be many predisposing causes determining simultaneously diabetes and epilepsy. The author describes an illustrative case.—*Medical Press and Circular*, May 16, 1900.

DERANGEMENT OF THE WATER-SECRETING POWER OF DISEASED KIDNEYS.

IT is well known that disease of the kidneys may exist in the absence of usual symptoms, including albuminuria and tube casts; but even when these are present it is desirable to know the extent of the disease, and especially the degree of interference with function. Studies that have recently been made in regard to variations in the freezing-point of the urine seem to promise helpful results in this direction. It has been found that in cases of diffuse disease of the kidneys, the determination of the reduction in the freezing-point of the urine is capable of disclosing quite characteristic changes in renal activity. If the disease attains a degree and extent rendering impossible compensation through increased activity on the part of healthy portions of the kidney, it may be determined from the freezing-point and the amount of the urine that the absolute number of molecules eliminated with the urine in twenty-four hours is abnormally small—molecular oliguria. In healthy persons the osmotic pressure of the urine corresponding to the reduction in the freezing-point is generally greater than that of the blood. The increased osmotic pressure of the urine is related to increased functional activity on the part of the kidneys. The latter is impaired in the presence of diffuse disease of the kidneys, and the reduction in the freezing-point of the urine is in general less than that of the urine in health.

Although healthy kidneys generally secrete concentrated urine, they are also capable of secreting urine whose molecular concentration is considerably less than that of the blood. If greatly diluted urine is eliminated, the water-secreting power of the kidneys exceeds their absorptive power. After the drinking of excessive amounts of water the molecular concentration of the urine may fall to a freezing-point of −0.10° C. It has been shown that kidneys, the seat of diffuse disease, lost not only their water-absorbing but also their water-secreting power in greater or lesser degree. While the freezing-point of the urine in health varies between −3° and −0.10° C., the limits gradually approximate in the presence of diffuse disease of the kidneys in accordance with the character and the severity of the case. Hyposthenuria is therefore but a one-sided symptom of the lessened accommodative power of the kidneys to the needs of the organism in regulating the excretion of water.

Kövesi and Róth-Schulz (*Berliner klinische Wochenschrift*, 1900, No. 15) undertook a series of investigations to determine the changes that occur in the power of the kidneys to secrete a greatly diluted urine in the presence of diffuse disease of the kidneys of various kinds. The method of procedure was as follows: The urine was collected for twenty-four hours, at intervals of four hours, in separate receptacles, and the freezing-point of each specimen was determined. On the following day 1.8 litres of water were administered in the course of an hour, the urine was voided at intervals of half an hour, and the amount and the freezing-point were determined. In healthy persons the kidneys exhibited a great power of accommodation to the variations in the amount of water ingested. The reduction in the freezing-point of the urine rapidly declined as much as 0.10° C. or more after copious drinking. The secretion of greatly diluted urine generally ceased within two or three hours, and was gradually replaced by the evacuation of urine of moderate concentration.

In cases of parenchymatous nephritis it was found that the power of the kidneys to secret dilute urine was greatly reduced, and apparently in proportion to the severity of the renal disease. In cases of interstitial nephritis, on the other hand, the power of the kidneys to secrete dilute urine was, in comparison with the kidneys in health, little if at all diminished. Finally, it was found that the water-secreting power of the kidneys, as well as their power of concentrating the urine, was not impaired in cases of compensated valvular diseases of the heart. In the presence of compensatory derangement, however, the diluting-power of the kidneys was diminished, as in the transition from parenchymatous to interstitial nephritis.

From these investigations it appears that the function of the kidneys is altered in a materially different manner in the presence of contracted kidney and of parenchymatous nephritis respectively, the difference residing in the varying limits of accommodation of the kidneys with relation to the amount of fluid in the organism. These limits are quite considerable in cases of interstitial nephritis, but are diminished in cases of parenchymatous nephritis in accordance with the severity of the disease. It has also been thought that the diminution in the concentration of the urine is more marked in cases of parenchymatous nephritis. The results of the present investigation indicate, however, that the characteristic distinction between parenchymatous and interstitial nephritis resides not in the varying amount of the reduction in the freezing-point of the urine, but in its variability.

The reduction in the freezing-point of the urine in cases of disease of the kidneys depends upon (1) the localization and the degree of the morbid process, which together determine the extreme limits of variability of the concentration of the urine; (2) the amount of water ingested; (3) the degree of preservation of the permeability of the kidneys to solid molecules.

In every case of nephritis a certain amount of water will, in accordance with the permeability of the kidneys to solid molecules, yield urine that is isotonic with the blood. If so much is drunk that this amount of water is sent to the kidneys, the variety of renal disease will have no influence upon the freezing-point of the urine; if less be drunk, the reduction in the freezing-point will be marked in cases of interstitial nephritis, and inconsiderable in cases of parenchymatous nephritis. If, however, more water be drunk than is necessary for the secretion of isotonic urine, the results will be the reverse, and more dilute urine will be secreted in cases of interstitial nephritis than in cases of parenchymatous nephritis. If, in cases of renal disease, the permeability of the kidneys to solid molecules is diminished, and if this diminution is but imperfectly or not at all compensated for, the molecular concentration of the blood is increased and the reduction of the freezing-point exceeds 0.56° C. This result may not appear, or it may be modified if so much water is retained that the increase in the molecular concentration of the blood is prevented, in spite of an increase in the absolute number of solid molecules, or if the proteid metabolism falls so low that the reduced permeability of the kidneys suffices for the elimination of the resulting solid molecules, or if, finally, healthy portions of the kidneys assume vicariously the functions of the diseased portions.

It has been shown that increased osmotic pressure of the blood cannot be considered as the cause of uræmia, as the osmotic pressure may be increased without the occurrence of uræmia, and it may be normal in the presence of uræmia. The studies that have been made in regard to the functional activity of the kidneys by the methods under consideration show that the amount of molecular diuresis can be determined, and in marked cases molecular oliguria can be recognized from a determination of the reduction in the freezing-point and the amount of the urine passed in twenty-four hours. The determination of the freezing-point of the blood is capable of showing whether molecular diuresis is adequate for the elimination of metabolic urinary molecules. If molecular diuresis, as compared with metabolism, in accordance with diminution in the permeability of the diseased kidneys to solid substance, is insufficient, then the reduction in the freezing-point of the blood increases.

Hyposthenuria indicates a reduction in the water-absorbing power, and the more or less marked negative results of the dilution test indicate a reduction in the water-secreting power of the kidneys. If the last two alterations occur in the presence of disease of the kidneys, the usual independence of the elimination of water and that of the solid constituents of the urine is impaired or lost. In the latter event the amount of water eliminated by the kidneys is closely dependent upon the elimination of the solid molecules, so that it is determined by the permeability of the kidneys to solid substances.

The Plague has reappeared in Oporto, a case having been reported on June 23d. This is the first that is known to have occurred in that city since the epidemic was officially declared at an end on February 7th last.

BILLS FOR IMPROVING THE STATUS OF THE CONTRACT SURGEON IN THE UNITED STATES ARMY.

In the Medical Record of March 17th ult., some remarks were made upon the injustice from which the contract surgeons who served in the Spanish-American war undoubtedly suffered, and to which those now in the Philippines and elsewhere are compelled to submit; and the suggestion was thrown out that these disabilities be so far as possible removed and the standing of this necessary branch of the service be established once and for all. This course would seem to be for the best interests of the army and the country at large. It has at last been clearly shown—and the surgeon-general himself has become an unwilling convert to these views—that there is now no hope whatever of obtaining from Congress any increase in the number of the medical corps of the regular army. This on the face of it may not appear to be a far-sighted policy, and probably will not commend itself as such to the judgment of the "man in the street," who will not unnaturally be disposed to think that an increase in the army should carry in its train a corresponding enlargement of the army medical corps, and that at least the army medical corps should be numerically strong enough to attend to the needs of the regular army. However, the opinion of Congress has been otherwise, and it has decided that in the future it will rely upon the medical profession in civil life to supply the additions to the medical staff that may be required with an army in the field. Consequently the question which now confronts the military authorities is how to adjust in the most satisfactory manner the grievances of the acting assistant surgeons and to establish the conditions of their successors upon a firmer and more equitable basis.

The surgeon-general with this end in view has introduced two bills for which he has secured the approval of the Secretary of War. Of the aforesaid bills one provides that acting assistant surgeons of the army should have the same rights and privileges as regards leaves of absence as commissioned officers of the army—this clause applies to the future only; and further, that acting assistant surgeons appointed since May 1, 1898, shall be paid for absence on sick-leave. The other grants commissions as assistant surgeons of volunteers with the rank of first lieutenant to acting assistant surgeons who have served one year, and the rank of captain to those who have served as such lieutenants two years.

These bills, although an earnest of the wish of the surgeon-general to do justice to the men who so patriotically answered their country's call during the Spanish war, and so far as they go quite satisfactory, yet are, in the opinion of the men themselves, too limited in scope. It is held that the bills in question do not deal in a generous way, and in a manner befitting this great and rich republic, with those contract surgeons who were dismissed from the army on account of disease incurred while in discharge of their duty, or who returned to their homes broken in health and unable any longer to follow their profession. The Association of Acting Assistant Surgeons, therefore, has caused to be drafted a bill which is now before Congress embodying both the bills introduced by the surgeon-general—with slight amplifications—and its own. This bill provides for back pay, rank, etc., for acting assistant surgeons who served during the Spanish war, and who were dropped for illness or disability, and also enacts that those who have served for one year or more shall be commissioned assistant surgeons of volunteers with the rank of first lieutenant mounted, subject to honorable discharge whenever their services are no longer needed.

The government would have acted more wisely had it increased to a very considerable extent the strength of the army medical corps, for the fact must be borne in mind that an army medical officer, in order to be competent to fulfil his duties efficiently, needs special training. But as the "powers that be" have determined to place reliance mainly upon members of the medical profession drawn from civil life, it would be unjust, as well as an extreme act of folly, not to treat these men equitably and liberally; for it stands to reason that, if such a course be not followed, the inevitable result will be that in case of war surgeons will be lacking. Therefore, aside from the legality and justice of the question, which are evident enough, the bill of the Association of Acting Assistant Surgeons now before Congress should become law, if only as a matter of expediency.

CHOREA AS A PYOGENIC DISEASE.

A TENDENCY has arisen of late to consider chorea as an infectious disease, although such evidence as exists in favor of this view is circumstantial, rather than direct, and the chain is yet incomplete. A point to which some significance can be attached is the probability that acute rheumatism, with which chorea exhibits certain relations, is also of infectious, though perhaps of multiple, origin. In support of the infectious origin of chorea is the report by Westphal, Wassermann, and Malkoff (*Berliner klinische Wochenschrift*, 1899, No. 29) of a case of acute articular rheumatism, followed by chorea, and complicated by endocarditis and nephritis, in which they succeeded in isolating from the blood, the brain, and the endocardial vegetation a streptococcus capable of inducing polyarthritis in lower animals. The pyogenic nature of both polyarticular rheumatism and chorea had previously been suggested by other observers, one of whom, Mircoli (*Berliner klinische Wochenschrift*, 1900, No. 14. p. 303) now reviews his earlier investigations on this subject. Among seventeen cases of rheumatic chorea, pyogenic cocci were found in the joints in fourteen, staphylococci preponderating, while in three the diplococcus lanceolatus was present as the etiological agent. From a number of considerations, acute rheumatism is looked upon as a variety of pyæmia, but without suppuration; and chorea as a manifestation of the cerebral localization of the pathogenic agency.

The Annual Tetanus Epidemic is due next week.

News of the Week.

Yellow Fever has appeared this summer in many places in Cuba where no cases have occurred in several years. The United States troops have escaped hitherto, except in Quemados and Santa Clara. Up to the last week in June there were but three cases of the disease in Havana. The rains this season have been more than usually heavy in the island.

Philadelphia Pediatric Society.—At a stated meeting held June 12th, Dr. Joseph Sailer exhibited a child presenting a fluctuating swelling in the occipital region, with thrill on palpation, and a murmur on auscultation, which was thought to be due to a form of venous aneurism. Dr. Alfred Hand presented a communication entitled "Acute Adenitis (Glandular Fever) in Children, with Remarks on Terminology and Treatment." Dr. J. P. Crozer Griffith presented a report on three cases of influenza simulating glandular fever. Dr. H. D. Marcus read a report of a case of gravel. Dr. W. R. Nicholson reported a case of infection with the bacillus pyocyaneus. Dr. Charles A. E. Codman reported a case of leucocythæmia.

New York State Conference of Charities and Correction.—Invitations were recently issued by the Hon. William R. Stewart, president of the New York State board of charities, to fifty persons interested in charities and charitable work, to meet in the United Charities Building, at 105 East Twenty-second Street, New York, to organize a "State Conference of Charities and Correction." At this meeting the following officers were elected: *President*, Hon. William P. Letchworth, of Portage; *Vice-Presidents*, Mr. Robert W. De Forest, of New York, Hon. William J. Morgan, of Albany, and Rev. Thomas A. Hendrick, D.D., of Rochester; *Secretary*, Mr. Homer Folks, of New York; *Assistant Secretaries*, Mr. Frederic Almy, of Buffalo, Dr. John F. FitzGerald, of Rome, and Mr. Clarence V. Lodge, of Rochester; *Treasurer*, Mr. Frank Tucker, of New York. It is proposed that the first meeting of this conference shall be held in Albany in November next. In the main the work of the New York State Conference of Charities and Correction will be almost identical with that of the national conference of the same name, except that its scope of labors will not extend beyond the limits of New York State.

Pathological Society of Philadelphia.—At a stated meeting held June 14th, Dr. D. J. McCarthy demonstrated the histological changes in the cells of the sympathetic ganglia from animals suffering from rabies. Dr. M. P. Ravenel presented a communication in which he reported several instances in which bovine tuberculosis was transmitted to human beings. Dr. J. Hendrie Lloyd presented a large cystic kidney from a patient who exhibited aphasia due to uræmia. Dr. Lloyd and Dr. A. M. Seabrooke exhibited the heart and spleen from a patient who had passed through an attack of typhoid fever, and developed symptoms of malignant endocarditis, for the relief of which antistreptococcic serum was unsuccessfully employed. The heart presented vegetations on the mitral leaflets, and the spleen was greatly enlarged and infarcted. Dr. A. O. J. Kelly presented the breasts removed surgically from a woman on account of malignant disease. One of the growths was apparently a carcinoma, while the other was complicated by an enormous chronic hæmatoma. Dr. H. L. Williams exhibited the heart and aorta from a patient in whom gold wire and electrolysis had been employed for the cure of an aneurism of the aorta.

Dr. James F. McKernon has recently been elected professor of otology in the New York Post-Graduate Medical School and Hospital.

College of Physicians of Philadelphia.—At a special meeting held June 18th, the president, Dr. W. W. Keen, announced the completion of the $50,000 library endowment fund.

Dentistry at the International Medical Congress.—It has been decided by the executive committee of the Paris congress to admit as members of the congress all dentists who are duly qualified in France or abroad, even though they are not qualified in medicine or surgery. Members of the dental profession who wish to join the congress will be attached to the section of stomatology.

The Institute of Homœopathy.—At the fifty-sixth annual meeting of this society in Washington last week the following officers were elected: *President*, Dr. W. W. Van Baum, of Philadelphia; *Vice-Presidents*, Drs. A. B. Norton, of New York, George Royal, of Des Moines, and Flora N. Ward, of San Francisco; *General Secretary*, Dr. Eugene H. Porter, of New York; *Recording Secretary*, Dr. Wilson A. Smith, of Chicago; *Treasurer*, Dr. T. Franklin Smith, of New York; *Registrar*, Dr. Henry C. Aldrich, of Minneapolis.

The National Eclectic Medical Association held its thirtieth annual meeting last week in Atlantic City. The following officers were elected: *President*, Dr. E. Lee Stanley, of St. Louis; *First Vice-President*, Dr. J. D. McCann, of Monticello, Ind.; *Second Vice-President*, Dr. A. B. Young, of Memphis, Tenn.; *Third Vice-President*, Dr. J. R. Duvall, of Atlanta, Ga.; *Recording Secretary*, Dr. Pitts Edwin Howes, of Boston; *Corresponding Secretary*, Dr. N. A. Graves, of Chicago; *Treasurer*, Dr. W. T. Gemmill, of Forest, O. The next meeting will be held in Chattanooga, Tenn.

A Would-Be Disseminator of Smallpox.—A man in an Illinois town was angered by the health authorities, who insisted upon the vaccination of his daughter, and devised a novel plan for revenge. There were some cases of smallpox in the town pesthouse, and the fool deliberately made his way into the place in order to infect himself and his clothing with the germs of the disease and so spread it through the town. But he was so pleased with his trick that he couldn't help telling of it, and now the health people have caught him and bathed him, and will keep him in quarantine for some weeks.

The Study of Tropical Diseases by an Army Medical Board.—It is stated in the *Boston Medical and Surgical Journal* that a board of medical officers has been appointed to meet at Camp Columbia, Quemados, Cuba, for the purpose of pursuing scientific investigations with reference to the infectious diseases prevalent on the island of Cuba. The board will act under instructions from the surgeon-general of the army. The detail for the board consists of Major Walter Reid, Surgeon U.S.A., and Acting Assistant Surgeons James Carroll, Aristides Agramonte, and Jesse W. Lazear. It is understood that the board will devote attention chiefly to the investigation of yellow fever. Dr. Agramonte has been studying this disease in Havana for the past eighteen months, while Major Reid and Dr. Carroll, at the Army Medical Museum in Washington, have been engaged in an exhaustive study of Sanarelli's bacillus and serum, the results of which have already been made public. The work of the board will be done in the army laboratory at Quemados.

Pharmacists in the Public Services.—At a meeting of the Executive Committee of the Louisiana State Pharmaceutical Association, held at New Orleans, June 6, 1900, resolutions were adopted indorsing the action of the American Pharmaceutical Association in its efforts to obtain recognition of the profession in the army, navy, and Marine-Hospital service of the United States, and a fair compensation for the duties performed by the pharmacists in these services. Resolutions were also adopted indorsing the movement to obtain for the hospital stewards of the Marine-Hospital service the change in title from that of "hospital steward" to "senior," "junior," and "assistant pharmacist," with the respective pay of $1,200, $900, and $720 per annum, with the present perquisites, and the concessions now granted junior medical officers.

Reciprocity in Medical Licensure.—At the Washington meeting of the American Institute of Homœopathy the committee on legislation made a report advocating uniformity in medical license laws of the various States which will permit an exchange of licenses between States. The co-operation of the American Medical Association and of the National Eclectic Association and other organizations interested in medical licensure is to be requested. The draft of the bill submitted, which will be introduced in Congress, authorized the appointment of a commission of three physicians, representing respectively the American Medical Association, the American Institute of Homœopathy, and the National Eclectic Medical Association, to examine existing laws of the various States, and to recommend such additional legislation as may be found necessary to secure a uniform and efficient standard of qualification.

Complaints against British Army Hospitals in South Africa.—A despatch to *The Sun* from Cape Town states that *The Times* of that city has published an interview with a colonial volunteer, who complains bitterly of the hospital arrangements. He declares that the accommodations, clothing, and food are insufficient, and that there are extortion and robbery by the orderlies, who are largely left without supervision owing to the paucity of medical officers. He speaks in terms of the highest praise of the nurses from Netley.

The "Goutte de Lait" Society is an organization established recently at Rouen, France, with the object of furthering a rational infant feeding. Every effort is made to induce mothers to nurse their own infants, but when this is impossible, the society furnishes a specially prepared and sterilized milk in suitable quantity for one or two sous a day.

The Centenary of the Royal College of Surgeons.—It is proposed to celebrate the centenary of the foundation of the Royal College of Surgeons of England on July 25th and 26th next. On Wednesday, the 25th, there will be a conversazione at the college in the evening. The following day a meeting will be held in the theatre of the University of London in the afternoon, and this will be followed by a festival dinner in the hall of Lincoln's Inn.

A Children's Hospital at Athens.—It is stated in the *British Medical Journal* that, on the initiative of Princess Sophia of Greece, a hospital for children has recently been built in Athens. It is appropriately named "Saint Sophia." The hospital consists of twelve separate buildings, each destined for the accommodation of patients suffering from one form of disease. Four of these are set apart for contagious cases. The new hospital was lately formally opened in the presence of the whole royal family of Greece, the high officers of state, and the municipal authorities of Athens.

Missionaries Lose a Hospital.—Three woman medical missionaries, Drs. A. H. Kelsey, Kaku Sudo, and Hana Abe, the two latter being Japanese, some time ago established the Negishi Hospital, near Yokohama, and ran it in conjunction with their missionary work. Recently, however, the Buddhists gained control of the hospital, and decreed that, while the ladies might continue in medical charge, there should be no more Christian doctrine taught there. The three physicians have, therefore, left the institution, and have opened a dispensary in the neighborhood, where they may resume their medical missionary labors.

Unveiling of the Hahnemann Statue.—The statue of Samuel Hahnemann, which has been erected on the east side of Scott Circle, Washington, was formally dedicated on the afternoon of June 21st. The statue was formally presented to Dr. C. H. Walton, president of the American Institute of Homœopathy, by Dr. J. H. McLelland, of the memorial committee. Dr. Walton then presented it to the government, and it was accepted by Colonel Bingham, superintendent of the public buildings and grounds of Washington. Attorney-General Griggs delivered a brief address. As the draperies were removed from the statue, an ode to Hahnemann was read by Dr. William Todd Helmuth, of New York. The statue, which is of bronze, is the work of the sculptor Niehaus, and its artistic merits were certified to by the National Sculpture Society before permission was given for its erection in Washington.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending June 23, 1900. June 18th.—Passed Assistant Surgeon A. R. Alfred detached from the *Texas* and ordered to the Asiatic station via the *Nippon Maru*, sailing from San Francisco, July 10. The following are commissioned assistant surgeons, to take rank from June 7, 1900, in the order named: J. J. Snyder, H. A. Dunn, A. Stuart, E. M. Blackwell, W. H. Ulsh, M. V. Stone, C. R. Burr, G. F. Freeman, R. O. Marcour, J. K. Payne, Jr., J. Stepp, C. H. DeLancy, F. M. Bogan, R. K. McClanahan, W. E. G. High. June 20th.—Passed Assistant Surgeon G. A. Lung, order of May 25th modified; ordered to the Cavite naval station. June 21st.—Assistant Surgeon J. C. Thompson detached from the naval hospital, Yokohama, Japan, and ordered to the *Newark*.

Obituary Notes.—Dr. Julius Althaus died in London on June 11th, at the age of sixty-seven years. He was a graduate of the University of Berlin in 1855, and soon thereafter settled in London. He was well known for his writings on diseases of the nervous system, and especially on the therapeutic applications of electricity. He was one of the founders in 1866 of the Hospital for Epilepsy and Paralysis.

Dr. Benjamin Douglas Howard died at Elberon, N. J., on June 21st, at the age of sixty years. He was born in England, but was graduated in medicine from the College of Physicians and Surgeons in this city in the class of 1858. He served during the Civil War as surgeon in the regular army, and at the close of the war, after a period of study abroad, was appointed professor of operative surgery in the medical department of the New York University. Subsequently he held chairs in several other medical schools, and in 1873, his health failing, gave up practice and went abroad. He finally settled in London, and took out in 1877 the qualifications of M.R.C.S. Eng. and F.R.C.S. Edin. He was on a visit to this country at the time of his death.

Dr. Tommaso Crudeli, of Rome, well known for his writings on hygiene, died recently. He was formerly professor of anatomy and later of hygiene at the University of Rome, and was an Italian senator.

Dr. B. W. MacNichol died at his home in Westchester, this city, on June 22d, of pneumonia, at the age of forty-two years. He was born in Rondout, and was graduated from the Jefferson Medical College in 1884. He was for several years health officer of the town of Westchester before its incorporation into New York City.

Dr. Lloyd Morris Horwitz died at Helena, Mont., on June 22d, at the age of thirty-eight years. He was graduated from the college department of the University of Pennsylvania in 1882, and from Jefferson Medical College in 1884, serving subsequently as resident physician in the Philadelphia Hospital. He was a son of Dr. Phineas J. Horwitz, U.S.N., of Philadelphia.

Progress of Medical Science.

New York Medical Journal, June 23, 1900.

Inflammation of Meckel's Diverticulum with Resulting Gangrene of the Intestine, Simulating Appendicitis.—W. P. Nicholson reports the case of a young man aged twenty years, who was seized with abdominal pain simulating colic and referred to the left of the umbilicus. Gradually the symptoms of intestinal obstruction developed while the pain shifted to the region of the right iliac fossa. Later the condition became such that a diagnosis of appendicitis with general peritonitis was made, and the abdomen was opened. A coil of distended intestine, jet-black in color, was found crossing the wound at a right angle. The surrounding coils were bound together by lymph. In separating the coils of intestine, the gangrenous portion presented the appearance of bifurcating into two unequal parts, and these were separated. The smaller, about the size of the thumb, was followed in a direction upward, inward, and backward toward the mesentery, to which its bulbous tip seemed attached by strong adhesions. When this was separated, the gangrenous portion of the intestine was easily withdrawn from the cavity, and it was now seen to be the small intestine, entirely gangrenous for about seventeen inches, with a blind tube about five inches long springing from the convex border. Another coil of intestine that had been in contact with the gangrene presented a gangrenous spot about the size of the thumb-nail, and the omentum that covered it was totally gangrenous. The intestine was resected and joined with a Murphy button, the omentum was tied off, and after thorough washing of the abdomen the gangrenous spot was brought up to the wound and well packed about with iodoform gauze, and much of the wound left open. The patient was put to bed in as good condition as when the operation was begun. The vomiting ceased after this, and there was apparently some improvement; but later in the day evidence of increasing failure developed, and he died eighteen hours after the operation. The specimen proved to be a Meckel's diverticulum, inflamed and gangrenous, though there was no evidence of any band constriction, and no obstruction in this sense.

The Value of the Tuberculin Test in the Diagnosis of Pulmonary Tuberculosis.—J. M. Anders collates the experience of various observers, and gives his own in three cases in which the tuberculin test gave a positive reaction which was verified by the subsequent course of the cases. Anders has a fixed belief that tuberculin will tend to occupy its true sphere of usefulness just in proportion as the profession will in future keep in mind two rules as a guide—to wit, moderate dosage and the limitation of its usage to suspicious (incipient) cases and those that are unrecognizable by other means. He entertains no doubt that if these principles were enforced the re-use of tuberculin as a diagnostic agent would rapidly become general, and the results prove highly satisfactory. Finally, if the use of tuberculin as a therapeutic measure in tuberculosis was abandoned (since this rests upon a misconception of the nature of the agent), much of the opposition to an invaluable aid in the diagnosis of latent and incipient cases would be removed. A valuable bibliography is appended.

The Advantages of the Pneumatic Cabinet or Differentiator in the Treatment of Pulmonary Tuberculosis.—J. C. De Vries explains the theory of action of the pneumatic cabinet, the main effect of which is the reduction of pulmonary congestion. It is a most powerful measure for the arrest of hæmoptysis, but when a profuse bleeding points to acute local necrosis as its cause, the cabinet must be used with great caution and in such a way as to diminish vascular tension without tissue distention until the bleeding vessel has closed. In general the cabinet is an instrument by means of which the following results are sought: (1) The strengthening and developing of weak and poorly expanded lungs; (2) the arrest of pulmonary disease in its earlier stages; (3) the prolongation of life with comparative comfort in those cases of pulmonary disease in its later stages in which a cure is impossible.

Perimetric Diagnosis.—By J. W. Sherer.

Boston Medical and Surgical Journal, June 21, 1900.

The Law of Dying Declarations.—M. J. Sughrue summarizes the laws bearing on this point. Among the facts stated we note that it is not necessary that the declarant should be actually breathing his last; even though he lived some time, the declaration is competent if made under a sense of impending death. The form of the declaration is immaterial. It may be made orally, in writing, or may be communicated by signs. In passing upon the weight to be given to dying declarations the jury have a right to consider all the circumstances under which it was made, and all the conditions by which the dying person was surrounded, and the state of mind of declarant, as shown by all that was said and done. Conduct, deportment, condition, all should be noted by the person who is to be a witness. Declarant's conduct in saying farewell to his relatives, in making such provision as is made by persons about to die; if the declarant is a Catholic, if he receives extreme unction, this is of importance as indicating the state of mind. It will be found a most useful practical rule in these cases first to ascertain the state of mind of the dying person, and after that an expression by him that he has no hope of recovery, then to listen to a recital of the story of the crime. It is because of a failure to proceed in this way that physicians frequently obtain an account of a crime which cannot be used in evidence, and it is more often because of inadvertence than want of knowledge; but the result is equally disastrous so far as a successful prosecution is concerned. Particularly is this true in abortion cases, in many of which, apart from the evidence obtained at the autopsy, there is no testimony save the dying statement of the person operated upon, which by reason of the carelessness or ignorance of the person hearing the statement is worthless as evidence.

A Case of Extra-Uterine Pregnancy.—F. Holyoke gives notes of an autopsy made on a woman nine and a quarter hours after death. She complained of terrible abdominal pains, went into collapse, refusing to see a physician, and died. The autopsy showed that large, black, tarry clots covered the omentum, and the abdominal cavity was filled with clots and serum. Beneath the omentum there was found what looked, at first sight, like a large, rupture ovarian cyst with a very vascular wall to which the omentum and intestines were extensively and firmly adherent. This cyst lay between the folds of the right broad ligament. It reached as high as the umbilicus. The cyst wall was ruptured in the upper anterior part. The uterus was pressed high up out of the pelvic cavity to the left, which accounts for the inability to find the os by vaginal examination before the autopsy. This abnormal position of the uterus was produced by the combined pressure of extravasated blood in the posterior cul-de-sac and the forcible bulging of the tumor anteriorly. The uterus was six inches long, the cervix softened and filled with mucus. The body of the uterus was soft and thickened proportionately to its size, though the enlargement was more in the long axis. The lining of the uterus was softened and very pale. The tumor was ruptured at the site of the placenta. In breaking up adhesions the sac wall tore readily, showing, beneath, the amnion, unbroken and adherent throughout to its covering, which was composed of the anterior and posterior layers of the broad ligament; the pregnancy being tubal in origin, and primary rupture having occurred in the early months. The amnion contained a six-months fœtus, lying transversely with its breech toward the right ilium.

The Marks Produced by Pistol Shots.—G. De N. Hough has made experiments with various pistols and bullets of different calibre. The marks consist of the bullet-hole, burn, smut, and tattoo. The articles deals too largely with figures and comparisons to be abstracted, but it is a valuable contribution to the literature of pistol-shot wounds.

Closing Statement for the Remonstrants to the Massachusetts House Bill No. 917, entitled "An Act for the Further Prevention of Cruelty to Animals." Before the Joint Committee on Probate and Insolvency, March 15, 1900.—By H. C Ernst.

Realism in Medicine.—By A. T. Cabot.

Philadelphia Medical Journal, June 23, 1900.

A Contribution to the Study of Exophthalmic Goitre.—Alfred Gordon cites cases in which goitre followed genital affections, floating kidney, nasal affections, etc. He finds that clinical observation, experiments in laboratories, and facts of autopsies, all compel us to look at the disease as having a nervous origin. Scientists generally admit that all the phenomena are the result of a permanent irritation of the vasodilator nerves. Three tables are given, one showing the results of medical treatment, one of operations on the thyroid gland, and one of operations on the cervical portion of the sympathetic nerve. In conclusion the author says that if the sympathetic nerve is the immediate cause of exophthalmic goitre the treatment must be directed to that nerve. If the syndrome of the disease is the result of a mechanical pressure on the sympathetic nerve the pressure must be removed, and if the symptoms persist the sympathetic must be operated upon. If the syndrome of the disease is the result of reflex influence from some remote affection, as fibroid uterine tumors, nasal polyps, etc., these must be removed; and if the symptoms persist the sympathetic nerve must be operated upon. If the syndrome of the disease occurs during the course of any spinal or other organic nervous disease operation should be abstained from. If there is no apparent cause the sympathetic nerve may be operated upon. We should never operate upon the hypertrophied thyroid gland. Medical treatment can be used if the patient refuses an operation, but under it we can never expect any permanent cure or entire removal of the symptoms.

Scarlatina: Some Further Experiments.—William J. Class, believing that the diplococcus described by him as the specific causative factor in scarlatina has had its specificity demonstrated beyond reasonable doubt, has undertaken a search for an antitoxin. A toxin fatal to mice was obtained from pure cultures. Female swine were used for testing susceptibility. A serum has been prepared, and the author purposes to test its effects in the first suitable case of scarlatina that presents itself. He feels confident that investigation will prove the germ he has described to be the true cause of the disease.

Annual Address on General Medicine before the American Medical Association.—By J. A. Witherspoon.

Mütter Lectures of the College of Physicians of Philadelphia.—By John B. Roberts.

Angina Pectoris.—By Clifford Allbutt.

Journal of the American Medical Ass'n, June 23, 1900.

Pathology of Acquired Heart Disease in Children.—J. Dutton Steele first considers the nutrition of the heart in childhood, and finds that the tissues respond more quickly and more readily to stimulation and grow more vigorously in early life than after puberty. The tissues of the child are more yielding and more likely to give way under a sudden distending force than the more closely knitted tissues of older people. The local nutrition of the heart is apt to be better than in the adult because the nutrition of the organism as a whole is better. The effect of acute rheumatism on the heart is studied, and it is found that heart lesions are commoner than after rheumatism in the adult, and rheumatic diseases in children appear very virulent. Puerperal infection in the new-born, acute infectious diseases, diphtheria, measles, rachitis, and scarlatina are all considered in their influence upon the heart. Peri- and endocarditis are not so common as inflammations of the myocardium. In pancarditis any of the three tissues may be the seat of the greatest involvements. Measles has little or no effect on the heart. Lesions of the cardiac tissues are lastly discussed.

Diagnosis of Heart Disease in Children.—J. P. Crozer Griffith says the first thing is to determine whether heart disease present is congenital or post-natal. The principal diagnostic symptoms of the first are cyanosis, clubbing of the fingers, thrill, characteristic murmurs, and the absence of any great enlargement. In general it may be said that in diagnosis of post-natal cardiac affections in childhood we should observe the following points: avoid making a diagnosis from the presence or nature of murmurs alone; remember the altered position of the right side of the heart and of the apex-beat in childhood; remember that the presence of an accentuated pulmonary second sound is normal, not pathological; remember that compensation is acquired very easily in childhood, and that the absence of symptoms does not prove the absence of cardiac disease; remember that the most suggestive symptom is dyspnœa, and that œdema must be studied most carefully before it becomes of value as a diagnostic symptom.

Symptomatology of Valvular Heart Disease in Children.—F. A. Packard says heart disease, especially in childhood, has no symptomatology or no group of symptoms pointing to the heart. The child is in some respects more of a free agent than is the adult; becoming uncomfortable from effort, it remains quiet; made dyspnœic by exercise, it ceases its play, while the adult must continue at his work. Fifty-six cases are analyzed. Twenty-nine patients had shortness of breath, ten had palpitation, nine œdema of the legs, seven precordial pain, six epistaxis, five headache, five had been anæmic, four had abdominal pain, four cyanosis, and four blood-spitting. The existence of any abnormality makes careful examination imperative as to the functional activity and physical condition of the heart.

Prognosis in the Heart Diseases of Children.—A. V. Meigs says the prognosis should be more hopeful in children, as a general thing, than in adults. This is because the tissues in the latter are stiffer and, it may be said, almost brittle. Probably the most important difference between prognosis in children and adults is that the former have the better chance of recovery owing to the opportunity they have of outgrowing the disease.

The Pathology of Congenital Heart Disease.—Alfred Hand says many classifications have been suggested, but none is thoroughly satisfactory, and some are too broadly comprehensive. Faults of development are divided into those that occur early (cor biloculare or triloculare), anomalies arising between the sixth and twelfth weeks, and defects occurring about the twelfth week resulting in anomalies of the valves, persistence of fœtal opening, etc. Other changes are usually the result of fœtal endocarditis.

Some Points in the Management of Obstetric Cases in Private Practice.—Joseph Brown Cooke compares a pregnant woman to a ship at sea. The probability is that no accident will occur, yet the greatest watchfulness is necessary to reduce still further the chance of anything going wrong. In the first place, an accurate history of every case should be kept from the time the patient is first seen to the end of the puerperium. The urine should be examined within a week of the patient's first visit, then monthly until the end of the seventh month, and after that weekly. Another point of importance is the maintenance of absolute asepsis from the beginning to the end of labor. Three weeks before labor is expected, the author sends to the patient's house a wooden box containing four half-gallon bottles of distilled water; one pint of boric-acid solution for the infant's eyes and mouth immediately after birth; one pint of standard sterile salt solution for infusion; three agate basins or trays, one for sponges, one for towels, and one for receiving the placenta with the gush of blood that follows it, and a two-weeks' temperature chart for the nurse's use. The author has discarded every form of so-called aseptic bag, and makes no attempt to carry anything sterile to his cases except operating-gown in a muslin case, gauze, cotton, cord dressings, and sutures of silk and catgut. Instruments and silkworm gut, if it is needed, are boiled in a long, narrow copper tray of such size and shape that it will hold any obstetrical forceps together with cord, scissors, catheter, douche-tube, and any other instruments that may be required in special instances, covered with the minimum amount of water, to secure rapid boiling.

Some of the Physiological Methods and Means Employed by the Animal Organism in its Continual Struggle against Bacteria for Maintenance of Life and Health.—By S. J. Meltzer.

A Protest against Some of the Evils in the Profession of Medicine.—By J. A. Witherspoon.

British Medical Journal, June 16, 1900.

A Case Bearing on the Parasitic Nature of Mammary Cancer.—A. Marmaduke Sheild reports the case of a woman, thirty-six years old, who came to him in June, 1898, suffering from Paget's disease of the left nipple. The case was watched until the diagnosis was definitely established. The so-called psorosperms were found in scrapings of the patch, but there was no perceptible deep induration or signs of cancer present. Nevertheless, in order to make sure of the prevention of cancer, the entire breast was removed. Examination of the skin revealed the usual appearances of malignant dermatitis, but there was no evidence of cancer in the breast beneath. All went well until April, 1900, when a lump appeared in the skin near the sternal end of the scar. This swelling, which was hard, about the size of a large pea, and red in color, was excised and found to be a spheroidal-celled carcinoma, with much fibrous tissue. There was also extreme vacuolation of the epithelial cells—so-called psorosperms. The author regards this case as one showing that the infective nature of so-called malignant dermatitis of the nipple is very extensive and insidious, and takes place far more early than is generally believed. We can hardly doubt, he says, that in this instance there was a connection between the two affections. There was certainly no cancerous change in the mamma to be detected, and he will not admit that "cell proliferation" could have existed or spread so far.

An Easy Method of Mounting and Preserving Mosquitos.—D. C. Rees describes the following simple method which is employed in the laboratory of the London School of Tropical Medicine: "Kill the mosquito by placing it in an ordinary killing bottle, or if this is not available a little chloroform or tobacco smoke will do as well; when dead turn it over on its back, separate the legs if they are together, place a large drop of thick xylol Canada balsam on a slide, invert this gently on to the mosquito, and in this way it is picked up without any chance of injury; then with a fine needle spread out and arrange the wings and legs, and if necessary press down the thorax very carefully. Next pour on some thin xylol Canada balsam; as this runs out it straightens the proboscis and antennæ, and they do not, as a rule, require to be touched. Put the specimen on one side to harden, then chip off the excess of Canada balsam, place glass ring on, and fill up the chamber that is thus formed with Canada balsam. The upper surface of the Canada balsam should be convex, so that when the cover-glass is applied no air bubbles are included. Allow the specimen to harden before sending by post. If the glass rings are not at hand the specimen will keep quite well in the Canada balsam alone, and the last part of the mounting may be completed after the specimen has been sent home. If the mosquito is intended for photographing great care must be taken in mounting it so that it lies as far as possible in one plane."

The Treatment of Pneumonia.—Referring to a previous report of a case of pneumonia treated with Dover's powder, A. de Winter Baker relates the case of a boy thirteen years old, who was suffering from pneumonia of the left lower lobe complicated with otitis media. Two days after the lad came under treatment, tubular breathing was heard in patches at the base of the left lung behind and also slightly at the left apex. The patient was sleepless and delirious. The author ordered Dover's powder gr. v. every four hours, and says the result was magical. The delirium was quieted, the skin acted freely, and the general aspect improved immensely. The dose was subsequently reduced to gr. iiss., and the remedy was continued for about two days. The boy had no alcohol during the acute stage, and only after the temperature fell a little port wine was given to stimulate the appetite. After the Dover's powder was commenced the temperature never rose above 103° F., whereas it was 104° F. the previous day. There was never any necessity for the administration of oxygen or strychnine. The author attributed the good results obtained in this case almost entirely to the Dover's powder.

A Neglected Point in the Treatment of Strangulated Hernia.—C. Hamilton Whiteford says that in a case of this nature the surgeon usually concerns himself chiefly with the condition of the strangulated bowel, which, if gangrenous, is either drained or resected, and if viable is pushed back into the abdomen. In the latter case the patient probably remains absolutely constipated, continues vomiting, and dies within forty-eight hours. He is suffering from an accumulation, above the obstruction, of liquid filth which is rapidly poisoning him. The point which is so frequently overlooked is that his chance lies in the direct evacuation of these intestinal contents. This can be done only by draining the distended bowel through a large tube for several days. A few cases of advanced strangulated hernia end in recovery after reduction of the strangulated bowel, by discharging enormous quantities of liquid fæces per anum, but the majority die with unemptied intestines. This drainage of distended bowel, the author says, is simply the application to strangulated hernia of the principles involved in the treatment of obstructions taking place within the abdomen.

The Management of the Anæsthetic in Cases in which Respiratory Impediment Exists.—By Dudley W. Buxton. The writer remarks upon certain cases in which interference with respiration occurs in the course of anæsthesia. First, obstructions arising in the upper air passages may be due to enlarged tonsils with a partially occluded nasopharynx, or to pharyngeal abscess, enlarged tongue, or old adhesions between the posterior wall of the pharynx and the tissues about the faucial arches. Two instances in children are quoted. There may also be mechanical interference intensified by the anæsthetic. Cases are cited. Posture is another difficulty, especially when the patient must be placed more or less upon the face and in semi-prone postures. When chloroform is used, the hampered chest movements may produce cyanosis. The following propositions are thought worth tabulation: (1) The individual patient possesses a certain respiratory power. Individuals differ enormously in this respect, and it is the business of the anæsthetist to make himself acquainted with what the author terms the "personal respiratory equation of the patient." (2) This individual power of respiration is interfered with by every form of anæsthetic, more by some than by others, but under any anæsthetic the power of inspiration and expiration is lessened, and in some cases to a very marked degree. (3) This lessened respiratory power may be of little or no consequence under normal conditions, but it becomes a factor of grave danger should any intercurrent cause of respiratory obstruction occur.

Surgical Aspects of Constipation.—S. L. Woolmer records two cases to demonstrate a rare sequel to the most common morbid condition known. Aneurismal dilatation of the colon as the result of chronic constipation exists, but works on surgery do not mention it. In both instances cited the condition of the patient was reduced to one of great gravity. Nothing short of operation could give relief. The histories are given with illustrations. In both cases, the site of the tumor was the last portion of the sigmoid flexure.

The Employment of Alcohol as a Means of Disinfection and the Theory of its Action.—Salzwedel and Elsner have performed a series of experiments by dipping threads in various bacterial cultures and then dipping the threads in an alcoholic solution. They find that for the sterilization of threads infected in this way with staphylococci pus, the bactericidal effect is most certain when the solution has about five per cent. alcoholic strength. In general it appears that the effect is heightened by a slight warming of the alcohol, but the temperature should not exceed 30° C. They further believe that the disinfecting effect of alcohol is due to its dehydrating properties, whereby an environment is established inimical to bacterial development.

Influenza and Chronic Heart Disease.—Dr. Schott (Bad Nauheim) presents several statistical tables showing the distribution of influenza during recent epidemics and the relative proportions between the total number of deaths in some of the European armies and deaths due to cardiac disease. He claims that his figures show that influenza leaves many cardiac evils in its train.

Deutsche medicinische Wochenschrift, June 14, 1900.

The Importance of the Palatine Tonsil in Young Children as a Port of Entry for Tuberculous Infection.—F. F. Friedmann, believing that the tonsils are the seat of the first manifestations of a number of infectious processes, has carried out a number of histologico-bacteriological examinations to determine whether in children they may not serve as the entrance point in tuberculous disease. Ninety-one autopsy cases and fifty-four living subjects were examined. The processes are described. From the work done it is thought that tonsillar tuberculosis exists under two conditions—a primary infection from food and a secondary infection from sputum containing bacilli. In spite of Koch's doubting that a single instance of human tuberculosis can be positively and without objections attributed to eating the flesh or drinking the milk of a tuberculous animal, the author can see no other explanation for a number of his cases. Primary infection from food is much more frequent in children than the secondary from infectious sputum.

The Dangers of Lumbar Puncture.—F. Gumprecht relates an instance of sudden death after lumbar puncture, making the sixteenth in the literature. The preceding fifteen are briefly referred to. He adds two other instances in which death was not sudden, but occurred a few hours after puncture.

French Journals.

Treatment of Tuberculosis of the Kidney.—Tuffier says the diagnosis includes, besides a recognition of the affection, a knowledge of the condition of the opposite kidney. When we say that every renal tuberculosis diagnosticated should lead to extirpation, it is equivalent to stating that lesions already severe and extensive are to be treated surgically, since positive manifestations are often to be made out only when the condition is already somewhat advanced. Catheterization of the ureter does not always give the key to diagnosis; it is attended with some dangers, and it is a procedure which is justified only by special clinical circumstances, which are, after all, quite rare. A study of the total quantity of urine without catheterization of the ureters usually permits of serious presumptive evidence as to the state of the renal filter, and in his own experience never deceives. Purulent urine suddenly becomes clear and thus gives testimony as to the functional activity of a single kidney. As often this bacillary localization has an injurious effect upon the general health of the patient, surgical intervention is called for whenever it is possible. Lumbar nephrectomy is the method of choice. The operation when entirely justifiable gives brilliant and lasting results, and is a step in advance in the therapy of this affection.—*Journal des Praticiens*, June 9, 1900.

Secondary Cancer of the Chyliferous Passages; Chyliform Ascites.—Nattan-Larrier concludes that primary cancer of very small volume can give rise to an enormous secondary cancer; just as the secondary cancer can spread by way of the veins and produce cancer of the liver. In the same manner it may become generalized by way of the lymphatics and produce cancer of the lymphatic passages. Secondary cancer of the mesentery, of the thoracic duct, and chyle ducts may evolute in a latent manner and give other signs of a cachexia of rapid course and a moderate chyliform ascites. Obliteration of the thoracic duct and invasion of the mesentery are not sufficient to produce chylous ascites or chyliform ascites if there is not added a solution of continuity or an obliteration of the chyle ducts susceptible of impeding the course of the chyle. Cancerous invasion of the peritoneum when associated with cancer of the thoracic duct can also give rise to chyliform ascites.—*Le Bulletin Médical*, June 9, 1900.

Treatment of Pertussis by Deep Injections of Oil of Gomenol.—Leroux and Pasteau, led by the favorable action of the remedy in bronchitis and phthisis, have tried first inhalations and then deep injections of oil charged with gomenol. Gomenol is a pure natural essence obtained by distillation from a variety of Melaleuca viridiflora cultivated in New Caledonia. Forty patients were experimented upon. From 5 to 10 c.c. of a five-per-cent. oil were injected in the gluteal regions. A series of charts are given with detailed observations in eighteen cases. The results were generally favorable, there being diminution in the number of attacks and shortening of the disease, the average being twelve to fifteen days. Treatment should be persisted in four or five days after the last seizure. The technique of injection is given.—*Le Bulletin Médical*, June 13, 1900.

Renal Tuberculosis.—Albarran says that Tuffier recognizes the value of ureteral catheterization whenever doubt exists about the supposedly healthy kidney. In point of fact these doubts always exist. Tuffier is in error in supposing that the catheter must remain *in situ* for twenty-four hours; from a few minutes to one or two hours is often sufficient. The author says he has practised catheterization of the ureters over one thousand times without accident. He has seen brilliant results from nephrectomy in tuberculous pyonephroses in very cachectic patients with high temperature. Catheterizing the ureters permits us in almost all cases to diagnosticate the state of both kidneys, and presents no dangers when properly done.—*Gazette des Hôpitaux*, June 7, 1900.

Gummata of the Palatine Vault.—Fournier showed a case of atresia of the fauces consecutive to gummous infiltration, and described two forms of lesion, one circumscribed or nodular, and one due to diffuse infiltration causing tumefaction rather than tumor. Five characteristics serve to facilitate diagnosis from the very beginning. They are: deformity of the velum, redness, thickening, hardness or firmness, and immobility or quasi-immobility. When perforation occurs there may be a single or multiple opening of varying diameter, or there may be marginal loss of tissue, or adhesion of the centre with the sides drawn back like curtains at a window, or almost the entire velum may be destroyed. Regurgitation of liquids from the nose in swallowing is one of the most striking symptoms. Another is nasal voice. Ninety-five per cent. of all cases are of the diffuse variety.—*Journal des Praticiens*, June 9, 1900.

Pediatrics, June 15, 1900.

Dangerous Communicable Diseases, How Spread, together with Some Suggestions as to their Restriction.—M. K. Allen says the so-called contagious diseases are usually spread through the medium of atmospheric dust. People should be made to know that dust from handkerchiefs containing dried secretions is laden with germs, and hence is a source of danger. Each soiled handkerchief "should be placed in a paper bag, the top twisted shut, and there remain until it can be boiled." He thinks it not improbable that typhoid is sometimes spread by means of dust containing the germs of the disease. One-third of all children who die under ten years of age die of tuberculosis, and nine millions of the present inhabitants of this country will, at the present rate, die of this disease unless something is done to prevent it. Pneumonia, influenza, diphtheria, typhoid, smallpox, and other contagious diseases are considered in relation to quarantine, disinfection, the responsibility of notification, and the duties of the health board.

A Case of Pneumonia in a Baby Six Weeks Old.—Abraham Goltman relates an instance in which the temperature was 105° F., and the respirations 80. There was visible rapid pulsation in both subclavians and carotids. Stress is laid upon the value of stimulating the benumbed respiratory centre by cold and hot water douches and fairly large doses of drugs considering the age. Strychnine gr. $\frac{1}{150}$ was administered every six hours. Alternating hot and cold plunges for five minutes at a time appeared to work marvellous results.

Some Remarks on Three Symptoms of Rickets.—W. N. Berkeley finds that in many reported cases of paraplegia, anæmia, pseudoleukæmia, hypertrophic cirrhosis, etc., one is strongly tempted to affirm that the real underlying condition was simply rickets. He discusses the three symptoms: rosary, those referable to the head, and those referable to the liver and spleen. In one case related the diagnosis of sarcoma of the spleen had been made.

Foreign Body in the Air Passages.—By J. M. Ray.

Revue de Médecine, May, 1900.

Functions of the Thyroid Gland.—G. Gauthier says that there is no room to doubt that there is a relation of cause and effect between normal functioning powers of the thyroid gland and of the nervous system. The action of the gland is not simply reflex or sympathetic, but direct and intimate upon the development and the nutrition of the nerve cells. Certain cardio-vascular troubles depend upon thyroidism; thyroidin has been proved experimentally to be a heart poison, and like digitalis to have cumulative properties. An injection of thyroid juice lowers blood pressure and dilates the peripheral arteries. In conclusion, all pathological conditions dependent upon a lowering of nutrition may be traced to deficiency of thyroid substance and will often be benefited by thyroid treatment.

Desquamation in Typhoid Fever of the Adult.—Paul Remlinger reports six cases in which desquamation of the skin was observed, which began just at the time when the temperature began to fall. It was scaly in nature, intermediate between that of measles and scarlet fever, and began and was most marked on the lateral portions of the thorax and abdomen. It was limited to the trunk, but in three cases coexisted with alopecia. The author holds that this desquamation is the result of trophic cutaneous disturbance, like falling of the hair. As a prognostic sign it is favorable, indicating the approach of convalescence.

Clinical Study of Some Infectious Diseases.—By H. Roger.

Infantile Gastro-Enteritis.—After a purge and washing out the bowel, a teaspoonful of dry beer yeast or a dessertspoonful of fresh yeast dissolved in 50 or 60 gm. of tepid boiled water should be introduced. The catheter should be withdrawn and the child be kept quiet. Renew two or three times a day. Liquid diet should be given till the fever falls.

Correspondence.

PRIORITY IN THE PUBLIC-BATH QUESTION.

To the Editor of the Medical Record.

Sir: How you manage to be so well informed on all matters medical and hygienic is a marvel. This is illustrated by your editorial of May 12, 1900, in which you were good enough to defend my claims to priority in having introduced public baths in this country, which, as will be shown by an exhibit at the Paris Exposition, is in advance of all others in furnishing the poor with perennial cleansing baths free of all cost.

As a matter of fairness I would ask you to point out the untenability of Mr. Brown's reply to your editorial of May, 1900. You wrote: "Failing to overcome the opposition of Mayors Grant and Gilroy, the doctor 'found' an earnest and able coadjutor in Mr. Goodwin Brown, who in 1895 brought about the passage of a mandatory act, . . . while Mr. Brown deserves credit for aiding Dr. Baruch in this important enterprise, etc."

Any reasonable reader would understand that "this important enterprise" referred to the establishment of free public baths, for which I had been working since 1889, and in which you have taken such great interest for many years. But Mr. Brown chooses to twist your language into meaning he was my coadjutor in the passage of the mandatory act. My connection with the latter is expressed in a letter from Mr. Brown dated April 18, 1895, as follows: "It affords me pleasure to say that the matter which you gave me enabled me to lay before the committee unanswerable arguments, and to you I largely ascribe the credit of the most important measure of the session."

Simon Baruch, M.D.

New York, June 9, 1900.

MOSQUITOS AS A MEANS OF CONTAGION IN LEPROSY.

To the Editor of the Medical Record.

Sir: Replying to Jonathan Hutchinson's statement which you quote in The Medical Record, April 7th, page 616: "The suggestion that mosquitos are a means of contagion in leprosy, has had its advocates. It is, however, I think, conclusively negatived by the fact that of the European immigrants into leprosy districts, scarcely any contract the disease" (*Archives of Surgery*). Let me say that that fact proves nothing. In Japan it is the most notoriously malarial districts, therefore those most infected by mosquitos, Kumagato, Myasaki, Awamori, etc., that are the most leprous. How would Jonathan Hutchinson harmonize that fact with his fish-alimentation theory?

Because in leprous districts it is not the European doctor, nor the immigrant Sister of Mercy who becomes contaminated with leprosy, nor the immigrant negro in malarial districts who contracts malarial fever, is it reasonable to conclude that leprosy is not contagious (inoculable), and that malarial fever is not transmissible by mosquitos? Would any one, because of this last circumstance, dare to say that it is conclusively negatived that mosquitos are a means of contagion in malarial fever?

In the case of the conveyance of plague to man by means of fleas, Dr. Munro, in Montenegro's work, "Bubonic Plague," published in America by William Wood & Company, cites Bandi and Stagnatti, who, observing how few medical men and nurses were attacked by plague, could not believe that the fleas play so important a rôle, since the very greatest care did not prevent fleas passing from the sick to the doctors or their assistants. Yet Simonds' ingenious experiments showed that the plague is transmitted from the rat to man by means of fleas. The healthy rat has very few fleas on him, because he is careful of his toilet. But a sick rat becomes absolutely covered by these insects, because he is neglectful of himself. Simonds put two rats in a cage, one ill of plague, having fleas on it; the other healthy, having none. The healthy one became affected after the death of the sick rat. He then put two rats in a cage separated by a wire netting, one sick of plague, the other healthy, but both without fleas. The sick one died, but the other remained healthy. Thus not until the second intermediary-host factor was at work did contagion take place. Intermediary-host function of fish and mosquitos, in my opinion, is a frequent source of contagion in leprous Japan. There the carp, which feeds mainly on the larvæ of mosquitos, is eaten raw. It is the feast dish, the turkey of Japan, and when served is cut up alive and eaten while the flesh still quivers. If this carp has fed on mosquitos which have sucked a leper's blood, is it unreasonable to believe that it may be the carrier of leprous spores of a bacillary disease from man to man? And because European immigrants to that leprous country may rarely contract leprosy, as rarely as they eat the living carp, is that reason to conclude that mosquitos there may not be a means of leprous contagion?

Albert S. Ashmead, M.D.

THE MODERN HOSPITAL AND ITS RESIDENT STAFF.

To the Editor of the Medical Record.

Sir: In your issue of June 9th appears a report of the meeting of the Medical Society of the County of New York on the evening of May 28th. Among the papers read before that body is one by me entitled "The Governor and His Staff, Being a Glance at the Personnel of a Modern Hospital and a Plea for a Permanent Resident Staff." Your reporter disposes of my paper in three lines, and in those three lines he makes three points: that I dwelt on the incompetence of hospital internes; that I ridiculed the hospital governors, and finally that I failed to offer a remedy for the alleged abuses.

I simply said that the visiting surgeons took no cognizance of a case except their attention was called to it by the house staff; that this house staff sometimes meant a student graduated about five or six months; that by the present hospital system this raw young man was made the judge, the sole judge of what must be done, and done quickly, in a given case; that it requires more judgment and a riper experience to decide offhand and quickly the thing to be done in an emergency, in which an error of judgment may mean death to the sick man, than those young gentlemen—members of the house staff—from the nature of things can possess; for remember, they are green and inexperienced as yet, and not over the furor of enthusiasm that the importance of their high place has inspired.

I said further that if the science of surgery was so rapidly and easily mastered by those young juniors, we have had a wrong conception of the obstacles to be overcome and the great difficulties to be surmounted in acquiring a knowledge of that art.

The man sent from the hospital as its official representative to diagnose the case of a sick woman, whose friends made application for her admission, reported that she was suffering with a contagious disease, and rejected her on that account, though her family physician, who was present, and is the writer, could not agree with him in such diagnosis and was afterward sustained by an expert from the department of health. The physician sent out on this memorable occasion was a very young junior who graduated the previous year, and who had not the slightest compunction to measure swords professionally with a practitioner of twenty years' experience. Another case was cited by me from personal experience in which the ambulance surgeon who was summoned declared a man was suffering from alcoholism, and handed him over to a policeman, who promptly, under protest from the writer, placed him in a cell where he died four hours later. The autopsy revealed fracture of the skull as the cause of death; further examination of the brain and tissues made it plain that the man could not have been addicted to the use of intoxicants—in short, that he was a temperance man.

The errors of judgment, professional and otherwise, committed by these young hospital juniors led me to conclude that their incompetency was clearly proven.

Now, about my ridicule of the hospital governors. This is what I said: that when they put a young man in uniform and gave him charge of an ambulance it was their duty to see that the young so-called surgeon had sufficient knowledge of his business to enable him to make a diagnosis in ordinary cases; that if sometimes diagnosis was difficult, the patient should get the benefit of the doubt, which he did not get; that the governor did not act for the best interests of the hospital, nor with due appreciation of the rights of the community—not to speak of the grievous wrong done to the patient when he sent a young and altogether inexperienced physician to the bedside of one who was desirous of availing himself of the benefits of the hospital. In that case the young doctor, overconfident and bumptious, made a wrong diagnosis, one that reflected on the family physician, put the life of the patient in jeopardy, and put another hospital to unnecessary trouble. I also said that when the governor appointed a man on the house staff, it was for the distinct reason that he knew less than the man he was called on to succeed, and that for the governor's conduct in this matter there was to be found no precedent in the other learned professions, in which merit and known ability are the prime factors in every case where success or promotion is the thing to be attained.

If this is ridiculing the governors, then your correspondent is right. Thirdly, and in conclusion, your reporter says I failed to offer a remedy for the alleged abuses. The correspondent of another paper who was present at the meeting does not agree with your reporter on this point, for he says: "Dr. A. Jacobi spoke briefly in discussion of Dr. Hillis' paper. With much of it he agreed, but he did not see how a better condition of affairs in some respects criticised by Dr. Hillis was practicable. One reform, which he thought might be productive of good results, would be to have the city pay the staff doctors in the institutions which it controls, thereby making it worth their while to stay in the service after they had attained some experience. In conclusion, Dr. Hillis suggested that the house staffs of hospitals should be made up of older and more experienced men, and that they should not be turned away to make room for new applicants just as they have acquired the experience that makes them valuable. Juniors should not be left in charge of a hospital. A six months' graduate of a law school would not be called to argue a case before the supreme court, and Dr. Hillis could not see why a six months' graduate of a medical school should be called on to operate in a case of life or death. Old doctors who have outgrown the manual skill to operate should be employed in the hospitals as an appellate division of the hospital court, where their knowledge and experience could be of use in advising the younger men. 'The worst of all hospitals,' said Dr. Hillis, 'are those where the power of appointing the staff is in the hands of clergymen or of a religious order, regardless of creed or denomination.'" THOMAS J. HILLIS.

June 26, 1900.

STATISTICS OF THE WOMAN'S HOSPITAL FOR 1898 AND 1899.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Will you kindly give space in the columns of the MEDICAL RECORD for the publication of the following statistics, which show the total number of capital operations performed in the Woman's Hospital from January 1, 1898, to January 1, 1900, the character of the cases, and the death rate:

Service of	Vaginal Hysterectomies.	All Other Abdomino-Vaginal Operations	Supra-pubic Hysterectomies	All Other Supra-pubic Abdominal Operations	Total Number of Operations.	Number of Recoveries	Number of Deaths.	Percentages of Deaths.
T. A. Emmet.	1	..	1	14	16	15	1	6.25
H. D. Nicoll..	7	5	29	92	133	127	6	4.51
C. Cleveland..	32	39	29	75	175	162	13	7.42
B. Emmet....	2	4	5	65	76	72	4	5.26
H. T. Hanks.	8	6	10	113	137	125	12	8.75
Totals.....	50	54	74	359	537	501	36	6.70

These figures are made up from the "Record-books of Cases" on file in the hospital, and the medical board pledges itself for the carefulness, fairness, and accuracy of the representations in the facts here given. The records are accessible to any one, properly accredited, who may desire to inspect them. Dr. Bache Emmet was absent in Europe for eight months in 1898, during which time his service was discontinued.

HENRY D. NICOLL, *Secretary of the Medical Board.*

OPERATION IN CANCER OF THE UTERUS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR. I beg to request the correction of a slight, but to me important, error in the report of my remarks on the subject of uterine cancer at page 1067 of the MEDICAL RECORD. I am reported as saying that, in my opinion, "there is no case of malignant disease with adeno-carcinomata of the fundus for which hysterectomy was justifiable, according to the records." What I did say, and have maintained for over twenty years, is, that there is no case of malignant disease of the uterus except cancer originating in and limited to the fundus, for which hysterectomy was justifiable. In proof of this declaration I referred to the melancholy, and not very creditable, records of total ablation for cancer of the cervix, while an absolutely safe and better method of treatment had been amply demonstrated for over a quarter of a century. JOHN BYRNE, M.D.

314 CLINTON STREET, BROOKLYN.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, June 7, 1900.

WILLIAM H. THOMSON, M.D., PRESIDENT, IN THE CHAIR.

Memorial Address on the Life of Dr. Fessenden Nott Otis.—DR. T. GAILLARD THOMAS read a short address, in which he reviewed, in a fitting manner, the work of the late Dr. Fessenden N. Otis (see page 1073). He was followed by Drs. L. Bolton Bangs and Edward L. Keyes, after which the following resolutions were presented by Dr. Richard H. Derby, and unanimously adopted by the Academy:

"*Whereas*, The New York Academy of Medicine has heard of the death of Dr. Fessenden Nott Otis at New Orleans on the 24th of May, 1900, in the seventy-sixth year of his age;

"*Resolved*, That the following minute be spread upon the records of the Academy:

"Dr. Otis was born in Ballston, N. Y., and was graduated from the New York Medical College in 1852. He was connected for many years with the College of Physicians and Surgeons of this city as clinical teacher, professor and emeritus professor of genito-urinary diseases. He held positions in many of the hospitals in the city. Upon the special subjects which he taught, he was a widely recognized authority. His contributions to the medical press were numerous. Strong in his convictions, he had the courage of them, and while his theories may have been not infrequently challenged, his frank and genial temperament, his freedom from personal littleness or professional jealousy will always be cherished by those whose privilege it was to know the man.

"As an author in other fields than that of medicine, and as an artist of reputation, the world has sustained no slight loss.

"The New York Academy of Medicine hereby records its appreciation of this well-spent life, this loyal devotion to the best interests of science, and this example of a high character."

Pathology of Insolation.—DR. IRA VAN GIESON read a paper on this subject. He stated that the problem of the pathology of insolation, which was still unsolved, was important not only in itself, but also in its relation to other sets of phenomena, such, for instance, as the similarity of certain manifestations of insolation to those in poisoning by snake venom, the losses of consciousness, comatose, convulsive, and tetanoid conditions in general, and to the coma of diabetes and uræmia in particular. The problem was mainly one for the physiological chemist, and the pathological anatomist must follow in his wake. Although, since the great epidemic of sunstroke in 1896, opinions regarding this condition had become unified as regards treatment, we knew next to nothing about its pathology. We could only surmise. Among the various theories which had been advanced, the following were worthy of consideration:

Bacterial origin of sunstroke: Recently the bacterial origin of the disease had been suggested, and perhaps we should not dismiss the theory too peremptorily. Briefly, the theory was that the increase of body heat or the exposure to the conditions under which sunstroke was liable to occur permitted certain bacteria to become infective. The absence of prodromata and sudden onset of the disease argued against this theory.

The caloric theory: The theory that the symptoms of heat-stroke were due to the direct action of the heat was the oldest theory, and had recently been brought into prominence again by the experiments of Goldscheider, Flatau, Ewing, and others, who had found certain changes in the neurons of animals after exposing them to very high temperatures. The animals were placed in heated ovens and then resuscitated, and it was found that their exposure to the heat was followed by lesions in the nerve cells. This theory, Dr. Van Gieson said, failed to explain the origin of the hyperpyrexia in the human subject, and in the animals experimented upon the changes in the cells might have resulted from some concomitant condition, and were not, perhaps, directly due to the heat, although this was the exciting cause. There might have been accompanying changes in the blood. It was known that high temperatures in other diseases were not always accompanied by neuron changes.

The autotoxic theory: The speaker said that his investigations and experiments at the Pathological Institute of the New York State hospitals, during the epidemic of sunstroke in 1896, convinced him that the manifestations of the disease were the result of some poison. It seemed to be a good example of an acute poison originating in the body, and acting most violently on the nervous system, particularly on the ganglion cells which governed the heart and controlled the vasomotor apparatus. The delirium, convulsions, opisthotonos, the mental derangement, etc., could be at least partly interpreted by the changes in the ganglion cells produced by a poison of autogenous origin. In cases which resulted in recovery within a few hours, there was probably very little degeneration of the ganglion cells. Between this grade and those in which the cells were permanently managed, there were probably many intermediate conditions. The source of the poison, as well as its relation to the cessation of perspiration prior and during the attack, were unknown. The sudden onset of the disease in the great majority of cases favored the autotoxic theory. Animal experimentation by Dr. Levene and the speaker had shown that the virulence of the autogenous poison was fully as great as that of snake poison, and in some respects resembled its action. The urine of convalescent patients, when injected into the blood circulation of rabbits, was found to be decidedly hypertoxic, and injections of blood serum taken from two patients gave prompt and decisive results.

Cessation of perspiration: The two classes of animals which perspired most, namely, human beings and horses, were the ones which showed the most classical types of sunstroke, and from this it might be inferred that the occurrence of sunstroke was more or less intimately connected with the cessation of this function. On the other hand, the cessation of the perspiration might be the secondary manifestation of toxic involvement of this secretory function of the sympathetic. It is said that swine showed symptoms of heat-stroke, but it was quite a different disease from that observed in human beings. In swine, when overheated, it was said that the fat which enveloped the animal actually became liquefied, and it was claimed that the melted fat had been extruded both from the gut and mouth. Probably the succession of some of the initial manifestations, expressed in general terms, was as follows: The exciting cause in the form of high external temperature induced a change in the blood: The nature of this change was not known. It might be a change in density, in chemical constitution, or in the addition of a hypothetical toxic agent derived from autogenous sources. The latter factor seemed less probable than either or perhaps both of the first two conditions. As a result of this the angioparesis took place. We should naturally surmise that the angioparesis was a sequence of the paralysis of the vaso-constrictor nerves due to the toxic action of the altered constitution of the blood, if its direct action on the walls of the smaller vessels could be eliminated. The cessation of perspiration and accumulation of carbonic oxide were concomitant with the angioparesis. With the angioparesis and stasis began the hyperpyrexia, for this interfered with the heat loss to the extent of some ninety per cent. The loss of consciousness also was to be attributed to the change in the blood which induced retraction of the higher neuron aggregates. The best working-hypothesis of sunstroke was the theory of auto-intoxication. In fact, sunstroke seemed one of the most outspoken examples of the autotoxic diseases, and should be a most interesting field of investigation. There might be no actual poison derived from the body which gained entrance to the blood, but if the blood was changed in its density or chemical composition, under the conditions imposed by the external caloric agency, this was nevertheless a form of auto-intoxication. Whatever this change in the blood was, it certainly seemed to take place quite suddenly. It would be interesting to compare the blood as affected by snake venom with the condition in sunstroke. In both affections the clotting property of the blood post mortem seemed impaired.

Dr. P. A. Levene briefly referred to the existing theories of the mechanism of sunstroke. These were: (1) The direct action of the temperature on the heart and diaphragm, resulting in asphyxia; (2) direct local active irritation of the skin, resulting in angioparesis, which in its turn retarded the circulation; hence, accumulation of carbonic oxide and asphyxia; (3) high perspiration, causing fall of the blood-pressure; (4) paralysis of the heart produced by heat affected the kidneys, and the disturbance of the function of the kidneys was responsible for the symptoms of sunstroke; (5) the autotoxic theory. Nearly all the theories were speculative. The speaker referred to the fact that in sunstroke there was a marked diminution in the amount of urine secreted and a decrease in the quantity of urea and other ingredients, the specific gravity of the urine being lowered. This fact could not be explained by an organic change in the kidneys (as parenchymatous nephritis), as no albumin or casts could be detected in the majority of urines analyzed. There must be another cause for these changes in the character of the urine secretion. Pfaff, of Harvard, had recently demonstrated that defibrinated blood influenced the function of the kidneys in a similar manner to that produced by sunstroke. This would suggest that extreme heat produced changes in the blood (as a result of the abnormal function of the skin or other organs), similar to those produced by defibrination, or probably even rendered the blood less coagulable than normally. The latter fact was observed by some pathologists in cases of sunstroke. This would be a corroboration of the autotoxic theory. Another explanation for some of the symptoms of sunstroke might be found in the concentration of the blood. Under the old theory which attributed the symptoms of sunstroke to concentration of the blood, it was supposed that the blood became concentrated to such a degree that the heart was unable to propel it. It was more probable that when the blood became concentrated the proportion of salts was increased, and there were a corresponding increase in the osmotic pressure and a depression of the cells of the surrounding tissues. A condition similar to retraction of the cells probably took place under these circumstances.

Dr. George M. Parker, who was a hospital interne at the time of the epidemic of sunstroke in 1896, said that the mortality of the cases under his observation at that time was about sixty-six per cent., the deaths occurring from twelve to thirty-six hours after the onset of the attack. The symptoms were those of an acute general poison. The temperature range was a very wide one, in some cases going as high as 110° and 112° F. Comparatively few cases of sunstroke occurred until after the hot weather had lasted for several days. In one case coming under his observation the attack was followed by motor aphasia, with paresis of the lower extremity, which at the end of three months had not entirely disappeared. He said that the value of early treatment of sunstroke by means of applications of ice or ice-water could not be overestimated. Those patients who received early attention usually recovered rapidly, whereas in those who were neglected for a considerable length of time the reduction of temperature was very slow. The treatment consisted of applications of ice or ice-water, with vigorous rubbing, and considerable stimulation.

Dr. Charles A. Whiting gave his experience with sunstroke cases during the epidemic of 1896. He emphasized the statement made by Dr. Parker that the cases were rare during the first two or three days of the hot spell, and then began to multiply rapidly. The patients usually became delirious when the temperature rose above 106° F. As a stimulant, camphor, given subcutaneously, seemed to be very efficacious.

SECTION ON SURGERY.

Stated Meeting, May 14, 1900.

Charles N. Dowd, M.D., Chairman.

Choledochotomy.—Dr. Howard Lilienthal presented a patient, about thirty-five years old, who was admitted to the Mt. Sinai Hospital December 14, 1899. She first had jaundice six years ago after childbirth. She was then well until three months ago, when there developed epigastric pain, shooting into the back, but not in the right side. There was no colic, but severe intermittent pain. There was no vomiting or distress after eating. The pain recurred every five or six days. Constipation was present; the stools were never clay-colored. About one month ago jaundice occurred after an attack of pain. On admission the pulse was 92, respirations 24, and the temperature 100.4° F. The urine was acid in reaction; specific gravity, 1.024; otherwise negative. The liver extended from the fifth interspace to a finger's breadth below the border of the ribs in the mammary line; its border was about horizontal. There was firm resistance in the epigastrium, most noted under the upper part of the right rectus. The patient was decidedly jaundiced. On December 15th the temperature was 101.2° F. She had not much pain. On December 18th the urine contained bile, albumin, pus, and epithelial, hyaline, and granular casts. The patient's general condition seemed to be improving. On December 18th choledochotomy was done. The gall bladder was not tense. No stones were felt. The cystic duct was apparently free. The common duct contained a mass which, on incision, was found to consist of eight or nine small faceted stones about the size of hickory nuts. Before incision a purse-string suture was made around the point of intended incision. Twelve other stones were obtained from the common duct by milking. A probe passed through into the duodenum. The purse-string suture was then tightened and was reinforced by a few silk sutures. In the upper part a short drain of gauze surrounded by rubber tissue was carried straight down. After the operation there were some vomiting and a mild nephritis which subsided under appropriate treatment. On December 24th the first dressing was changed. The packing was taken out; there was no leakage. The sinus was filled with iodoformized gauze through an endoscope. On January 17th she was discharged, and she has been practically well ever since.

Sarcoma of Dislocated Testicle.—Dr. James Pedersen presented R. M——, aged twenty-seven years. When he was thirteen years old his left testicle was driven through the inguinal ring to the internal abdominal ring, if not entirely into the abdomen, by a severe blow from a flying base-ball. The only immediate effect was local pain on exertion. Apparently neither this nor the failure of the testicle to descend again into the scrotum received any attention. He did not even report the matter to his parents. Gradually a tumor formed in the left inguinal region, and with its growth the local pain on exertion increased. Then frequency of micturition developed. He allowed the condition to take its course throughout the intervening fourteen years until last January, when the pain on exertion had become so great that he could scarcely stand up. The patient's general condition was now very poor; his anæmia and his emaciation combined with his dwarfish stature, presented a sorry spectacle. Local examination showed an apparently normal right testicle; the left half of the scrotum was empty, the corresponding inguinal canal occluded; no evidence of hernia was present. Occupying the left inguinal region was a prominent, rounded tumor, which sloped away toward the median line, but which filled the hypogastrium also and encroached upon the right inguinal region. The tumor could be felt per rectum, on reaching high up. The diagnosis was sarcoma. Operation was advised and accepted. After the patient had had a preliminary week of rest in bed, and liberal diet and stimulation, the tumor was removed February 3d, through the ordinary median incision. The omentum was found adherent over a considerable area of the upper surface of the growth; numerous adhesions bound it to the surrounding structures, and it was tightly wedged in the pelvis between the bladder and the rectum, to both of which it was adherent. When the tumor had been shelled out of the pelvis the pedicle was found springing from the region of the left internal abdominal ring, and a secondary growth was discovered, which from about the middle of the primary extended upward behind the peritoneum to, if not involving, the left kidney. The patient's condition making expedition necessary, the pedicle had to be ligated *en masse* and the retroperitoneal growth, at its junction with the primary, was ligated in two portions and cut. There was considerable hemorrhage from this point. After ascertaining that the bladder had not been wounded, gauze drains were inserted and the abdominal incision was closed. The patient was in extreme shock at this stage, but under active hypodermatic stimulation and the systematic use of high enemata of hot saline solution with coffee he recovered rapidly. Four hours after the operation his pulse was good and his general condition surprisingly so. During the first four days the rectal temperature ranged from 102.8° to 101° F., and the pulse from 112 to 84. On the fifth day the temperature began to rise. On the sixth day the dressings were much soiled with a brownish fluid of fecal odor. Two small drainage tubes were therefore substituted for the gauze wicks, and irrigations of the sinus were instituted. After three or four days the discharge became purulent and the fecal odor disappeared. On the seventh day the patient complained of pain in the left inguinal region. Examination showed a small tumor presenting in the region of the internal abdominal ring. It had the physical characters of intestinal hernia, and as it was reducible with a gurgling sound it was so regarded. It continued to recur, however, in spite of well-directed attempts to keep it back. Apparently as the result of the repeated manipulations, the tumor became inflamed, and by evening of the following day it had increased considerably in size and become irreducible. It was boggy and no longer tympanitic; it now formed an elongated mass, its lower extremity dipping into the upper limit of the scrotal sac. There were no subjective symptoms of strangulation. An ice-bag was kept applied. The following morning the patient complained of increasing pain in the tumor region. The irregular temperature had risen somewhat during the night and there had been considerable sweating. An abscess was, therefore, suspected. Dr. De Garmo, who kindly saw the patient in consultation, excluded incarcerated intestinal hernia and made out a cyst containing fluid (possibly pus). Acting upon his advice an exploratory puncture was made. The needle entered a thick-walled sac and drew off about three drachms of straw-colored serum. In the course of the next twenty-four hours the cyst refilled and the site of the suspected abscess became manifest by a slight prominence of the inguinal region on the same side. Under ether an incision was now made over the scrotal tumor and carried upward across Poupart's ligament. From the former site an egg-shaped cyst, apparently the remains of the former tunica vaginalis, was easily enucleated. From the abscess cavity a large quantity of very foul pus was evacuated. A drainage tube was inserted and the wound closed. From this point on the patient did perfectly well. He was allowed to sit up three weeks after the first operation. The sutured portions of both wounds healed by primary union. Both sinuses were closed by the end of the seventh week. Dr. F. C. Wood, to whom the tumor was submitted for examination, reported it to be a large round-celled sarcoma, devoid of any remnant of testicle tissue. Dr. W. B. Coley, who now kindly saw the patient for me with the view of determining whether injections of the mixed toxins of erysipelas and the bacillus prodigiosus should be resorted to, found that the secondary growth was too widely generalized. Equally, and for the same reason, removal by operation of this growth was impossible. As to the patient's condition at present, instead of being scarcely able to stand up, he now goes about with comparative comfort, and he has gained a little in weight. Micturition is normal.

Abscess of Gall Bladder and Liver; Gall Stone in Common Bile Duct; Kinking of Stomach from Adhesions; Gastric Ulcer; Recovery by Choledectomy and Gastro-Enterostomy.—Dr. Robert F. Weir exhibited a woman aged thirty-five years, on whom he had, in December last, for a distended and painful gall bladder, with temperature elevation and chills, and paroxysmal vomiting, incised the abdominal wall and opened the gall bladder, which contained some two or three ounces of pus, and which had ulcerated through on its posterior wall and had thus invaded the liver tissue, in which there was found a communicating abscess holding over an ounce of pus. Nothing in the way of concretion was found in the gall passages, nor were there jaundice or clay-colored stools present. Many adhesions outside the gall-bladder were encountered. The gall-bladder was drained by a retained tube through which bile flowed moderately for a short time. Her attacks of vomiting soon recurred and were associated with pain in the gastric and hepatic regions. The stools were not clay-colored nor was jaundice present. She re-entered the New York Hospital April 2d, having lately had chills and fever added to her symptoms. There was marked tenderness over the gall-bladder region, and it was thought that this was distended. The incision was along the outer edge of the rectus, which muscle was drawn to the median line after section transversely of its anterior sheath, and then later its posterior sheath was secondarily divided. This gave a large exposure to the parts. The adhesions of the omentum were slowly released, and the gall bladder was found in good condition. As the parts were cleansed it was recognized that a movable calculus was in the upper part of the common duct. This was removed by incision and the wound sewed up. Then a marked kinking of the stomach near the pylorus by adhesions was found which was unloosened, when palpation of the pylorus revealed a sharply thickened mass the size and shape of half an almond on its posterior wall running into the stomach and clearly marking the site of an ulcer. This was treated through the same wound (showing thus its scope) by a posterior gastro-enterostomy combined with entero-anastomosis by the Gallet method. The patient made a rapid recovery. The buttons were discharged on the ninth and thirteenth day respectively. The gall stone was about the size of a bean.

Dr. Howard Lilienthal said that this subject was very rapidly growing in interest, and that operations were becoming more and more frequent. He wished to relate an experience that he had this year with a near relative of his, which showed how differently one will act when such a condition is brought home to you. An old lady about sixty years of age had a very marked attack of cholecystitis which was evidently complicated by gall stones. The fever was moderate but the pain was extremely severe. The gall bladder was palpable and the jaundice was quite deep, disappearing soon after the attack. He believed that taking into consideration the age of the patient and the fact that, after all, a great many individuals have had attacks of that sort and have gotten over them, conservatism was the right thing. This old lady recovered. She might never have another attack. Until he was convinced that there was what might be called "clinical sepsis" which bade fair to become alarming, he would be slow to urge operation upon the gall bladder in old people. In patients of that age the old-fashioned cholecystotomy with removal of the gall stones, even perhaps leaving a fistula, he thought would more surely conserve their lives than anything else he knew of.

Dr. Charles A. Powers, of Denver, was in accord with the remarks of Dr. Lilienthal relative to conservatism, especially in older people. The differential diagnosis between diseases of the gall bladder and bile ducts had been a matter in which, on a number of occasions, he had been absolutely unable to give a positive opinion before operating. No less than three times during the past year had he been in doubt as to whether there was an acute inflammation of the gall bladder or of the appendix. In each instance he made a short incision midway between the two, and with the finger swept the interior; in each instance the gall bladder, and not the appendix, was at fault.

Sarcoma of Mesentery; its Extirpation, with Eight and One-Quarter Feet of Small Intestine; Peritonitis; Death.—Dr. Robert F. Weir showed a specimen of a large sarcoma originally involving the mesentery and subsequently invading the small intestines, which had existed in a man forty years of age, and had been recognized by him for about two months. Prior to that time he had had frequent attacks of indigestion. From February 4th to the date of his entrance to the New York Hospital, March 2d, he had had continued pain in the lower abdomen, in which a mass centrally situated was felt through the abdominal walls, slightly movable but sensitive to touch. It was larger than a cocoanut. A laparotomy done on March 5th showed that it was, as previously diagnosticated from the absence of intestinal obstruction or hemorrhage, of mesenteric origin, and that its nature was, as expected, sarcomatous. It was dislodged with but little effort from the pelvis, which it well filled, being attached to the left side of the brim. In raising up the tumor at the front the small intestine, which was here largely involved, gave way and allowed one or two tablespoonfuls of yellow mucus to escape; though the opening was immediately plugged and the peritoneum adjacent forthwith cleaned and irrigated, this infection had a large influence on the subsequent progress of the case. The tumor being raised above the skin level it was seen that a large resection of the intestine would be necessary to remove the mass. This was decided upon, as the patient's condition was good. It was accordingly done, the mesenteric vessels, when recognized, being duly clamped and ligated prior to division. When ablated it was found that some seven feet and six inches had been removed, but as some eight inches more of the intestine demanded removal by reason of defective circulation, a total of eight feet and two inches was taken away. Instead of an end-to-end anastomosis a lateral union by Murphy's button was resorted to, as it had been shown in several cases that gangrene of the free ends occurred. These ends were simply twisted and duly seared. The patient succumbed to peritonitis at the end of thirty-six hours, due, most probably, to the infection incurred at the operation. It had been shown that a greater length than this, in which the lower end was about one foot from the ileo-cæcal valve, had been successfully removed. The longest piece of bowel taken away was twelve feet, but this patient did not survive. One other resection of eleven feet was survived, and one year later the patient was in perfect health. It was believed that no more than one-half the small intestine could be removed without affecting nutrition. One should always leave as much as one took away.

Differential Diagnosis in Diseases of the Biliary Passages.—Dr. George E. Brewer read this paper which will appear in a future issue.

Concerning the Peritoneum and the Treatment of Diffuse Exudative Peritonitis.—Dr. A. A. Berg read this paper (see page 1113).

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 23, 1900:

	Cases.	Deaths.
Tuberculosis	178	135
Typhoid fever	18	9
Scarlet fever	107	8
Measles	304	14
Diphtheria	257	30
Laryngeal diphtheria (croup)	8	3
Cerebro-spinal meningitis	0	6
Chicken-pox	19	0
Smallpox	4	1

Diagnosis of Incipient Forms of Pulmonary Tuberculosis.—Senator, of Berlin, says the best criteria for an early diagnosis are as follows: "Analysis of the sputum; inoculation of it into animals; reaction to serum and to tuberculin; leucocytosis when it is possible to eliminate all other causes capable of producing it; auscultation and percussion when they reveal changes limited to the apex of the lung; different degrees of expansion of the apices; the artificial catarrh induced by the use of potassium iodide; tuberculous lesions of other organs; previous pleurisies; the habitus phthisicus; cough and sweating."—*British Medical Journal.*

Women's Brains.—Mr. Alexander Sutherland writes in *Nineteenth Century* for May upon "Woman's Brains." Mr. Sutherland points out that as the result of recent investigations it is proved that the average man has from ten to twelve per cent. more brain weight than the average woman, but in proportion to the weight of her body woman has six per cent. more brain than man has. Her average runs about fifty ounces of brain for every pound of weight in her body, while man in proportion to his body has only forty-seven ounces. But, on the whole, he says that "however or wherever we make the inquiry," it is always seen that when men and women are of equal height and weight the men have something like ten per cent. more brain than women. The average brain of a man of genius in only 9.3 per cent. more than that of the ordinary individual. The average woman is to the average man as the average man is to the man of genius, if the weight of brains were to settle it. Lest the average male should be inclined to vaunt himself over his sisters, Mr. Sutherland tells him that even if it were demonstrated that the average woman, because she had ten per cent. less brain weight, had therefore ten per cent. less intellectual capacity than the average man, it would have to be remembered that even then ninety per cent. of the women are the equals of ninety per cent. of the men, and this would seem to imply that the average man has to recognize about forty per cent. of the women as his superiors in intellect.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended June 23, 1900:

		Cases.	Deaths.
Smallpox—United States.			
District of Columbia, Washington	June 9th to 16th	8	
Illinois, Cairo	June 2d to 9th	1	
Indiana, Evansville	June 8th to 16th	2	
Iowa, Ottumwa	April 28th to May 5th	1	
Kentucky, Covington	June 8th to 16th	9	
Louisiana, New Orleans	June 8th to 16th	35	6
Shreveport	June 2d to 9th	5	
Massachusetts, Fall River	June 8th to 16th	3	
Lowell	June 8th to 16th	3	
Michigan, Grand Rapids	June 8th to 16th	2	
Minnesota, Minneapolis	May 26th to June 9th	26	1
N. Hampshire, Manchester	June 8th to 16th	9	
Ohio, Cleveland	June 8th to 16th	28	2
Youngstown	June 8th to 16th	1	
Pennsylvania, Pittsburg	June 8th to 16th	2	
Porto Rico, Ponce	May 27th to June 4th	1	
South Carolina, Greenville	June 8th to 16th	2	
Utah, Ogden	May 1st to 31st	3	
Salt Lake City	June 8th to 16th	5	
Washington, Spokane	June 8th to 16th	1	
West Virginia, Charlestown	June 12th	10	
Smallpox—Foreign.			
Austria, Prague	May 28th to June 2d	11	
Belgium, Antwerp	May 19th to 26th	1	2
Brazil, Rio de Janeiro	April 13th to May 11th	..	16
Canada, Province of Montreal	June 4th	30	
England, Liverpool	May 26th to June 2d	2	
London	May 26th to June 2d	7	
France, Nice	May 25th to June 6th	3	
Paris	May 26th to June 2d	..	1
Germany, Stettin	May 19th to 26th	1	
Gibraltar	May 20th to 29th	4	
Greece, Athens	May 19th to 26th	4	2
India, Bombay	May 8th to 15th	..	24

INDEX.

A

Abbe, Robert, spinal fracture in paraplegia, 353.

Abdomen, adhesions in the, 601 ; diagnostic significance of acute exudations in the, 158 ; distention of the, as an indication for exploratory laparotomy in intestinal obstruction, 817 ; foreign bodies in the, after operation, 552 ; general examination of the, when opened during operation, 375 ; grave lesions of, defying diagnosis, 285 ; pistol wound of the, 112 ; sonorousness of the, 121 ; technique of closure of wounds of the, 461 ; treatment of circumscribed abscess of the, 333 ; treatment of viscera of the, through the colon, 815.

Abdominal disorders in women, neuroses depending upon, 1049 ; incisions, methods of closing, 847 ; section, best posture in bed after, 823 ; section, post-operative treatment of, in women, 1098 ; wounds, closure of, by means of buried silver-wire net (healing in of filigree pads), 676.

Abrams, Albert, progressive pernicious anæmia and malignant disease of the stomach, 718.

Abscess, migratory, becoming autonomic, 888 ; perigastric and periduodenal, 694 ; subphrenic, 221.

Acetanilid, poisoning by, 552.

Acid intoxication, study of, 772.

Acidity, 113 ; relation of gastric and urinary, 1112.

Acne, treatment of, 731 ; vulgaris, etiology and treatment of, 123

Aconite, poisoning with, 33.

Acromegaly, 33 ; a case of, 213, 214 ; with symptoms of Raynaud's disease, 69.

Acting assistant surgeons in the army, 561.

Actinomycosis, 645 ; a case of, 1008 ; in man, 31, 763 ; in man in America, 336 ; the organism and lesion of, 829.

Adams, William, death of, 327, 392.

Addison's disease, a family with, 816 ; following typhoid fever, 1091 ; influence of suprarenal preparations in, 160 ; treatment of, 1104.

Adenoids, persistent, in a middle-aged woman, 1091.

Adiposis dolorosa, 856.

Adler, I., muscular rheumatism, 529.

Adnexa, danger of coitus in inflammation of the, 70.

Adrenals, diagnosis of growths of the, 528 ; lesions of the, 153.

Advertising, medical, in religious journals, 190.

Agglutination in infectious diseases, 145 ; in tuberculosis, 1095 ; mechanism of, 771.

Agglutins, influence of, in the infected organism, 25.

Ainhum, a case of, 647.

Air, liquid, therapeutic value of, 1101.

Air passages, catarrhal affections of the upper, indications for constitutional treatment of, 667 ; foreign bodies in the, 198 ; peanut in the, 360.

Aix-les-Bains, 163.

Albumin, formation of sugar from, 28 ; unimportance of the presence of a trace of, in otherwise healthy urine, 114.

Albuminuria, 285, 596 ; febrile, 119 ; influence of high altitude on, 886 ; pathogenesis of cyclic, 543.

Alcohol, case of unusual tolerance of the organism for, 163 ; effect of, on the brain, 887, 963 ; food value of, 596 ; local application of, in gynæcology, 600 ; physiological effects of, 170 ; relation of, to hard work, 890 ; therapeutic employment of, 157 ; therapeutic employment of, in Europe, 66 ; use of, in health and disease, 595 ; use of, in relation to life insurance, 32 ; disinfection by, 1131.

Alcoholism, digitalis in the treatment of acute, 998 ; historical notes on the sanatorium treatment of, 410 ; in the United States army, 748.

Alexander, L. S., one result of attempted abortion in the early weeks of gestation, 360.

Alexins, 511.

Allbutt, Thomas Clifford, notice of book edited by, 930.

Allen, Charles Warrenne, the inoculation wound of lues, 445.

Allen, Horace P., death of, 328.

Allyn, Alvin B., death of, 726.

Alopecia areata, new treatment for, 1019.

Alpine Ambulance Association, 131.

Alter, Francis W., a new nasal splint, 570.

Althaus, Julius, death of, 1128.

Altitudes, high, contraindications to, 380.

Altoona (Pa.) Academy of Medicine and Surgery, officers of the, 62.

Aluminum acetate, disinfecting power of, 470.

Alveolar catarrh in children, 162.

Ambulance system in New York, needed reforms in, 15, 130, 189, 563 ; service in Great Britain, 106.

Amenorrhœa, manganese citrate in, 27 ; pathological, from other than constitutional causes, 694.

American Academy of Medicine, 1014.

American Association of Genito-Urinary Surgeons, 782, 870.

American Climatological Association, 827, 875, 972.

American Dermatological Association, officers of the, 812.

American Gynæcological Society, 775, 849.

American Institute of Homœopathy, annual meeting of the, 1087, 1127.

American Laryngological Association, 781, 867.

American Medical Association, 989, 1048, 1098 ; general sessions, 989, 999, 1056 ; officers of the, 1000 ; president's address, 989 ; section on materia medica and therapeutics, 997, 1053, 1103 ; section on obstetrics and diseases of women, 994, 1048, 1065, 1098 ; section on pediatrics, 997, 1051, 1099 ; section on practice of medicine, 990, 1002, 1056 ; section on surgery and anatomy, 992, 1003, 1060 ; the MEDICAL RECORD report of the, 1037.

American Neurological Association, 779, 856.

American Orthopedic Association, 1069, 1105.

American Pediatric Society, 777, 858.

American Surgical Association, 774, 844.

American Therapeutic Society, organization of the, 813.

Ammonia, excretion of, in the urine, 887.

Ammonio-formaldehyde, effects of, 872.

Amnesia, a case of, 1019.

Amputation in childhood, conical stump after, 693 ; osteoplasty in, 466 ; splint for use after, 286.

Amyloid, colloid, and mucoïd substances, the chemical relationship of, 188, 304 ; sections stained with iodine, mounting, 332.

Anæmia, dietetics of, 156 ; leucopenic, 769 ; pernicious, 830, 1109 ; pernicious, a chronic infectious disease, 332, 677 ; pernicious, and malignant disease of the stomach, 718 ; pernicious, antistreptococcic serum in, 817 ; pernicious, condition of the blood in, 643 ; pernicious, etiology, 65 ; pernicious, red corpuscles not stained by methylene blue in, 424 ; pernicious, with yellow bone marrow in the epiphyses, 1095 ; secondary, simulating pernicious anæmia, 25 ; splenic, 71, 764 ; tropical, 248.

Anæsthesia, amputation without, 728 ; by a mixture of chloroform and ether, 204 ; by injection into the spinal canal, 246 ; chloroform and ether, 120 ; elevation of the glottis during, 993 ; ether, from a medical standpoint, 1045 ; ethylic-bromide, 765 ; ethyl chloride preliminary to ether, 964 ; general, 32, 435 ; in cases in which a respiratory impediment exists, 1131 ; local, in major operations, 203 ; local, in the radical treatment of hernia, 161 ; nitrous oxide and ether, 31, 627 ; nitrous oxide and oxygen, an unprecedented case of prolonged, 364 ; pathological findings in a case of general and cutaneous, 732 ; Schleich's method of local, 555 ; study in, 596.

Anæsthetics, administration of, to children, 916 ; new apparatus for administering, 435, 524.

Anakhre, 248.

Anatomical specimens, how to send, by mail, 823.

Aneurism, aortic, electrolysis for, 151 ; aortic, tracheal diastolic shock in, 71 ; aortic, treatment of, 126 ; electrolysis in the treatment of aortic, 248 ; gelatin injections in the treatment of, 197, 426, 832 ; innominate, 32 ; iodide treatment of, 832 ; ligation of the right subclavian for, 888 ; of the aorta, 655 ; of the descending aorta, 554 ; of the innominate artery, 380 ; of the renal artery, extirpation of the, 848 ; of the subclavian artery, 241 ; syphilis of the aorta as a cause of, 28 ; thoracic, 736 ; thoracic, presenting through the sternum, 646 ; wire for introduction into the sac of an, 31.

Aneurismal varix and injury to the median nerve at the elbow, 732.

Angina, Ludwig's, 70 ; pectoris, at the menopause, 512 ; pectoris, cases of, 331 ; pectoris, erythrol tetranitrate in, 124 ; pectoris, self-help of the organism in, 380 ; pectoris, treatment of, 1112 ; pectoris with endocarditis, 512 ; rare varieties of phlegmonous, in infants, 681 ; ulcero-membranous, 1044.

Angiotribe, experience with the, 211, 687.

Angiotripsy, 515, 994.

Aniline colors, antitoxic nature of the, 695.

Ankle, dislocation at the, 361.

Ankylostomiasis in Puerto Rico, 686 ; in the Leeward Islands, 1093.

Anosmia, complete, 203 ; congenital bilateral, 69.

Anshutz, E. P., notice of book by, 1020.

Antenatal injuries, damages claimed for, 371.

Anthrax, 791 ; bacteriological investigation of a case of, 68 ; human and bovine, 211 ; of the thigh, operation for, 643 ; serum treatment of, 340 ; treatment of, 931.

Antifebrin, poisoning by, 552.

Antipyresis, 644.

Antisepsis, studies on internal, 374.

Antitoxic sera, elimination of deleterious substances from, 843.

Antitoxins, genesis of, 923 ; sale of, by the New York health board, 239.

Antivenene, 969.

Antivivisection, accusation by an advocate of, 194 ; bill, 1036.

Antrum of Highmore, cancer of the, 302 ; catarrh and suppuration of the, 463.

Anuria, transfusion of saline fluid in, 114.

Anus, closure of rents implicating the sphincter, 25 ; fissure of the, 599 ; formation of an artificial, 661, 701, imperforate, 200 ; treatment of chancroids of the, 959.

Aorta, atheroma of the, 33 ; radioscopic appearance of the normal, 599.

Aortitis, 254 ; gonorrhœal, 1044.

Aphakia, congenital, 764.

Aphasia, sensory, 145 ; will-making in, 643.

Apomorphine as a hypnotic, 508.

Apoplexy, uterine, 245.

Apostoli, Georges, death of, 895.

Appendectomy, reprobation of normal, 592.

Appendicitis, 203. 844 ; association of chronic, with disease of the right adnexa, 948 ; cases of, 608 ; colitis as an etiological factor of, 1004 ; complicated with miscarriage, 638 ; early operation in, 694, 727 ; floating kidney mistaken for, 363 ; hæmatemesis in, 289 ; hockey-stick incision in, 329, 390 ; improved operation for, 328 ; in a hernial sac, 66 ; in children, 1051 ; indications for operation in, 600 ; in the course of muco-membranous colitis, 424 ; leg crossing an alleged cause of 87 ; ligation of the stump in, 131 ; medical aspects of, 66 ; new method of entering the abdominal cavity in operating for, 417 ; nomenclature of, 130 ; operation for, 156 ; operation for, in 1867, 430 ; operation for, at two sittings, 44 ; operations for, in young women and girls, 1069 ; pathology and treatment of, 243, 251 ; prognosis in, 332 ; results of the so-called conservative treatment of, 226, 259 ; some conditions simulating, 897, 934 ; statistics of the treatment of, 89 ; treatment of, 33, 168, 286, 346, 378, 383, 432, 463, 518 ; unusual condition of the skin and kidneys following operation for, 1035 ; when shall we operate for? 837 ; with gangrene and rupture of appendix and cæcum, 66.

Appendicular colic, 376.

Appendix, abscess of the, rupturing into the sac of a reducible inguinal hernia, 727 ; a tuberculous, 1009 ; foreign body in the, simulating gall stone, 303 ; inversion of the uncut, 91.

Archives of Neurology from the Pathological Laboratory of the London County Council, 166.

Arm, interscapulo-thoracic amputation of the, 336, 374.

Armstrong, Lewis, death of, 22.

Army, acting assistant surgeons of the, 1125 ; bill to define the status of acting assistant surgeons of the, 194 ; conscription in the British, 28.

Arrow poison, 287.

Arrowsmith, Joseph E., death of, 64.

Arsenic, antidote to, 75 ; in the organs, 376 ; in the treatment of cancer, 744, 937 ; normal existence of, in animals, 29.

Arterial tensions in childhood, 277.

Arteries, changes in the, in the young, 72 ; in the arms, rare anomalies of the, 246.

Arteriosclerosis, 462 ; a pronounced case of, 1010.

Arthritis, acute suppurative, in children, 240 ; etiology and treatment of urethral, 117; deformans 1057 ; deformans and polyarthritis chronica villosa, 422 ; deformans, electrical treatment of, 597 ; deformans in childhood, 233, 470 ; gonorrhœal, 693 ; mechanical and traumatic, 925 ; treatment of, 165.

Ascites, chyliform, 244, 544, 730 ; chyliform, due to cancer, 1132 ; chyliform, in syphilitic cirrhosis of the liver, 29 ; hemorrhagic, 113 ; milky, with leucocytes of lymphatic origin, 466 ; operations for, 931 ; surgical treatment of cirrhotic, 128.

Ashmead, Albert S., succus cinerariæ maritimæ in cataract, 349.

Association of American Medical Colleges, 1086.

Association of American Physicians, 772, 829, 843.

Association of Military Surgeons of the United States, 1015.

Asthenopia, causes of failure to relieve, 65.

Asthma, 1016 ; atropine for, 383 ; pathology of bronchial, 887 ; suprarenal extract in, 482.

Astragalus, tuberculosis of the, 1071.

Ataxia, hereditary, 1090 ; permanent nonprogressive, 1044.

Athens, a children's hospital at, 1128.

Athetosis and kindred affections, 198.

Athletics in the public schools, 285.

Athrepsia infantum, 1101.

Atlee, Washington L., death of, 111.

Atrophy, primary neurotic, 192.

Auditory canal, ceruminous and epithelial impactions in the external, 1078.

Aural surgery, present state of, 332.

Auto-intoxication, 464 ; as a factor in nervous diseases, 694.

Autopsies, earliest recorded, in America, 330.

B

Bacillus aerogenes capsulatus, infection by the, 1042 ; encapsulated, in the nasal mucosa, 160 ; pyocyaneus and its pigments, 72 ; the plague, 174.

Backache as a symptom of rectal disorder, 766.

Bacteria, absorption of, by the lymphatic ganglia, 695 ; adaptation of pathogenic, to different species of animals, 770 ; effect of liquid-air temperature upon, 766 ; influence of temperature on, 599 ; peculiar property possessed by some pathogenic, 842 ; struggle of the animal organism against, 815.

Bactericide, a new, 556.

Bacteriology, application of, to public health, 242 ; relation of, to clinical medicine, 771.

Bacteriuria, 426 ; associated with congenital dilatation of a ureter, 874.

Bahamas, climate of the, 472.

Bailey, Pearce, traumatic hemorrhages into the spinal cord, 573.

Baginsky, Adolph, notice of book by, 122.

Baldwin, J. F., inversion of the uncut appendix, 91.

Balleray, G. H., early operations for cancer, 602.

Bandage, a new T-, 232.

Banti's disease complicated by splenic anæmia, 24.

Barber shop, hygiene of the, in Boston, 813 ; menace of the, 190.

Barometric pressure, effects of increased, 198.

Barry, William F., gunshot wound of the kidney, 500.

Bartholow, Roberts, notice of book by, 382.

Bartleson, S. P., death of, 154.

Barton, Amy S., death of, 551.

Basedow's disease, see *Exophthalmic goitre.*

Basiotripsy, objections to, 645.

Bassini's operation for hernia, 240.

Bassler, Anthony, placenta prævia and twins, 965.

Batalpashinski, bitter lakes of, 376.

Bathing, hygienic effects of, 163; in typhoid fever, 419.

Baths and exercises, treatment of cardiac disease by, 255 ; public, 810, 928, 1133.

Beabes, George M., death of, 1089.

Beck, Carl, ligation of the stump in appendicitis, 131.

Bedbugs as germ carriers, 747.

Beebe, Clarence Edwin, death of, 416.

Beef-worm in the orbit, 331.

Belcher, W. J., death of, 218.

Bell, George Huston, an operation for the relief of an incarcerated iris, 321.

Belladonna, poisoning by, 554 ; poisoning by the external use of, 68.

Benedict, A. L., the nomenclature of appendicitis, 130.

Bennett's fracture, 887.

Bennett, Thomas L., new anæsthetic apparatus, 524.

Benzoic acid, effects of, upon the urine, 374.

Berg, A. A., concerning the peritoneum and the treatment of exudation peritonitis, 1113; hospital surgical service conducted by a single chief, 746 ; remarks on subphrenic abscess, with a report of three cases, 221.

Beriberi, clinical features of, 291 ; disappearance of, from the Japanese navy, 891 ; in infants, 720 ; in the Australian pearling fleet, 648.

Berks County (Pa.) Medical Society, officers of the, 109.

Bernhard, Father, a predecessor of Kneipp, 288.

Beth Israel Hospital, laying the cornerstone of the, 1014.

"Bibliographia Medica," a successor to the *Index Medicus*, 459.

Bierhoff, Frederic, a new modified urethrotome, 659.

Bigelow, I. S., death of, 551.

Bile, abdominal extravasation of, 365 ; action of salicylate of sodium on the secretion of, 730.

Bile duct, surgery of the, 25, 338 ; surgery of the common, 461 ; traumatic rupture of the, 336 ; tumors of the, 691.

Bilharzia hæmatobia, 329, 733.

Biliousness induced by sea air, 204.

Biological examinations, a system of personal, 990.

Bird, John Stirling, death of, 686.

Birth, injuries about the shoulder at, 506.

Blackwater fever, histology and prevention of, 113.

Bladder, exstrophy of the, 1062 ; exstrophy of the, from ulcerative destruction of the scar of a suprapubic cystotomy, 544 ; extra-peritoneal rupture of the, 523 ; injuries of the, occurring in the course of gynæcological operations, 961 ; mensuration and capacity of the female, 204 ; operative relief of ectopic, 31 ; stone in the, relative merits of operations for the extraction of, 357 ; surgical asepsis of the, 1062 ; traumatic intra-peritoneal rupture of the, 160 ; treatment of exstrophy of the, 923 ; tumors of the, 732 ; washing the, 1076.

Blind, tactile sensibility of the, 557.

Blindness in Finland, 41 ; mirror test for simulated, 475 ; transient, in hysteria, 692.

Blister, painless, 165.

Blood, alkalinity of the, in certain pathological conditions, 470 ; basophilic granules in the red corpuscles of the, 423 ; changes in, at high altitudes, 973 ; changes in the, in disease, 791, 1021 ; diseases of the, in children, 378 ; diseases of the, in relation to surgery, 1016 ; granular degeneration of the red cells, 512 ; pathology of the, 1019 ; value of examinations of the, 991.

Blood cells, counting, 433.

Blood-letting vs. leeches, 747.

Blood poisoning, an unusual case of, 27

Blood pressure in health, 769 ; in neuropathic children, 1018.

Blood-vessels and lymphatics, relations between, 722.

Blue-blindness in contracted kidney, 201.

Board of charities of the State of New York, 413.

Boards of health, fifteenth annual conference of State and provincial, 956.

Boer war, medical matters in the, 59, 62, 106, 147, 149, 166, 195, 216, 236, 250, 295, 326, 344, 349, 391, 394, 414, 415, 419, 427, 458, 459, 471, 504, 516, 560, 602, 649, 697, 747, 789, 810, 820, 919, 926, 927, 693, 1023, 1045, 1047, 1127.

Bogardus, H. J., a simple and efficient rubber splint-shoe, 571.

Bogert, S. S., food poisoning, 195.

Bolton, Percival R., round ulcer of the duodenum, 494, 522.

Bones, endothelioma of, 202.

Bonynge, Francis G., death of, 22.

BOOK NOTICES :

- Accouchements obstétriques, la pratique des, par H. Variner, 824.
- Anæmia and some of the diseases of the blood-forming organs and ductless glands, by B. Bramwell, 566.
- Anæsthesia, general and local, by A. P. Heineck, 734.
- Anatomie clinique des centres nerveux, par Dr. Grasset, 1021.
- Appendicite, formes et traitement, par A. Broca, 734.
- Bacteria as related to the economy of nature, etc., by G. Newman, 382.
- Bacteriology in medicine and surgery, by W. H. Park, 653.

BOOK NOTICES:
Bee-hive therapia and repertory, by S. Jones, 381.
Brain, anatomy of the, by R. W. Whitehead, 1021.
Braithwaite's Retrospect, vol. 119, 381 ; vol. 120, 735.
Chemistry, essentials of medical, by L. Wolff, 824.
Children, acid and alkaline, by T. C. Duncan, 653.
Children, diseases of, by G. M. Tuttle, 381.
Christian science, by W. H. Purrington, 653.
Clinical Society's Transactions, vol. xxxii., 382.

Bullous eruption, fatal cases of congenital, in an infant, 842; of undetermined nature, 103.
Buntine, R. A., bravery of, in battle, 306.
Burgess, O. O., hypodermoclysis in typhoid fever, 362.
Burghard, F. F., notice of book by, 928.
Burial alive, 633; premature, rectification of, 78, 149.
Burlington County (N. J.) Medical Society, officers of, 154.
Burns, application to, 128; causes of death by, 334.
Burt, Stephen Smith, thoracic aneurism; two cases involving the descending arch of the aorta; with an autopsy, 736.
Butler, George Frank, notice of book by, 381.

C

Cacodylic acid in tuberculosis, 466.
Cæcum, adenocarcinoma of the, 245; and small intestine, successful double resection of the, 125; excision of the, 610; treatment of sliding hernia of the, 309, 343.
Cæsarean section, 69, 464, 532; indications for, 292; indications for, compared with symphyseotomy, craniotomy, and premature artificial delivery, 70; in the moribund, 543.
Cajeput oil, inhalation of, 331.
Calculi, diagnosis of renal, ureteral, and vesical by the *x*-rays, 1062; renal, 507; renal, glycerin in, 203; salivary, 417, 465; ureteral, 418; ureteral and renal, positive and negative diagnosis of, by the Roentgen rays, 336; urethral, 119; urinary, 201; vesical, high operation for, 513; vesical, in Sierra Leone, 332; vesical, relative merits of operations for the extraction of, 357.
Callison, Adolph, death of, 506.
Calomel, capillary emboli following injections of, 116.
Camac, William, death of, 638.
Camden (N. J.) District Medical Society, officers of the, 20, 896.
Camphor as a mouth wash, 698.
Cancer, arsenic in, 744, 937; circumscribed gastric, 464; criticism of the mechanical theory of the origin of, 200; cure of, 420; development of, in the lymphatic glands, 695; early operations for, 604; etiology of, 212, 341; experimental production of, 306; gastric, 479, 774; gastric, diagnosis of, 845; gastric, gastrectomy for, 467; gastric, in the young, 728; gastric, lymphatic involvement in, 928; gastric, study of the blood in, 924; incidence of, 564; increase of, in Great Britain, 307; increasing prevalence of, in America, 337; in early life, 960; intestinal, 480; laryngeal, 478, 867; meat-eating as a cause of, 88; nectrianin in, 676; occurring in acid parts of the body, 765; of both breasts, 770; of the breast, 567, 598, 640, 689, 931; of the breast, results of operation in, 765; of the large intestine, 376, 463; of the lip, spontaneous disappearance of, 848; of the œsophagus, treatment of the, 277; of the pancreas, history of, 115; of the prostate, 873; of the skin, 864; operation for, 521; operations for, in the aged, 1042; parasitology of, 426; pathological anatomy of gastric, 770; prevention of, 564; radical cure of, by arsenic, 937; rapidly recurring, 700; study of, 236; study of, at Harvard, 61; treatment of, 535; treatment of, by cataphoric sterilization, 587; treatment of inoperable, 480; treatment of, without operation, 426; uterine, 568, 1065; uterine, early diagnosis of, 115; uterine, operation in, 1134; vaginal, 775; parasitic nature of, 1130.
Cantrell, William A., death of, 111.
Cantwell, F. V., six nephrectomies, 451.
Cape May (N. J.) Medical Society, 1015.
Carbolic acid, poisoning by, 96; vinegar as an antidote to, 370.
Carbon dioxide, simple method of applying, 334.
Carbonic-acid baths, contraindications to, 383; elimination of, after repeated cold baths, 288; gas, therapeutic application of, 113.
Carbonic oxide in tobacco smoke, 162; chronic poisoning by, 641.
Carleton, Bukk G., notice of book by, 735.
Carotid artery, ligation of, for varix of the orbit, 468; traumatic aneurism of the, caused by a sewing-needle, 703.
Carpenter, Charles Raymond, splenic extract and the splenic function, 273.
Carpenter, Henry B., death of, 551.
Carrier, Georges, notice of book by, 566.
Carter, H. W., nitrous oxide and ether anæsthesia, 627.
Casein, absorption of, 159; ferments, pathogenic action of the, 69; pancreatic digestion of, 778.
Cassidy, Patrick, report of a severe *x*-ray injury, 180.
Castor-oil seeds, poisoning by, 332.
Casts, urinary, 201.
Cataract, cineraria maritima in, 165, 349; origin of so-called acute, 466; pathology and treatment of lamellar, 511; secondary or membranous, 161; spontaneous disappearance of senile, 508.
Catarrh of the upper air passages, indications for constitutional treatment of, 667.
Catelectrolysis in the treatment of skin diseases, 112.
Catgut, new method of sterilizing, 701, 760; the question of, 767.
Catheterism, aseptic, 65.
Catheters, saponic lubricant for, 474.
Cauda equina, tumor pressing upon, 7, 40.
Cavalry, wounded, removal and transport of, 243.
Cellular specificity and its bearings on neoplasms, 910.
Celluloid thread, surgical use of, 463.
Cerebellum, tumor of the, with drainage of fluid through the nose, 507.
Cerebral hemorrhage, strychnine as a factor in the causation of, 817.
Cerebrospinal fluid, escape of, from the ear after injury, 87.
Cerebrospinal meningitis, bacteriological study of, 1123; etiology of, 158.
Cervix uteri, metallic dilatation of the, 120.
Chalicosis pulmonum, 112.
Chambers, G. R., death of, 1041.
Chancre, extragenital, 103; of the lip in a child seven months old, 417.
Chancroids of the anus, treatment of, 959.
Chapin, Henry D., how the milk supply of New York may be improved, 230, 255; the effect of summer heat upon public health, 984, 1007.
Cheloid of the lobe of the ear, 653.
Chest, bullet wound of the, 420; control of hemorrhage in wounds of the, 687.
Cheyne-Stokes respiration, ocular phenomena associated with, 421.
Cheyne, W. Watson, notice of book, by 928.
Chicago, drainage canal of, 198.
Chickenpox and smallpox, 150; nephritis in, 1034.
Children, examination of sick, 29, 68.
Chiropodists, contesting, 325.
Chisel in the naso-pharynx, *x*-ray diagnosis of, 67.
Chloral, poisoning by, 412.
Chloretone, hypnotic effects of, 248; surgical uses of, 378.
Chloroform, administration of, 435; danger of administering, in the presence of a gas-flame, 160; deaths under, 243; dosage of, in producing anæsthesia, 688.
Chlorosis, retinal complications in, 290; treatment of, 75
Cholecystectomy for gall-stones, 977; removal of the mucous membrane of the gall bladder as a substitute for, 993.
Cholecystitis, jaundice, and gall stones, relationship between, 692.
Cholecystotomy, cases of, 240; with waterproof drainage of the gall bladder, 28.
Choledochotomy, 1136.
Cholelithiasis, see *Gall Stones*.
Cholera in India, 787, 895, 920.
Chorea and polyclonia, 30; and tænia, 343; arsenic in the treatment of, 331, 375; as a pyogenic disease, 1126; etiology of 374; influence of fever on, 115; lumbar puncture in, 792; psychical disturbances in degenerative, 557; relation of, to rheumatism, 1057; rheumatica, pyogenic origin of, 729; study of 112 cases of, 556.
Chorion epithelium and decidua in tubal gestation, 446.
Choroid, ossification of the, 544.
Christian science and psychiatry, 779; rational therapeutics *versus*, 213.
Chyluria, a case of, 741; nostras, 293.
Cigarettes, composition of, 17; effect of, 146.
Cinematograph in teaching surgery, 115.
Circumcision, 605, 1102.
Cirrhosis of the liver, 643, 644, 689, 728, 926; alcoholic, in a baby, 35; multilobular, 158; preascitic stage of, 163.
Clarke, John H., notice of book by, 1020.
Clavicles, fracture of both, 157, 243, 421; treatment of fractures of the, 426.
Cleary, John Clark, death of, 111.
Climacteric hemorrhages, causes of, 730.
Club-foot, astragalectomy for, 288; double, from neuritis, 73; tendon-transplantation for, 1071; treatment of calcaneus, 1069.
Cocaine, epileptiform convulsions following the intranasal application of, 499; poisoning by, 600.
Codeine for cough, 383.
Code of ethics, value of the, 240.
Cod-liver oil, addition of iodine and phosphorus to, 1103.
Cœliotomy, angiotribe in vaginal, 994.
Cold, effect of extreme, on injuries, 33; effect of, on microbes, 238; hardening to the action of, 287.
Colds, cause, prevention, and treatment, 462, 923.
Colectomy, two cases of, 286.
Colic, appendicular, 376; hepatic, treatment of, 384.
Colitis, amœbic, 434; chronic, 434; membranous, 433; muco-membranous, 424; mucous, 433; scorbutic membranous, 73.
College of Physicians of Philadelphia, 61, 150, 281, 458, 503, 636, 683, 725, 813 920; section on general medicine, 18 368.
Colles' fracture, malpractice suit following, 290; the cardinal pathognomonic sign of, 540.
Collins, Charles S., death of, 922.
Collins, Joseph, notice of book by, 565.
Collodion, styptic, 75.
Colloid, mucoid, and amyloid substances, the chemical relationship of, 188, 304.
Collum, Robert, death of, 252.
Colon, cancer of the ascending, 157; dilatation of the, 557; fatty tumor of the, 1015; hypertrophy and dilatation of, in an infant, 720; irrigation of the 1104. sarcoma of the, 1064.
Colored light, effect of, on the nervous system, 263.

Colostomy, iliac, by double ligature, 426; for permanent fecal fistula, 1003.
Colotomy, a modified inguinal, 419.
Columbia University, endowment of the chair of psychology at, 62.
Coma, diabetic, 560; diabetic, preventive treatment of, 383; diabetic, treatment of, 998.
Common sense in practical medicine, 246.
Compensatory processes in disease, 278.
Congress of American Physicians and Surgeons, 770, 826.
Conjunctivitis, bath epidemic of, 159; diplobacillary, of Morax, 145; membranous, diphtheria antitoxin in, 68; treatment of, 14.
Conklin, George H., death of, 686.
Constantinople, letter from, 743.
Constipation, beef-gall enemata in postoperative, 289; surgical aspects of, 113; treatment of, in childhood, 287; treatment of obstinate, based upon new points in the anatomy and histology of the rectum and colon, 1004.
Consumption, contagiousness of pulmonary, 808; open-air treatment of, at home, 199.
Consumptives, care of poor, 955; city hospital for, 788; isolation of, 891; sanatoria for, 116, 792; sanatoria for, in New York State, 194; small cottage sanatoria for, 875; State care of, 34, 82, 208; State hospital for, 682, 683; systematic treatment of poor, 814.
Contagious diseases in New York, weekly statement, 175, 440, 1138.
Convalescence, dietetics of, 995.
Convulsions in childhood, 244.
Cook, J. Elmer, death of, 111.
Cooper, John, death of, 594.
Cornea, affections of the, 118; corpuscular activity in the, 329; electrocautery in affections of the, 373; influence of new antiseptics on infected wounds of the, 334.

Diabetes mellitus, albuminuria in, 424; carbohydrate variations of febrile and alcoholic patients, 470; causation of coma in, 560; copaiba in, 58; dietetic treatment of, 159, 998; discussion on, 1053, 1057; double bromide of gold and arsenic in the treatment of, 597; etiology and treatment of, 1035; in a child with an unusual family history, 740; in children, 1099; in vagrants, 818; metabolism in, 769; notes on, 773; of apparently bacterial origin, 329; potatoes as a diet in, 247; preventive treatment of impending coma in, 383; relation of, to epilepsy, 1123; sugar-free milk in, 132; treatment of, 14, 807.
Diaminuria in relation to cystinuria, 71.
Diaphragm, influenzal spasm of the, 243.
Diarrhœa, 155; cinnamon in the treatment of tropical, 332; in children, clinical significance of the stools in, 1053; infantile, salol and petroleum in, 731; strongylus intestinalis in a case of, 830; summer, ambulatory and hospital management of, 819; summer, treatment of, 777; treatment of, in children, 75; tropical, 340.
Diazo reaction, 468.
Dickson, E. D., death of, 744.
Diet as a method of diagnosis, 198; in the treatment of disease, 32; in typhoid fever, 23.
Digestive disturbances in nursing infants, treatment of, 572.
Digestion, process of, after resection of about six feet of the small intestine, 243.
Digitalis, good and bad effects of, 833.
Dionin, 69, 137.
Diphtheria, 158, 881; and membranous croup, non-identity of, 345; antiseptic treatment of, 1060; antitoxin of, 611; antitoxin treatment of, 92, 194, 198, 646, 1093; complications of, 73; continuity of the toxic process in fatal cases of, 243; diagnosis and treatment, 23; essential toxic symptoms of, 68; house epidemic of, 426; immunity against, after the use of antitoxin, 1044; influence of the toxin of, on metabolism, 340; in mother during parturition and in newborn infant, 509; intubation in laryngeal, 277; mechanism of the action of the antitoxin of, 719; mediastinal emphysema in a case of laryngeal, 68; nasopharyngeal, 818; orrhotherapy of, in Cuba, 73; plea for a more extended use of antitoxin for immunizing purposes, 329; relation of membranous inflammation of the nose to, 118; toxic symptoms in, 648; treatment of, 68; varieties of the bacillus of, 843.
Diplegia, infantile cerebral, 192.
Diploma mill, raid on a Chicago, 1014.
Diplopia, monocular, in typhoid fever, 419.
Diseases, spread of dangerous communicable, in children, 1132.
Disinfecting steamer, 546.
Dislocations, after-treatment of, 508; of the shoulder, involuntary reduction of, 26; of the shoulder and hip, an easy method of reducing, 356; of the radio-carpal joint, 114; operative treatment of unreduced and irreducible, 1063.
Dispensary, attack on a, 1014.
Dog malady in England, 370.
Dormiol, 730.
Double Cross, Order of the, 151.
Douche-massage, 175.
Douglas, Charles J., historical notes on the sanitarium treatment of alcoholism, 410.
Douglass, M. E., notice of book by, 1020.
Drink question in Great Britain, 558.
Drop infection in tuberculosis, 1094.
Dropsy, renal, diuretics in, 155; treatment of cardiac, 741.
Drug clerks bill, 684.
Drug plants of the United States, investigation of the, 193.
Drugs, deadly, manufacture of, 704; pharmacological assay of, 1105.
Drunkenness, anti-alcoholic serum in, 289.
Dry Tortugas quarantine station, 724.
Dublin, high death rate in, 297.
Dudley, E. C., notice of book by, 930.
Dudley, Gardner, death of, 218.
Duel between hospital internes in France, 110.
Duncan, Thomas C., notice of book by, 653.
Dunckel, Walter A., some remarks on whooping-cough as seen in dispensary practice, 449.
Duodenum, congenital atresia of the, 302; non-malignant ulcers of the, 485; perforating ulcer of the, 303, 749, 884; round ulcer of the, 494, 522; ulcer of the, treatment of, 563.
Duotal in phthisis, 244.
Dural infusion, clinical and experimental studies of, 333.
Dwarfed growth, peculiar form of, 1035.
Dying declarations, law of, 1129.

Dysentery, 991; amœbic, 642; bacteriology of, 772; pernicious, 1043: in Fiji, 119; permanganate of potassium in, 165; saline treatment of, 332; terminal, 648.

Dysmenorrhœa, 792, 1099; intermenstrual, 726; relationship of, to appendicitis, 855.

Dyspepsia, nervous, 203.

Dysphrenia, 40.

Dystocia caused by Bandl's ring, 425, 471; due to fœtal and pelvic disproportion, prevention of, 970; unlooked for, in multiparæ, 25.

E

Ear, care of, in school children, 1101; escape of cerebro-spinal fluid from the, after injury, 87; extension massage of the ossicles, 156; loss of cerebral fluid from the, 245; maggots in the, 362; normal tympanum germ-free, 484; prevention of intracranial and intravenous complications in suppurative diseases of the, 877; production of local anæsthesia in the, 766; removal of a foreign body from the, 1042; suppuration of the middle, treatment of, 557; suprarenal extract in diseases of the, 483; treatment of eczema of the, 572; uncommon pyogenic infection of the middle, 284.

Earache, significance of, in children, 207.

Eastern Medical Society of the City of New York, officers of the, 19.

Eastman, Charles C., death of, 686.

Echinacea angustifolia, aphrodisiac properties of, 113.

Echinococcus cyst of the nose, 240.

Eclampsia, indications for premature delivery with special reference to, 970; pathogenesis of, 768; puerperal, 74, 246; puerperal, treatment of, by diuretic infusions, 1042; urinary secretion in, 645.

Eclectic Medical Association, 1127.

Ecthyma, contagion of, 426.

Eczema in young children, 293; treatment of, in children, 729; treatment of seborrhœal, 165.

Education, medical, in the United States, 454; overpressure, the bane of modern, 278; the physician as a factor in, 320.

Eggert, William E., death of, 789.

Einhorn, Max, the occurrence of mould in the stomach and its probable significance, 1025.

Elbow, complications following injuries about the, 286; dislocation of the, 599; external dislocation of the, 888; false joint after old fracture and dislocation of the, 388.

Elder, George, death of, 218.

Electricity, burns from, 290; in diseases of the nose, throat, and ear, 240; new applications of the undulating current in gynæcology, 289; static induced current, 294, 396.

Electrification, is static, a specific for organic and structural nervous disorders? 43.

Electrostatic wave current, application of the, 359.

Elephantiasis of both ears, 301.

Ellis, George Viner, death of, 927.

Elmira State Reformatory, report of the, 918.

Elsberg, Charles A., a preliminary note on a simple and new method of repeatedly sterilizing sponges by boiling, 1122; a preliminary report on a new and simple method of sterilizing catgut, 760.

Emaciation, hysterical, 289.

Embolism in the fundus oculi, 114.

Embryotomy with the Karl Braun keyhook, 652.

Emphysema, interstitial, a case of, 73; mediastinal, in a case of laryngeal diphtheria, 68.

Empyema, unusual ending of, 553; valvular drainage tubes in, 157.

Encephalitis, acute non-purulent, 555.

Encephalocele, successful removal of a large, from a child, 81.

Endocarditis, a case of, 973; bacteriology of, 146; caused by micrococcus zymogenes, 72; gonorrhœal, 1044; occurring in the course of tonsillitis, 71; streptococcal, 696; ulcerative, 68.

Endometritis, acute senile, 1068; steam in the treatment of, 506.

Enemata, beef-gall, in the treatment of post-operative and intestinal obstructions, 117.

English, D. E., the treatment of typhoid fever, 1120.

Enteric fever, not typhoid, 588.

Enteritis, dysenteriform, 161; treatment of acute, 75.

Enterocolitis of infants, guarana in, 1092; mucomembranous, 600.

Enteroptosis, notes on recent cases of, 199.

Enuresis, nocturnal, mullein oil in, 258; operative treatment of congenital, 556.

Enzymes and immunity, 792.

Eosinophile cells, relation of Charcot-Leyden crystals to, 1095.

Eosolate of calcium in diabetes and phthisis, 373.

Epidermolysis bullosa, 201, 820; hereditaria, 818.

Epididymis, tuberculosis of the, 218; tuberculosis of the, castration in, 292.

Epididymitis, guaiacol in, 339.

Epigastrium, collapse or death from blows on the, 598.

Epiglottis, tuberculous ulcer at the base of the, 301.

Epilepsy, 240; accidents due to attacks of, 202; amnesia following, 328; curability of, 290; cured by operation, 200; eosinate of sodium in the treatment of, 160; etiology and pathology of, 552; examination of the urine in, 24; Flechsig method of treatment, 719; in malaria, 121; relation of diabetes mellitus to, 1123; relation of migraine to, 71; relation of uric-acid secretion to, 773; santonin in, 378; strontium bromide in, 29; treatment of, 128; treatment of incipient, 1011.

Epileptic status, 367.

Epileptics, care and treatment of, 414; tolerance of the bromides by aged, 205.

Epileptiform convulsions following application of cocaine to the nares, 499; following injury to the head, relieved by operation, 373.

Epiphyses, surgery of the, 461.

Epiploitis following operation, 210.

Episcleritis periodica fugax, 465.

Epistaxis, 66; from the ethmoidal veins, 421; relief of, 75; through the lacrymal duct after plugging of the nose, 286; treatment of, 474.

Epithelioma, arsenical treatment of cutaneous, 513; multiple, developing upon lupus erythematosus, 162; multiple sebaceous, 160.

Eruptions, differentiation between the bullous, vesicular, and pustular, of early life, 639; winter and summer recurrent, 340.

Erysipelas, antistreptococcus serum in, 420; creolin in, 47; diplococci in, 113; treatment of, with bactericidal remedies, 380.

Erythema, premorbilliform, 70; septic maculo-papular, in follicular angina, 763.

Erythrodermie pityriasique en plaques disseminées, 863.

Erythromelalgia, 352.

Ether, bronchial disease not invariably a contraindication to anæsthesia by, 854; death under, 158; inhalant, the Gallant-Allis, 194; narcosis from, 436; practical points in anæsthesia by, 814; spasmodic closure of the larynx during the administration of, 200.

Ethics, code of, in relation to proprietary medicines, 24; medical, breach of, 672.

Ethmoidal cells, anatomy of the, 164.

Ethyl chloride, anæsthesia by, 437.

Eucaine B, local anæsthesia produced by, 199.

Eucalyptus, poisoning by the oil of, 243.

Eustachian catheterization, 923.

Exercise, effect of, upon the heart and blood-vessels in relation to the expectancy of life, 31.

Exophthalmic goitre, 121, 764, 1060, 1129; significance of migraine in, 76; symptoms and operative treatment of bronchocele in relation to, 72.

Expert testimony, 259, 370.

Exposition, medical matters at the Paris, 1096.

Extremities, treatment of crush injuries of the, 507.

Extubation, injuries from, 1102.

Eye, accommodation of the, to misfit glasses, 418; affections of the, in typhoid fever, 335; books injurious to the, 687; congenital lesions of the, in a child born of a woman recently recovered from typhoid fever, 293; diagnosis of some diseases of the, by the general practitioner, 379; differentiation and treatment of affections of the, commonly met with in family practice, 206; ectopia lentis, 156; embolism in the fundus, 114; enucleation of the, 155; gonorrhœa in its relation to diseases of the, 693; gumma of the iris and ciliary body, 646; largin in diseases of the, 554; malignant tumors of the, 32; oculomotor paresis following indirect violence, 470; pin transfixing the, 762; reflexes in relation to recruits, 70; relation of the anterior corpora quadrigemina to movements of the, 159; removal of the cervical sympathetic in certain diseases of the, 1017; retinal complications in chlorosis, 292; significance of hemorrhage within the, as to prognosis of life, 177, 215; splinter of wood in the, 555; symptoms on the part of the, associated with Cheyne-Stokes respiration, 421; value of symptoms relating to the, in the diagnosis of general diseases, 286.

Eyeball, abortive treatment of suppuration of the, 642; eviscero-neurotomy, 329.

Eyelids, electrocautery in affections of the, 373.

Eye-strain, relation of, to epilepsy, insanity, and allied conditions, 1084.

F

Face presentations, management of, 855.

Facial neuralgia, treatment, 165; paralysis, 916; paralysis complicating acute otitis media, 925; spasm, relation of, to errors of refraction, 71.

Falkland Islands, health conditions in the, 964.

Fallopian tubes, bacteriological researches in normal and diseased, 380.

Family diseases, 284.

Famine in India, 22, 192, 325, 895.

Fanoni, Antonio, antipneumonic serum, 431; the treatment of pneumonia, 169.

Fasting cure, 874.

Fatigue, the cure of, 203.

Fatty food in the prevention of tuberculosis, 973.

Fecundity, an instance of, 282.

Feeble-minded, points regarding the, 997.

Feet, deforming action of shoes and stockings on the, 67; tender, treatment of, 384.

Fegley, Orlando, death of, 506.

Femur, depression of the neck of the, in early life, 336.

Fest, Francis T. B., medical practice in Honduras, 194.

Fever, anomalous case of continued, with abscesses of the liver, 421; apyretic, 160; colloid silver in, 207; prolonged, of obscure origin, 1056.

Fever hospitals, cross infection in, 1093.

Fibroma molluscum, 246; case of, 74.

Fielder, Frank S., a criticism upon a new method of preparing the skin for vaccination by denudation with caustic potash, 143, 174.

Filaria sanguinis hominis, 885 ; metamorphosis of, in the body of culex ciliaris, 248.
Filters, failure of, in South Africa, 1072.
Finger, rare injury to the distal phalanx of the, 244.
Finland, venereal disease in, 470.
First-aid packages, 474.
Fish, poisonous, 645.
Fisher, Irwin, death of, 23.
Fistula, appendiceal, 1004 ; colostomy for fecal, 1003 ; fecal, 776, 849, 919 ; uretero-vaginal, 499 ; vesico-urethro-vaginal, 162 ; vesico-vaginal, 289 ; vesico-vaginal, with atresia of the urethra, 205.
Fitzsimmons, T. Dana, death of, 283.
Flat-foot, treatment of, 1107.
Fluhrer, William F., a new plan for washing the bladder, with a description of apparatus, 1076.
Fœticide, so-called therapeutic, 293.
Fœtus, expression of the, by the abdominal method, 202 ; intra-uterine strangulation of the, by the umbilical cord, 73 ; movements of the five-months, 544.
Folie à deux, 687.
Folliculitis, suppurative, of the scalp, 982.
Food, adulteration of, 413 ; influence on the health of chemical preservatives in, 351 ; inspection, sixteen years' experience in, 198.
Foods and drugs, pure, 563 ; legislation for, 455, 501, 593.
Foot, articulations of the, 1108.
Football, prohibition of, 238.
Foreign bodies in the trachea, effect of, 374.
Forestier, H., chronic vertebral rheumatism (rheumatic spondylitis) and its pseudo-neuralgic form, 175, 630.
Forests, wholesale destruction of, 147.
Formaldehyde, disinfection of rooms with, 28, 112, 117.
Forman, Samuel R., death of, 328.
Fortoin, advantages of, 719.
Fowler, George R., diffuse septic peritonitis, with special reference to a new method of treatment, namely, the elevated head and trunk posture to facilitate drainage into the pelvis, with a report of nine consecutive cases of recovery, 617 ; a report of three additional consecutive cases of recovery, 1038.
Fractures, after-treatment of, 508 ; ambulatory treatment of, 762 ; delayed union, thyroid extract in, 1094 ; infected extra-capsular, of the neck of the femur, 114 ; in children, 379 ; influence of the nervous system on the cure of, 513 ; injuries of the nerves due to, 647 ; massage and movement in the treatment of, 65 ; of long bones without deformity, 596 ; of the leg, use of fixation plates in, 692 ; of the neck of the radius, mechanism of, 31 ; open or operative treatment of fresh, 596 ; pathognomonic sign of Colles', 540 ; prognosis in, 1016 ; treatment of compound and ununited, 461 ; *x*-rays in, 202.
Fraenkel, Joseph, diseases of the thoracic division of the sympathetic chain, 1031.
Franklin, Thomas H., death of, 154.
Fridenberg, Percy, a mirror test for simulated blindness, 475.
Friedreich's ataxia, 512, 960 ; fatal case of, 150.
Frisch bacilli in nasal and oral mucous membranes, 747.
Frontal sinus and mastoid, associated disease of the, 808.
Frothingham, George E., death of, 789.
Früh, Carl D. S., a complication of miscarriage with appendicitis, due to traumatism, 638.
Fulner, George, death of, 814.
Furunculosis, treatment of, 1016.

G

Gallant, A. Ernest, the Gallant-Allis ether inhaler, 194.
Gall bladder, abscess of the, 1137 ; waterproof drainage of the, 464
Galloway, C. M., an abdominal varix, 825.
Gall stones, 155, 432 ; cases of, 1021 ; cholecystectomy for, 977 ; crepitus and friction in the diagnosis of, 71 ; diagnosis and treatment of, 993 ; importance of early operations for, 993 ; nervous symptoms of, 1050 ; nuclei of, derived from the intestine, 515 ; pathological and clinical phases of, 733 ; seat of pain in colic form, 728 ; symptoms of, in movable kidney, 113 ; uncommon manifestation of, 720.
Gangrene complicated by glycosuria, 26 ; multiple, in malaria, 467 ; white, *x*-ray injuries causing, 67.
Garcia, Manuel, the inventor of the laryngoscope, 811.
Gas, chronic poisoning by, 641 ; water-, danger of, 322.
Gastrectomy for adenocarcinoma, 179.
Gastric electrode, a modified Einhorn, 526 ; juice, method to determine the digestive power of the, 461 ; neurasthenia, 203.
Gastritis, fatal hemorrhage in chronic, 145 ; thrush fungus as a cause of, 553.
Gastro-enteric hemorrhage in the new-born, 1053 ; tract, endothelial neoplasms of the, 555 ; tract in nervous diseases, 461.
Gastro-enteritis, beer yeast in the treatment of, 30 ; complicating congenital syphilis, 289 ; in infants, 290 ; treatment of infantile, 1132.
Gastro-enterostomy in diseases of the stomach, 242.
Gastroplication, 241, 242.
Gastroptosis, 845.
Gastrostomy by Marwedel's method, 249 ; for cancer, 285 ; technique of, 288.
Gastro-succorrhœa, 242.
Gau, H. F., a new curette, 571.
Gauze, iodoform, and iodol, 75.
Gehring, Henry F., death of, 22.
Gellé and Rinné tests, 925.
Genitals, development of the female, 241 ; sensory capacity of the female, from a forensic point of view, 220.
Genito-urinary diseases, suppression of, by the State, 417.
Genius, home of, in Great Britain, 976.
Gestation, ectopic, see *Pregnancy, extra-uterine* ; protracted, 157.
Gibier, Paul, death of, 1040.
Gibney, Homer, the life of a plaster-of-Paris jacket, 965.
Gibson, C. L., cholecystectomy for gall stone, 977.
Gillespie, A. Lockhart, notice of book by, 520.
Girvin, Robert M., death of, 551.
Glanders, a case of, 1019.
Glandular fever, 1092.
Glass-blower's mouth, 599.
Glatzmayer, William, death of, 460.
Glaucoma following a single instillation of homatropine, 391 ; operative treatment of chronic, 329.
Glossodynia, 163.
Glycosuria, alimentary, 555 ; gangrene complicated by, 26 ; non-diabetic, 728 ; psoriasis associated with, 200 ; significance of glycuronic acid in the phenylhydrazin test for, 159 ; surgical operations during, 692 ; tests for, 161.
Goat vaccine among the Kabyles, 820.
Goitre, congenital, 731 ; etiology and symptomatology of, 119 ; frequency of, at different ages, 922 ; in Montreal, 72 ; syphilitic, 375 ; treatment of, 14, 165, 377.
Goldan, S. Ormond, an unprecedented case of prolonged anæsthesia with nitrous oxide and oxygen, 364.
Gonococci in living leucocytes, staining of, with neutral red, 233 ; rapid staining of the, 819 ; therapeutic uses of, 370.
Gonorrhœa, acute, and its complications, 693 ; chronic, 693 ; dangers of, to society, 155 ; history of, 693 ; in the pregnant woman, 693 ; in women, 646 ; in women, importance of the early recognition and treatment of, 379 ; in women, recent literature on, 71 ; marriage in relation to, 426 ; methylene blue in the treatment of, 498 ; relation of, to the male adnexa, 184 ; serious complications from faulty injections in, 600 ; treatment of, 888, 1091.
Gonorrhœal rheumatism, treatment of, 247 ; vulvo-vaginitis in children, indirect contagion in, 507.
Goodhue, E. S., a case of fracture and medical ethics, 672 ; leprosy in Hawaii, 133 ; leprosy legislation, 652.
Gordon, Frederick T., how to send moist anatomical specimens by mail, 696.
Gorham, John, death of, 252.
Gottheil, W. S., notice of book by, 122 ; suppurative folliculitis of the scalp, 982.
Gould, A. Pearce, notice of book edited by, 735, 1020.
Gould, George M., notice of book by, 653.
Goundon, 248.
Gout, action of various drugs and diets on the excretion of nitrogen in, 689, 743 ; artificial production of, 159 ; balneotherapy in, 374 ; dietetic treatment of, 552 ; electrical treatment of, 484 ; hot-air treatment of, 462 ; metabolism in, 114 ; piperazin in, 68 ; rheumatic, 418 ; terminating in acute myositis, 1091 ; the gelatinous form of sodium biurate in its bearing on the treatment of, 688, 742 ; treatment of chronic, 1091.
Goutte de Lait Society, 1128.
Gouty deposits, treatment of, 641.
Grant, Edward Frank, death of, 726.
Grasset, Dr., notice of book by, 1021.
Grave robbery, an alleged, 21.
Graves, Schuyler Colfax, the relative merits of operations for the extraction of vesical stone in the male ; with observations on the suprapubic and left lateral perineal methods, 357.
Graves' disease, see *Exophthalmic goitre*.
Graves' disease without exophthalmic goitre, 843.
Gray, Landon Carter, obituary of, 814 ; resolutions on death of, 1040, 1088.
Greanellé, W. J., a new gynæcological pad, 658.
Great Britain, medical census of, 371, 787.
Green, DeWitt C., death of, 328.
Green, W. O., a new T-bandage, 232.
Greene, Robert H., notice of book by, 930.
Grigg, W. C., death of, 604.
Grossmann, Fritz, notice of book by, 929.
Gruber, Frank, death of, 22.
Gruber, Josef, death of, 724.
Guaiac, reaction of the leucocytes to, 423.
Guaiacol, a new preparation of, 201.
Guam, sanitary progress in, 153.
Guiraud, Dr., notice of book by, 734.
Guitéras, Ramon, a recto-genital irrigating-tube, 350.
Gumma of the palatine vault, 1132.
Gunning, R. H., death of, 743.
Gunshot wounds, 419, 420 ; by small-calibre weapons, 338, 961 ; in the Santiago campaign, 156 ; of the kidney, 500 ; of the thoracic and abdominal cavities, 333 ; surgical aspects of modern, 162.
Gynæcological pad, a new, 658.
Gynæcology and gynæcologists in Europe, 98 ; aseptic minor, 1065 ; improved technique in operative, 995 ; parturition as a factor in, 1048 ; periods in, 1090 ; prophylaxis in, 208, 240 ; status of, in 1876 and 1900, 924.

H

Habirshaw, John, death of, 726.
Habitation of the poor, 59.
Hæmatemesis, 999 ; gastric ulcer, operative treatment of, 72 ; treatment of, 127.
Hæmatocolpos and hæmatometra resulting from congenital atresia of the vagina, 644.
Hæmatometra, a case of, 291 ; in a rudimentary horn of the uterus, 516.
Hæmaturia due to renal carcinoma, 959 ; malarial, 284.

Hæmochromatosis, etiology of, 65; pathogenesis of general, 43.
Hæmocytometer, clinical value of Oliver's, 330.
Hæmoglobinuria, paroxysmal, 293, 297; pathogenesis of periodic, 1045.
Hæmolysin and antihæmolysin, 244.
Hæmophilia in the negro, 468.
Hæmopneumothorax, 428.
Hæmoptysis, parasitic, 119; terpinol in, 293.
Hahnemann monument in Washington, 416; unveiling of the, 1128.
Hair, anomalies of the, 886; care of the, 212; loss of, 907; management of, during and after fevers, 814; peculiar condition of the, 768.
Hair-ball in the intestine, 687; in the stomach, 703, 726.
Hairy mole, an extensive, 739.
Hallux valgus and hallux varus, 463.
Hamilton, Allan McLane, the work done by the Marine-Hospital corps in Havana, 473.
Hamilton, Edward, death of, 42.
Hamilton, John B., notice of book by, 122.
Hammer toe, 693.
Hammond, William Alexander, death of, 64; resolutions on the death of, 154, 327.
Hamstrings, lengthening of the, for contraction after a burn, 766.
Hanan, James Taylor, disinfection of the umbilicus in abdominal operations, 823.
Hands, rare syphilitic lesion of the, 164; disinfection of the, 69.
Hanging, a study of, 108.
Hardin, Willett L., notice of book by, 929.
Hare, Hobart Amory, notice of book edited by, 736.
Haring, Isaac C., death of, 686.
Harlem Hospital, a new, 371.
Harlem Medical Association, officers of the, 1087.
Hartmann, H., notice of book by, 566.
Hastings, William H., death of, 327.
Hatchette, Frances C., death of, 686.
Havana, board of health in, 325; health of, 195; medical course at the University of, 894; vital statistics of, 415; work of the Marine-Hospital corps in, 473.
Hawaii, health conditions in, 946; leprosy in, 133; medical practice in, 156; neurological observations in, 553.
Hayes, Samuel, death of, 506.
Hay fever, suprarenal extract in, 482.
Hazel, Franklin B., death of, 595.
Hazzard, J. S. R., death of, 959.
Head, bullet wounds of the, 65, 114; nodding and head rotation, 862.
Headache, atropine in the diagnosis of, 688; treatment of neurasthenic, 784.
Health reports of the Marine-Hospital service, 88, 132, 176, 220, 308, 352, 372, 440, 484, 528, 572, 616, 660, 704, 748, 792, 891, 936, 1024, 1072, 1088, 1138.
Hearing in the insane, 29.
Heart, accentuation of the second pulmonary sound, definition and significance of, 151; active dilatation of the, 510; affections of the, following typhoid fever, 202; aneurism of the, 974; aneurism of the, in childhood, 291; antecedents of valvular disease of the, in children, 1101; arrhythmia of the, complicating fibroma uteri, 996; artificial Nauheim baths in the treatment of chronic disease of the, 914; a supporting apparatus in affections of the, 333; cause of pain about the, 484; clinical study of the causes of the first sound of the, 1017; congenital malformation of the, 860; coupling and redoubling of the second sound in mitral stenosis, 720; diagnostic significance of the second pulmonary sound, 730; digitalis in diseases of the, 1044; disease of the, without rheumatism, 161; disease of the, with unusual features, 933; diseases of the, causes of failure in compensation in, 254; diseases of the, in infancy and childhood, 284, 1130; exercises suitable for children with disease of the, 974; forced, 246; hypertrophy of the, in kidney diseases, 518; influence of mechanical irritation of the liver on the, 159; influenzal affections of the, 467; in relation to life insurance, 720; minor forms of dilatation of the, 843; mitral obstruction, 153; mitral regurgitation and pulmonary obstruction, 646; mobility of the, in change of position of the body, 818; multiple lesions of the, 73; murmurs of the, in infancy and childhood, 827; neurosis of the, 241; post-influenzal affections of the, 58; reflex, *x*-ray study of the, 67; relative importance of valvular and muscular lesions of the, 1058; relative intensity of the second sounds at the base of the heart, 45, 77; repose and exercise in diseases of the, 1043; rest in bed in the treatment of affections of the, in children, 73; rheumatic diseases of the, 642, 694, 1057; rupture of the, 26; solitary tubercle of the, 885; spontaneous rupture of the, 728; study of the wall of the, in diphtheria, rheumatic fever, and chorea, 962; suture of the, 245; tonics for the, 1055; treatment of diseases of the, 441; treatment of fatty, 490; treatment of wounds of the, by suture, 72; tricuspid and mitral stenosis with adherent pericardium, 468; valvular disease of the, 240; venous thrombosis as a complication of diseases of the, 843; widely conducted murmurs of the, 1044.
Heat, intense, in the Southern hemisphere, 239, 325; moist, therapeutic employment of, 333.
Hecker, Frederick William, death of, 460.
Hedges, E. W., mumps versus rheumatism, 738.
Heidelberg, woman admitted to the university of, 313.
Heineck, Aimé Paul, notice of book by, 734.
Heisler, John Clement, notice of book by, 929.
Helminthiasis, meningism from, 916; hemiplegia and aphasia in intestinal, 288.
Hemichorea, organic, 516; preparalytic, 163.
Hemiplegia and various associated symptoms, 691; claw-like hand in, 192; infantile, associated with aphasia, 26; infantile, following convulsions, 247.
Hemmeter, John C., notice of book by, 1020.
Hemorrhage, free drinking of water in, 103; gelatin in, 464; in pregnancy, treatment of, 164; post-partum, cured by simple drainage, 924; post-partum, prevention and treatment of, 53; saline infusion in, 362.
Hemorrhoidal nodes in earliest childhood, 600.
Hemorrhoids, application to excoriations on, 564; examination necessary before prescribing for, 65; treatment of, 75, 165.
Henpuye in the Gold Coast Colony, 113.
Hepatism and neuropathy, 988.
Heredity in disease, 1054; influence of, on disease, 599; in psychology, 418.
Herman, J. Edward, a consideration of the failure of antitoxin in operative cases of diphtheritic croup, 92, 194.
Hermaphrodite, 246; spurious, 643.
Hernia abdominalis, 1089; a neglected point in the treatment of strangulated, 1131; Bassini's operation for, 240; cure of inguinal, in men, 1061; diagnosis and treatment of strangulated, 299; diaphragmatic, 848; double inguinal, on the same side, 764; enterectomy for gangrenous, 157; epigastric, 689; in children, operation for, 743; in pregnancy, 198; local anæsthesia in the radical treatment of, 161; mortality after operations for large incarcerated, 162; new method of suture in operations for, 466; of the umbilical cord, 363; omental, 298; perityphlitis in the sac of a, 334; postoperative, 1019; properitoneal, 123; properitoneal and interstitial inguinal, 31; radical cure of, 463; relative bearing of the conjoined tendon and the internal oblique muscles upon the radical cure of hernia, 700; relative frequency of, in the sexes, and the various types in the female, 71; subpubic, 848; treatment of femoral, 378; treatment of, in children, 1060; treatment of inguinal, 259; treatment of sliding, of the cæcum or of the sigmoid flexure, 309, 343; truss management of, 300; umbilical, 198; umbilical, radical cure of a large, 426; ventral, 1061.
Herniotomy, sequelæ to, 521.
Heroin, effect of, on respiration, 115; in phthisis, 244; in respiratory diseases, 24; therapeutics of, 155, 380.
Herpes, neuralgic genital, 246; progenitalis, 961.
Hetol, treatment of tuberculosis with, 1043.
Hicks, Henry, death of, 42.
Hillis, John D., death of, 328.
Hine, Robert H., death of, 64.
Hinshelwood, J., notice of book by, 930.
Hip, amputation of the, 1017; anterior incision in resection of the, 770; dislocations of the, 846; early exploratory operations in tuberculosis of the, 338, easy method of reducing dislocations of the, 356; hysterical disease of the, 923; operation for ununited intracapsular fracture of the, 1109; treatment of congenital dislocations of the, 289, 1071; tuberculosis of the, 654.
Hip-disease, retardation of growth as a cause of shortening after, 1107; treatment of, 474.
Hip-splint, rubber shoe for the, 571.
Hirsch, William, puerperal insanity, 10.
Histology, employment of silver compounds in, 729.
Hockey-stick incision, 390.
Hodgskin, Frank, death of, 239.
Hoffmann, Hans R., death of, 506; resolutions on the death of, 551.
Holidays, public, 1012.
Holland, J. W., notice of book by, 929.
Holmes, Edward Lorenzo, death of, 328.
Holmquist, A. J., the auditory canal as an incubator, 362.
Honduras, medical practice in, 194.
Hood, Thomas B., death of, 506.
Hopkins, Gerald C., death of, 1015.
Hopkins, Woolsey, death of, 327.
Horner, J. S., the appendicitis question, 346, 519.
Horses, electrified oats reveal a possible danger to, 352.
Horwitz, Lloyd Morris, death of, 1128.
Hospital, a new, in Boston, 151; clinical laboratory, 991; for Crippled and Deformed Children in New York State, 1088; fund in London, 128; inspection of public, in New York, 1013; room in each dwelling, 120; Saturday and Sunday collection, 685; service conducted by a single chief, 746; ships in Japan, 17; the modern, and its resident staff, 1133; the woman's, statistics of, 1134.
Hossie, Thomas R., death of, 686.
Hough, John Stockton, death of, 814.
House, William S., death of, 196.
Houses, relative humidity of, in winter, 418.
Howard, Benjamin Douglas, death of, 1128.
Hubbard, Oliver Payson, death of, 460.
Humerus, fracture of the neck of the, 466; inward displacement of the lower epiphysis of the, 422.
Humidity of houses in winter, 418.
Hydatid cyst of the pleura, 335.
Hyde, James Nevins, notice of book by, 735.
Hyde, Samuel, death of, 429.
Hydrencephalocele, 1100.
Hydroa, generalized, in its relations to polymorphous erythema, 695.
Hydrocele, Hüter's operation for, 513; intra-abdominal bilocular, 60; loose for-

eign body in the sac of a, 553; of the cord following an operation for strangulated inguinal hernia, 73.
Hydrocephalus, acquired internal idiopathic, 351; chronic, spinal puncture in, 512; treatment of, by craniectomy, 858.
Hydrogen arsenide, 1097; peroxide as a local anæsthetic, 928; peroxide in the treatment of infected wounds, 962.
Hydronephrosis, 783.
Hydrophobia, a death from, in St. Vincent's Hospital, 686.
Hydropneumothorax, diagnosis, symptoms, and treatment of, 249.
Hydrorrhœa, nasal, 204.
Hydrotherapy in infancy, 160.
Hygiene and State medicine in the United States, 633.
Hymen, imperforate, 80.
Hyoid bone, fracture of the, 33.
Hyperchlorhydria, 967.
Hyperidrosis, facial, of nervous origin, 916.
Hyperkeratosic interdigital eczema, 292.
Hyperthermia, nervous, in women, 690.
Hypnotism, 640; alleged, in the courts, 504; fortune making by, 87.
Hypodermoclysis in shock, 418; in typhoid fever, 362; observations and suggestions concerning, 623.
Hypoglossal nerve, idiopathic partial inflammation of, 69.
Hypothermia, 157.
Hyssop, 158.
Hysterectomy, abdominal, 121; by the clamp method, 304; total abdominal, in suppuration of the adnexa, 202; without preventive hæmostasis, 35.
Hysteria, disorder of respiration in, 116; extreme emaciation in, 289; juvenile, 1089; transient real blindness in, 692; two practically important cases of, 729.
Hysteromyomectomy, supravaginal, 259.

I

Ichthyosis, 247; fœtal, 1053.
Icterus, acute infectious, 207.
Ideas, imperative, in the sane, 779.
Idelson, Valerius, death of, 1041.
Idiocy and imbecility, etiology of, 997; early diagnosis of, 762; infantile amaurotic, 1006.
Idiots, speech and sense perception in, 158.
Ilium, fracture of the anterior superior spine of the, by muscular action, 145.
Imbecility, diagnosis of, in early childhood, 245; Mongolian, in infants, 118.
Immunity, 610.
Impetigo, 426.
Impotence in man, 120.
Incubators, care of premature babies in, 819.
Indicanuria, relation of hydrochloric-acid secretion to, 765.
Indigestion, 1084; puerile, 74; relation of intestinal, to pulmonary disease, 240.
Inebriates, a State hospital for, 369.
Infancy, hydrotherapy in, 160; infrequency of the acute transmissible diseases in, 773.
Infant feeding, 1052; mortality, cause, and prevention of, 468.
Infants, nutrition and diseases of, 888.
Infection, latent, 65; nature's method of protecting the organism against, 512.
Infectious diseases, classification of, 208; eradication of, 924; excretion in the treatment of, 113.
Influenza, acute hemorrhagic poliencephalitis in, 246; attenuated forms of, 513; aural complications of, 377; cardiac affections due to, 467; heart trouble following, 58, 1131; in infancy, cerebrospinal symptoms in, 118; in various places, 108, 168, 196, 217, 251, 282, 296, 326, 350, 392, 428, 429, 634, 685; maniacal excitement during, 509; nephritis of, in children, 859; nervous depression as a sequel of, 462; skin eruption in, 201; treatment of, 197.
Infusion of salt solution, 245.
Infusoria, influence of fluorescent material on, 201.
Inguinal region, neural anatomy of the, 732.
Inhibition, a study of, 197.
Insane, care of the, 454; colony system of caring for the, 338; criminal, 1091; general paralysis of the, 599; hearing in the, 29; treatment of the, 200.
Insanity and crime in women, relation of the sexual function to, 251; changes in circular, 69; incipient, 103; infantile, 688; in the army, 636; malarial, 116, 696; puerperal, 10; relation of, to pelvic and other lesions, 290; the nails in, 1072; Turkish baths in, 462; uterine disease in the causation of, 1049.
Insects as carriers of contagion, 616.
Insolation, pathology of, 1134.
Insomnia, 243, 547.
Instruction, medical, some advances in, 1016.
Insufficiency, cardiac, 246.
Insufflation, intralaryngeal, 1041.
Internal secretions, physiology of, 831.
International Medical Congress, preparations for the, 963.
Intestinal fever, 641; movements, mechanism of the, 889; neuroses, 469; obstruction due to intussusception, 336.
Intestine, acute obstruction of the, 389; anastomosis of, in a case of tuberculous fistula, 462; anastomosis of the, with the Murphy button, 1003; antisepsis of the, in children, 572; a suture of the, 197; cancer of the, 480; cancer of the large, 376, 463; endoenteric suture, 72; excision of the, for malignant disease, 88; extensive resection of the, 159; hypertrophic tuberculosis of the, 1009;. ileocolic invagination of the, 333; multiple spurious diverticula of the, 1009; multiple stenosis of the, of tuberculous origin, 288; obstruction of the, due to persistent Meckel's diverticulum, 421, 778, 1042; obstruction of the, due to gall stones, 962; obstruction of, due to peritoneal bands, 1044; perforation of, by a splinter of bone, 440; perforation of the, ether inflation of the rectum in the diagnosis of, 25; primary resection of gangrenous, 26; repair after resection of the, 1004; resection of six feet of the, digestion after, 243; resection of the, 332, 349; sarcoma of the small, 1011; triple stricture of the, 70; tuberculous stricture of the small, 466.
Intubation, contraindications to, 521; difficulties of, 881; feeding in cases of, 1022; in diphtheria, 923; in private practice, 1102.
Intussusception mistaken for ectopic gestation, 80; mortality and treatment of acute, 339; two cases of, 655.
Iodine, intravenous injections of, 962.
Iodoform, poisoning by, in an infant, 638.
Irido-choroiditis due to intestinal auto-infection, 164.
Iris, operation for the relief of an incarcerated, 321.
Iritis, diagnosis of, 71; treatment of, 374.
Iron, action of, in chlorosis, 720.
Ischæmic paralysis, 591.
Ischio-rectal fossa, incised wound in the, from breaking of a chamber vessel, 362.
Italy, regulation of medical practice in, 550.

J

Jackson, Edward, notice of book by, 824.
Jackson, George Thomas, loss of hair—a clinical study founded on three hundred private cases, 907.
Jackson, H. C., death of, 743.
Jacobi, A., seventieth birthday of, 787, 811, 920.
Janeway, E. G., remarks on some of the conditions simulating appendicitis and peri-appendicular inflammation, 897, 934.
Janiceps, a case of, 291.
Japan, age of medical graduates in, 976; guarding against the plague in, 345; navy medical service of, 19.
Japanese, premature maturity of the, 307.
Jardine, Robert, notice of book by, 928.
Jaundice, exploratory operation in a case of persistent, 816.
Jaw, fracture of the, 361; multilocular cystic epithelial tumor of the, 114; sarcoma of the, 339.
Jesty, Benjamin, a pre-Jennerian vaccinator, 468.
Johnson, F. W., uretero-vaginal fistula, operation, cure, 499.
Johnson, William Crawford, the salicylates in pneumonia, 792.
Jones, Alfred E., death of, 594.
Jones, Charles E., resolutions on the death of, 111.
Jones, Stacy, notice of book by, 381.
Joseph, Max, notice of book by, 520.
Josephson, J. C., a case of iodoform poisoning in an infant two weeks old, 638.
Justus blood test for syphilis, 174.

K

Karschelt, E., notice of book by, 929.
Keeley, Leslie E., author of the "gold-cure" treatment, death of, 372.
Keith, George I., notice of book by, 1020.
Keller, Frank B., death of, 595.
Kemp, Robert Coleman, observations and suggestions concerning hypodermoclysis, 623.
Kendall, H. E., peroxide of hydrogen as a local anæsthetic, 928.
Kennedy, Charles B., death of, 328.
Kennedy, R. A., death of, 328.
Keratitis profunda, treatment of, 720.
Kernig's sign in meningitis, 286, 731.
Kessel, George, congenital hernia of the umbilical cord, 363.
Ketch, Samuel, resolutions on the death of, 283.

Ophthalmic veins, dilatation of the, 640.
Ophthalmology, development of, in the nineteenth century, 287; vasomotor system, and importance of drugs which act upon it, in, 240.
Ophthalmoplegia in tabes and Graves' disease, 296; tabetic, 199.
Ophthalmoscope, a new simple, 527.
Opiates, tolerance of the young child for, 365.
Opium, after-effects of the use of, in infancy, 923; habit, bromide method of treating, 1041; poisoning in an infant, 334.
Optic chiasm, lesions of the, 514; neuritis in children, 889.
Orange (N. J.) Practitioners' Society, organization of the, 459.
Orange peel, biological action of the essence of, 500.
Orbit, traumatic varix of the, 468.
Orchitis, acute, in an infant, 157; guaiacol in, 339; of mumps, 114.
Organotherapy, 831, 1104; scientific establishment of, 27.
Organs, therapeutic problem of regeneration of, 160.
Orleans Parish (La.) Medical Society, officers of the, 19.
Orrhotherapy, discussion on, 610; notes on, 68; the present status of, 1019.
Orthoform, antiseptic properties of, 245.
Orthopedic Hospital, the New York State, 685; surgery, use of *x*-rays in, 67.
Osborne, Joseph Davis, death of, 1015.
Osteo-arthritis, some clinical varieties of, 925.
Osteoclasis for correction of rachitic deformities, 1109.
Osteomalacia, treatment of, 29.
Osteomyelitis, acute, of the femur, 467; multiple, in an infant, 73; of the fibula with spontaneous casting off of the entire bone, 339.
Osteopathy and the law, 347; in Georgia, 191; in Kentucky, 104; in New York, 235.
Osteoplasty, secondary, 298.
Ostitis, typhoid, 74.
Othæmatoma, syphilitic, 863.
Otis, Fessenden Nott, obituary of, 959, 1073; resolutions on the death of, 1134.
Otitis media, electrolytic dilatation of the Eustachian tube in, 646; facial paralysis complicating, 925; importance of the early recognition of, by the general practitioner, 212; in grave diseases of infancy, 155; ossiculectomy in chronic, 510; suppurativa, infectiousness of, 204; treatment of suppurative, in young children, 924; thrombosis of the lateral sinus and jugular vein following acute suppurative, 508.
Otorrhœa, 158; treatment of, 115.
Ovarian hydrorrhœa, intermittent, 511.
Ovaries, avoidance of exsection of the, in connection with removal of diseased tubes, 1069; cysts of the, 164; cyst of the, impeding labor, removed by posterior colpotomy, 818; cyst of the, with twisted pedicle, in a young subject, 1092; cyst of the, with twisted pedicle, mistaken for appendicitis, 305; dermoid cyst of the, in a child of seven years, 1084; degeneration of the blood-vessels of the, 156; fibroma of the, 80; gangrenous dermoid tumor of the, 655; hæmatoma of the, 79; internal secretion of the, 850; multilocular pseudomucinous cystadenoma of the, 198; tumors of the, arising from accessory suprarenals, 120; unusual tumor of the, 554.
Ovariotomy, double, in a girl, 766; for functional nervous diseases occurring during menstruation, 601; in the fifth month of pregnancy, 30; in the Schauta clinic, 291; per anum, 334.
Overstudy, 330.
Overton, Frank, the physician as a factor in education, 320.
Ovulation and menstruation not independent functions, 1099.
Oxycamphor, 515, 555.
Oxyurides, an adult infected with, 27.
Ozæna, etiology and operative radical treatment of, 690; treatment of, 571.
Ozone, water sterilized by, 1023.

P

Paget, Sir James, death of, 167; obituary of, 23.

Paget, Stephen, notice of book by, 928.
Pain, heart, causes of, 484; in the left hypochondrium symptomatic of gas in the colon, 691.
Pain-sense in animals and man, 263.
Palate, motor innervation of the, 916.
Palsy, turners', 423.
Pan-American Medical Congress, 1013; committee on organization of the, 1088.
Pancreas, diseases of the, 1092; history of carcinoma of the, 115; primary carcinoma of the, 1009.
Pancreatic digestion, 988.
Pancreatitis, acute, 511.
Pantaloni, J., notice of book by, 566.
Paraldehyde, association of, with chloroform, 719.
Paralysis, acute ascending, hæmatoporphyrinuria in, 773; agitans, changes in the skin in, 543; autotoxic, 249; bilateral facial, 763; cerebral spastic, 192; epidemic, in children, 862; facial, 916; facial, complicating acute otitis media, 925; family periodic, 837, 1044; general, of the insane, 599; general, of the insane, etiology of, 722; infantile cerebral, 997; infantile pseudobulbar, 244; ischæmic, 591, 960; lead, 200; of the serratus magnus, isolated, 600; periosteal transplantation of tendons in, 767; Pott's, without changes in the cord, 288; transitory spinal, 291, 466; traumatic periodic, 244; unilateral progressive ascending, 692; Volkmann's ischæmic, 156.
Paranoia, clinical notes on a case of, 960.
Paresis and pseudo-paresis, diagnosis of, 338; general, relation of, to tabes, 42, 129; leucocytosis in, 338.
Paris, American nurses in, 789; cleanliness of, 175; letters from, 963, 1096; medical students in, 976.
Park, Roswell, notice of book edited by, 824.
Park, William H., notice of book by, 520, 653.
Parotitis caused by the action of potassium iodide, 288.
Partsch, Herman, seasickness and what to do with it, 986.
Patella, congenital dislocation of the, 1093; fracture of the, 285, 1063; operative treatment of fracture of the, 469; suture of fractured, 286; suture of fractured, through the periosteum, 507; treatment of fracture of the, 67, 474, 635; tuberculous ostitis of the, 762.
Patent medicines, sale of, 1022.
Pathological Society of Philadelphia, 19, 152, 193, 282, 458, 548, 683, 788, 896, 957, 1126.
Pathology, new words and new conceptions in, 159; progress and drift in, 397, 478.
Patriotism, practical, 131.
Payne, William Anderson, surgical odds and ends, 361.
Peck, Aaron Edgerton, death of, 460.
Pectoralis muscle, congenital defect of the, 244.
Pectoriloquy, 87.
Pedersen, Victor Cox, a means of accounting for gauze laparotomy pads, 408.
Peliosis rheumatica caused by traumatism, 1019; in a lymphatic child, 73.
Pelvic asymmetry, demonstration of, 855; hæmatoma following labor, 113; organs, surgery of the female, 74.
Pelvis, fracture of the, with rupture of the urethra, 118; justo-major, as a factor in the causation of perineal injuries, 285; measuring the, in the living woman, 292; relation of deformity of the, to lateral curvature of the spine, 1070.
Pemphigus, epidemic, 112; foliaceus, 695; vegetans, 201.
Penis, cancer of the, 157.
Penrose, Charles B., notice of book by, 823.
Pennsylvania, Associated Health Authorities of, 957.
Pennsylvania Society for the Prevention of Tuberculosis, 683.
Pennsylvania State medical examinations, 416.
Pentose, physiological chemistry of, 470.
Pentosuria, 769.
Peptone, albumose, nutritive value of, 383.
Pericarditis, rheumatic, 151.
Pericardium, adherent, 916; a method of opening the, 510; chronic abscess of the, 1017.
Pericardotomy, 77.
Perigastritis adhæsiva, 158.
Perineorrhaphy, 686.
Perineum, application for rigid, 75, 564; operation for complete laceration of the, 607; rupture of the, in coitus, 29, 435.
Periostitis, rheumatic, 597.
Peritoneum, disposition of the introvesical pouch in cases of distention of the vagina and uterus, 286; escape of urine into the, 380; pathology of the lymphatics of the, 336; pseudomyxoma of the, 120; tuberculosis of the, 161.
Peritonitis, diffuse septic, and the elevated head and trunk posture, 1029; operative treatment of tuberculous, 779; relative value of symptoms of, 1090; treatment of diffuse septic, 617; treatment of exudative, 1113; tuberculous, 1068.
Pertussis, see *Whooping-cough.*
Pessary, use of the, 886.
Pes valgus, treatment of, 767.
Peters, W. H., a piece of chewing-gum in the urethra, 825.
Perityphlitis in a hernial sac, 334.
Phagedæna of the nose, eye, and face in a syphilitic subject, 1092.
Pharmacists in the public services, 1127.
Pharmacopœia, U. S., for 1900, 1105.
Pharyngeal tonsil, death from operation on the, in a subject of hæmophilia, 588.
Pharyngotomy, subhyoid, for malignant growth of the larynx, 374.
Pharynx, comparative anatomy of the, 1035; physiology of the, 277.
Phelps, Elizabeth Stuart, notice of book by, 929.
Philadelphia County Medical Society, 62, 152, 153, 192, 368, 416, 503, 594, 683, 788, 957.
Philadelphia Neurological Society, 20, 192, 457, 593, 723.
Philadelphia Pediatric Society, 18, 152, 368, 504, 683, 894, 1126.
Philippine Association of Acting Assistant Surgeons U. S. A., 1039.
Philippines, a naval encounter in the, 698; commission to study disease in the, 467; contract surgeons wanted for the, 237; health conditions in the, 504, 1090; medical commission to the, 338; smallpox importation from the, 297.
Phimosis, reflex neuroses from, 552.
Phlebitis of advanced phthisis, 877; pulmonary embolus in, 424.
Phocas, Dr., notice of book by, 520.
Phorometer *vs.* Maddox rod, 329.
Phosphaturia, 164.
Phototherapy, 555; instrument for use in, 886.
Phthiriasis pubis, lotion for, 384.
Phthisiotherapy in Europe, 374.
Phthisis, diazo reaction in, 690; formic acid and the inhalation of formalin in, 200; healed, 1093; open-air treatment of, at home, 242; relief of vomiting in, 165; silver-nitrate injections in, 25, 193; some new drugs in the treatment of, 244; surgical treatment of, 24; treatment of cough in, 165; treatment of the night-sweats of, 75; use and abuse of drugs in, 248; see also *Consumption* and *Tuberculosis.*
Physical examination, new method of, 511; training in school and home, 959.
Physicians, gratuitous services expected of, 366; outrages on, 82, 86; proportion of, to the general population in the United States, 1024.
Picric acid, eruptions caused by, 145.
Pierson, William, death of, 1089.
Pilcher, Louis Stephen, degree of LL.D. conferred upon, 1038.
Pillsbury, S. Burke, death of, 1089.
Pistol shots, marks produced by, 1129.
Pituitary body, extract of the, 1105; study of the, 509; uselessness of, as a therapeutic agent, 1122.
Placenta, Dublin method of delivery of the, 1093; fibrinous polypi of the, 425; prævia, air-emboli in, 334; prævia in twin pregnancy, 200, 420, 965; prævia, rupture of the uterus in, 420; retention of the, for nine days, 510.
Placental tumors, 733.
Plague, a menace to the combatants in South Africa, 147; bacillus of, 174, 304; endemic centre of the, 647, 767; epidemic of, at Kolobovka, 29, 376; fleas of rats and mice as conveyers of infection to man, 455; Haffkine's prophylactic serum, 509; in ancient and modern times, 289; incubation period of the, 1018; in the lower animals, 961; in various places, 21, 63, 108, 150, 195, 199, 239, 283, 327, 372, 416, 425, 459, 503, 549, 592, 637, 685, 724, 790, 812, 892, 895, 921, 958, 1015, 1043, 1046, 1125; notes on, 417; pneumonia in, 331, 425; precautions against, 234; preventive inoculation against, 331; propagation of the, 1037; quarantine against, at Suez, 67; visit to the infected districts in India, 241.
Plantaris muscle, rupture of the, 923.
Plaster-of-Paris jacket, life of a, 965.
Pleura, friction sound of the, 330; hydatid cyst of the, 335.
Pleurisy, interlobular purulent, 691.
Pneumathæmia, 333.
Pneumatic cabinet in tuberculosis, 1129.
Pneumatic therapy from 1875 to 1900, 287.
Pneumatocele, 444.
Pneumococcus, toxins of, 251.
Pneumography, clinical, 1019.
Pneumohæmothorax, idiopathic, 596.
Pneumohydrothorax with displacement of the heart, 595.
Pneumonia, 118, 119; antitoxin of, 611; bilobar, with purulent pericarditis, 77; chronic, 923; chronic interstitial, induced by stone dust, 112; contusive, 513; disturbances of the sympathetic system in, 1035; Dover's powder in, 1131; family epidemic of, 505; history of the treatment of, 164; in children, 277; in a young infant, 1132; orrhotherapy of, 169, 991; pathogenesis and prophylaxis of, 248; pathogenesis and treatment of, in the light of the newer pathology, 207; pathology, etiology, and treatment of, 469, 816; plague, 331, 425; relation of, to pulmonary tuberculosis, 337; salicylates in the treatment of, 792; serum treatment of, 348, 431; surgical aspects of, 337; treatment of, 16, 337, 383; treatment of acute lobar, 678; treatment of croupous, 1103.
Pneumothorax, 768, 1109; acute surgical, intralaryngeal insufflation for the relief of, 1017; complicating whooping-cough, 1044; etiology of tuberculous, 115; in healthy persons, 740, 1021; in secondary sarcoma of the lungs, 163.
Poisoning by acetanilid, 552; aconite, 33; belladonna, 554; belladonna, from external application, 68; boric acid, 383; brass, 1043; carbolic acid, 96; carbolic acid, in an infant, 647; carbon monoxide, 641; castor-oil seeds, 332; chloral, 412; cocaine, 600; corrosive sublimate, 157; creolin, 156; cresoline, 863; eucalyptus, 243; iodoform, in an infant, 638; lead, 27; morphine, 27; opium, in an infant, 334; ptomain, 195, 198; salicylate of sodium, 114, 243, 286; snake-venom, 968.
Poisons, general antidote for, 165.
Poliencephalitis, acute hemorrhagic, from influenza, 246; combined superior and inferior, 240; in an adult, 597; superior, 244.
Poliomyelitis, acute anterior, in a youth of seventeen years, 692; acute anterior, of adults, 112; acute anterior, of infectious origin, in an adult, 817.
Polyarthritis chronica villosa and arthritis deformans, 422.
Polyclonia and chorea, 30.
Polydactylism, 65.
Polypus, nasal and postnasal, 157.

Polyuria and pollakuria, hysterical, 557.
Pony, Montana, climatic advantages of, 198.
Poor, housing of the, 59.
Porro's operation, a case of, 733.
Position and presentation, definition and application of the terms, 640.
Potatoes in the diet of diabetics, 247.
Pott's disease, anterior support in, 1070; of the cervical region with brachial paraplegia, 202; or fracture of the vertebræ, 243.
Poultices, use and abuse of, 241.
Practitioner, general, requisites of the modern, 614.
Practitioners' Society of New York, 342, 476, 739, 932.
Pregnancy and labor, anatomy of, 851; extra-uterine, 164, 289, 608, 639, 1129; extra-uterine, chorion epithelium and decidua in, 446; extra-uterine, differential diagnosis of, 768; extra-uterine, following attempted abortion in the early weeks of gestation, 360; extra-uterine, following cervical dilatation for the cure of sterility, 305; extra-uterine, normal pregnancy after operation for, 29; extra-uterine, pain as a symptom of, 727; extra-uterine, treatment of, 291; extra-uterine, vaginal operations in cases of, 733; extra-uterine, with unusual symptoms, 79; interstitial, 250; multiple, 289; pernicious vomiting of, 924; recurrent tubal, 688; simultaneous extra- and intra-uterine, 484, 511; stump, 1017; treatment of hemorrhage in, 164; treatment of tumors complicating, 971; toxæmia of, 970.
Pregnant women, the physician's duty to, before labor, 203.
Prendergast, Inspector-General, death of, 42.
Preservatives in food, influence upon the health of, 351; use and abuse of, 243.
Priestly, Sir William Overend, death of, 686, 791.
Prince, Christopher, death of, 416.
Prior, Israel, death of, 460.
Prize for essay on tropical army ration, award of the, 549; medal, award of the Senn, 1000; medal of the American Medical Association, award of the, 1000; Osiris, 20; Samuel D. Gross, of the Philadelphia Academy of Surgery, 457.
Proben, Charles J., some remarks on the treatment of syphilis, 582.
Professions, relative earnings of the, 786.
Prostate, affections of the, in young men, 588; Bottini's operation for hypertrophy of the, 705, 793, 927; cancer of the, 873; deformities of the, due to loss of tissue, 872; operation for cancer of the, 731; treatment of abscess of the, 121, 378; treatment of gonorrhœal affections of the, 30; treatment of hypertrophy of the, 24, 1062; treatment of tuberculosis of the, 648; vasectomy in hypertrophy of the, 339.
Prostatectomy, 1029; perineal, 560, 598; suprapubic, 117.
Prostatitis, 247.
Prostitution, the question of legal control of, in America, 57.
Prudden, T. Mitchell, progress and drift in pathology, 397, 478.
Pruritus, treatment of, 556.
Psoriasis, glycosuria associated with, 200; oil of cade baths in, 1044; primary lesion of, 340; treatment of, 202, 384, 572.
Psorospermosis, generalized, 691.
Psychic insult, death from, 687; therapeutics, 1105.
Psychology, heredity in, 418.
Ptomain, paralysis caused by, 249; poisoning, 195, 198.
Ptosis, intermittent hysterical, 204.
Public health, effect of summer heat upon, 984, 1007.
Public service against private work, 651.
Puerperal eclampsia, 74, 246; infection, analysis of fifty-seven cases of, 420; infection, antistreptococcus serum in, 420; infection, management of, 213; infection, medical treatment of, 383; insanity, 10; mania with albuminuria, 339; sepsis, 74; sepsis, antistreptococcus serum in, 120, 641; tetanus, 425.
Puerperium, effect of vaginal irrigations during labor on the, 200; nursing during the, 161.
Puerto Rico, medical practice in, 417; relief work in, 150.
Pulmonary artery, thrombosis and fat embolism of the, 883.
Purpura hæmorrhagica, 1100; etiology and pathological anatomy of, 293; visceral affections related to, 515.
Purrington, William H., notice of book by, 653.
Pus organisms, rôle of, in skin diseases, 247.
Pustule, malignant, bacteriological investigation of a case of, 68.
Pyelonephritis, 782, 783.
Pyle, Walter L., notice of book by, 653.
Pylorectomy, 376, 881; technique of, 691.
Pylorus, benign obstruction of the, 844; congenital hypertrophy of the, 176, 600; gastro-enterostomy for cancer of the, 1017.
Pylorus, stenosis of the, 305, 1110; stenosis of the, following corrosion by lye, 465; stenosis of the, in infancy, 731.
Pyosalpinx complicating uterine myoma, 291; removal of, in the early puerperium, 339; retroperitoneal drainage of, 298.
Pyramidon, therapeutic uses of, 117, 244.

Q

Quackery, reason for the success of, 87.
Quadriceps tendon, sphere of the, 766.
Quarantine, national, 785; regulation to insure safe scientific passenger traffic from an infected locality to a non-infected one, 219.
Quénu, E., notice of book by, 566.
Quinine, intramuscular injections of, 249; manufacture of, in Bengal, 87; palatable effervescing, 165.

R

Rabies, diagnosis of, 842; diagnosis of, in the dog, 888; epidemics of, 548, 550; histological diagnosis of, 556; in New York City, 832; inoculations against, in Berlin, 368; post-mortem diagnosis of canine, 820.
Rain baths, 1023.
Railway carriages, disinfection of, in Germany, 132; hygiene, 329.
Ramsay, William R., death of, 922.
Rankin, Egbert Guernsey, notice of book by, 1020.
Ransom, J. B., rain baths, 1023.
Ranula, bilateral intermittent, 201; congenital, 556.
Ration, candy in the army, 616; the tropical army, 593.
Ray fungi, characteristics of the, 959.
Raynaud's disease, a case of, 824; diagnosis of, 988; symptoms of, in a case of acromegaly, 69.
Reciprocity in medical licensing, 235, 1127.
Rectal prolapse, treatment of, 925.
Recto-genital irrigating tube, 350.
Rector, Joseph M., an interesting case of labor complicated by utero-abdominal fixation, 411.
Recto-vaginal hæmatoma, 27.
Recruits incapacitated by a physician, 591.
Rectum, absorption and metabolism in feeding by the, 602; acquired non-malignant stricture of the, 47, 81; adenoma of the, 7; backache as a symptom of disease of the, 766; deformity of the, 243; etiology of non-malignant stricture of the, in women, 240; feeding by the, in children, 157; imperforate, treatment of, 286; practical notes on disease of the, 23; prolapse of the, in children, 467; resection of the, 699, 962; treatment of ulcerative stricture of the, 424.
Red Cross, masquerading under the insignia of the, 725; work of the, in the Philippines, 282.
Reeves, Josiah, death of, 64.
Reflexes, clinical study of the, 780; deep, of the lower extremities, diagnostic value of, 639; superficial and deep, 642; toe, 888, 1112.
Refraction, relation of facial spasm to errors of, 71; the past and present of, 716.
Relapsing fever, a case of, 112.
Remington, Joseph P., notice of book by, 565.
Resonance, cracked-pot, 121.
Respiratory reflex, 159; and lingual tractions, 335.
Retina, concussion of the, 157; glioma of the, 465; recurrent, hemorrhage of, 342.
Retropharyngeal abscess of auricular origin, 204.
Rhachischisis, 861.
Rheumatic and neuropathic states, 767; gout, 418.
Rheumatism, 1057; acute inflammatory, 204, 328; balneotherapy in chronic, 374; cerebral, 113; chronic articular in childhood, 470; chronic vertebral, 175, 630; dietetic treatment of, 552; discussion on, 603, 605; electricity in chronic, 674; hot-air treatment of, 462; muscular, 529; treatment of, 554, 585, 605, 643; treatment of gonorrhœal, 247.
Rheumatoid arthritis, excretion of nitrogen in, 889; gout and rheumatism, the distinguishing features of, 925; pathology and treatment, 925.
Rhinitis, acute, 544; atrophic, 782; recurring membranous, due to Friedländer's bacillus, 782; treatment of hypertrophic, 380.
Rhinoplasty, Israel's method of, 513.
Rhinoscleroma, 866.
Ribard, Elisée, notice of book by, 520.
Richards, Ellen H., notice of book by, 566.
Rickabaugh, Jacob, death of, 826.
Rickets, 468, 960; changes caused by, in the growth of the epiphyseal cartilages, 1045; enlarged liver in, 162; three symptoms of, 1132.
Riding-pain in the patella, 512.
Ringworm of the scalp, treatment of, 1093.
Rinné and Gellé tests, 925.
Robinson, A. R., observations on the treatment of cancer, 535.
Robinson, Byron, notice of book by, 735.
Robinson, William F., death of, 726.
Roche, Thomas Francis, death of, 686.
Rockwell, A. D., the static induced current, 130, 396.
Rodent ulcer, formalin in, 243.
Rodgers, Lyman, death of, 154.
Rodman, William W., death of, 595.
Roentgen ray, avoidance of the harmful effects of the, 521; burns from, 508, 647; diagnosis of urethral and renal calculi by the, 336; depilation by, 243; error in examination by, 65, 1061; in pregnancy, 704; in the treatment of sarcoma, 112; limitations and value of examinations by the, 65; medical employment of, 67; severe injury from the, 180; surgical cases illustrated by, 554; treatment of lupus by the, 887, usefulness of, 601; value of, in diseases of the chest, 198; value of, in fractures, 202.
Roentgen Society, foundation of a, 956.
Roentgen, Wilhelm Conrad, award of Barnard medal to, 922.
Rogers, Philip F., a remarkable case of chloral poisoning, 412; osteopathy and the law, 347.
Rome, Anglo-American nursing home in, 456.
Rose, A., the nomenclature of appendicitis, 130.
Rötheln, 1053.
Royal College of Surgeons, centennial of the, 166.
Rumination, 552, 1045.
Russia, corporal punishment in, 375; limiting the output of physicians in, 369.

S

Sachs, B., two cases of tumor pressing upon the cauda equina, removal, recovery, 7, 40.
Sadtler, Samuel P., notice of book by, 565.
Sailors, sanatoria for, 279.
de Saint Blaise, G. Bouffe, notice of book by, 520.
St. John's Guild, gift to the, 895.
St. John's Long Island City Hospital, opening of the, 64.
St. Luke's Hospital, changes at, 550; new superintendent of, 896.
St. Vincent's Hospital, association of the alumni of, 1087; case of Ward against the, 1013.
Salicylic acid, endermic application of, 127.
Salicylate of sodium, poisoning by, 114, 243, 286.
Saliva, influence of, on gastric digestion, 332.
Salivary calculus, 417, 465.
Salivation, reflex, from abdominal disorders, 694.
Salophen, therapeutic value of, 244.
Salpingitis, 1068.
Sanatozon, 555.
Sanatoria for consumptives in New York State, 194; for sailors, 279.
Sanatorium treatment of tuberculosis, 1094.
Sane, imperative ideas in the, 779.
Sangue, Ernest Brewster, death of, 372.
Sanitation, sensational, 659.
Sarcoma, mixed toxins in the treatment of, 613; of the colon, 1064; of the sphenoidal sinus, removed without return after $3\frac{3}{4}$ years, 699; of the stomach in a child $3\frac{1}{2}$ years old, 131; of the tibia, 523; recurrent spindle-cell, successfully treated with the mixed toxins, 125; spontaneous disappearance of a, 694; treatment of, by cataphoric sterilization, 587; *x*-ray treatment of, 112.
Sarcomatosis, extra-visceral, 645.
Satterthwaite, Thomas E., non-malignant gastric and duodenal ulcers, with illustrative cases, 485.
Savill, Thomas D., notice of book by, 382.
Scalp, suppurative folliculitis of the, 982; unusual form of tumor of the, 866.
Scaphoid bone, fracture of the, 887.
Scapula, removal of the shoulder girdle for sarcoma of the, 245.
Scarlet fever, 656; experiments in, 960, 1129; lymphatic glands in, 74; micro-organism in, 373; rash of, 1053; treatment of, 127; without eruption, 114.
Scarlett-Dixon, Mary J., death of, 239.
Scattergood, Dr., death of, 559.
Schenk, S. L., deposed from the chair of embryology at Vienna, 63.
Schminkey, I. F., death of, 373.
School, breakdowns in, 1100; hygiene of the, 241; alleged dereliction of the health board in relation to the, 787; medical inspection of, 61, 158, 284; psychiatry in the, 334; visual defects acquired in, 155.
School children, measurements of, 861.
Schott, Th., on the treatment of fatty heart, 490.
Schröder, Ernest, death of, 111.
Schuylkill County (Pa.) Medical Society, officers of the, 61.
Sciatica, 163, mechanical treatment of, 202, 601; treatment of, 763.
Sciatic nerve, tensile strength of the, 241.
Science, an international association for the advancement of, 546.
Scientific investigation, position of the universities in regard to, 66.
Sclerosis, lateral, 1122; multiple, 858; multiple cerebrospinal, 338; multiple, with symptoms of progressive muscular atrophy, 39.
Scoliosis, 1069; in an infant, 558; nervous affections related to, 527.
Scorbutus, 1100, 1110.
Scurvy, cause of, 926; experimental inquiry into, 817; infantile, 73, 112; land, 245.
Scurvy-rickets in a boy, 26.
Sea air and sea baths, therapeutic uses of, 992; biliousness induced by, 204.
Seasickness, death from, 140; treatment of, 986, 1097; kola in, 348.
Seminal vesicles, treatment of gonorrhœal affections of the, 30.
Senile bronchitis, 768.
Senility, Metchnikoff's serum against, 148, 161.
Sepsis, puerperal, 74.
Septicæmia, puerperal, antistreptococcus serum in, 1043.
Serous membranes, inflammation of, 465.
Serpents, poisonous, of North America, 204.
Serum treatment, discussion of, 610; notes on, 68; of pneumonia, 348.
Sex, determination of, 374.
Sexual function, correlation of, with insanity and crime, 330, 733; relation of the, to insanity and crime in women, 251.
Shakespeare, Edwin O., death of, 1015.
Shaw, Henry L. K., the tonometer, a new instrument to determine the amount of blood pressure, 181.
Shaw, John Cargill, death of, 155; resolutions on the death of, 551.
Sherwell, S., the use of arsenic, etc., in cancerous and other malignant neoplasms, 744.
Shock, hypodermoclysis in, 418; surgical significance of, 507.
Shoulder, congenital dislocation of the, 331, 1108; easy method of reducing dislocations of the, 356.
Shultz, R. C., a peanut in the air passages, 360.
Shuttleworth, G. E., notice of book by, 824.
Sickness, cost of, 220.
Siegfried, Charles A., death of, 111.
Sigmoid flexure, gangrenous perforation of the, 298; treatment of sliding hernia of the, 309, 343.
Sigmoidoscope, pneumatic, 156.
Silver catgut, 373; wire as suture material, 681.
Singers' nodes, sequelæ of, 69.
Sinus, frontal, empyema of the, 639; frontal, ethmoidal, and sphenoidal, abscess of the, 155; frontal, growth in the, 1064; frontal, suppuration of the, 245; of the head, negative politzerization of the, 203.
Shell, injuries produced by a six-pounder Hotchkiss, 114.
Skiameter, 67.
Skin, absorption through the unbroken, 1054; cancer of the, 864; certain diseases of the, with unusual features, 599; changes in the, in paralysis agitans, 543; diseases of the, accompanying diabetes, 1059; diseases of the, catalectrolysis in, 112; endothelioma of the, 819; eruption on the, in infectious diseases of the digestive tract, 925; influenzal eruption on the, 201; leukæmic lesions of the, 72; parasitic diseases of the, necessity of limiting the spread of, 864; permeability of the, in warm-blooded animals, 484; resistance of the red corpuscles in some diseases of the, 376; rôle of pus organisms in diseases of the, 247.
Skin-flaps, transplantation of, without pedicle, 28.
Skin grafting, suit to recover damages for, 325.
Skull, compound depressed fracture of the, 27; punctured wound of the, 598; tuberculosis of the flat bones of the, 73.
Sleep, the bromide, 200.
Sleeping-apartments, hygiene of children's, 647.
Sleeplessness, 547.
Sloane Maternity Hospital, Society of the Alumni of, 813.
Smallpox and chickenpox, 18, 150; bichloride baths in, 764; diagnosis of, 721; during pregnancy, 598; facts observed in an outbreak of, at Essex, 280; injection of gelatinized serum in hemorrhagic, 70; in various places, 237, 238, 282, 297, 326, 415, 548, 788, 811, 957, 1088; pseudo- or modified, 1002; salol in the treatment of, 114, 391, 1035, 1042.
Smegma bacillus, 764.
Smith, Andrew H., serotherapy in pneumonia, 348.
Smith, Charles Carroll, death of, 283.
Smith, Edwin M., death of, 595.
Smith, Stephen, form of legislation which will enable cities, towns, and villages in the State of New York to establish hospitals for the treatment of tuberculosis, 252.
Smith, Wickliff, death of, 22.
Smith, William L., death of, 480.
Smoking among the young, 821.
Snake-bite, antivenene in, 26; treatment of, 1075; yellow vision after, 836.
Snake poisoning, chemistry, toxicology, and therapy of, 204.
Snake-venom, 968; nature and action of, 332.
Snow, William Benham, the application of the electrostatic wave current, 359.
Society for the Prevention of Cruelty to Children, legal status of the, 237.
Sociological status of the physician, 826.
Somberger, S. J., transposition of vital organs, 738.
South Africa, diseases of, 599; war in, see *Boer war*.
Spasmus nutans, 240.
Species, improvement of the, 284.
Specimens, moist anatomical, mailing of, 696.
Spermatozoa, a specific immunizing serum against, 333.
Sperminum, 384.
Sphenoid, fatal suppuration of the, 557.
Sphygmograph, clinical uses of the, 34, 313.
Sphygmomanometer, tests of the, 769.
Spinal cord, bullet wound of the, 780; concussion of the, 164; lesions of the lower end of the, 1060; pathology of the lower part of the, 249; syphilis of the, 153; traumatic hemorrhages into the, 573; tumor of the, 858.
Spinal curvature, forcible correction of, 1105.
Spinal perimeningitis, 1044.
Spinal roots, section of the posterior, 857.
Spine, congenital lateral curvature of the, 162; distortion of the, 639; fracture-dislocation of the, 887; fracture of the, 26, 353; movements of the normal, 1069; progressive ankylotic rigidity of the, 336; rheumatism of the, 175; sclerosis of the, 117; surgery of the, 651; scorbutic, 1106; tuberculosis of the, 1106; typhoid, 596.
Spitting nuisance in Brooklyn, 685; regulations to abate the, 893.
Spleen, double, 302; excision of the, 243; hypertrophy of the, difficult of explanation, 932; shape and relations of the, 259.
Splenectomy, 24, 1090, 1094.
Splenic anæmia complicated by diabetes mellitus, 24; extract and the splenic function, 273; pseudoleukæmia, 764.
Splints, expanded metal for, 543.
Spondylitis deformans, 161; rheumatic, 630; rhizomelic, 192, 424, 640.
Sponges, sterilizing, by boiling, 1122.
Sporothrix, a new pathogenic fungus, 829.
Sprains, 988.
Sprue, treatment of, 339.
Squire, C. L., the Morton-Rockwell discussion, 562.
Stacke's operation, eighty consecutive cases of, 332.
Staining-forceps, a new, 198.
Staphylitis, 197.
Stark, Dr., death of, 42.
Static induced current, 130, 562, 746.
Status epilepticus, 367.
Stave of thumb, 887.
Steam, gynæcological application of, 425; hæmostatic action of, 474; sterilizing properties of unconfined superheated, 286.
Stercoræmia following delivery, 116.
Sterilization of the hands, 1092.
Stevens, A. A., notice of book by, 735.

Stewart, Sir Thomas Grainger, death of, 236, 392.
Stickler Memorial Library, 326, 895,
Stimson, Lewis A., an easy method of reducing dislocations of the shoulder and hip, 356.
Stoeckel, Gustav Mozart, death of, 327.
Stomach, absorption and fat-splitting in the, 423; acute dilatation of the, 242; auto insufflation of the, 242; cancer of the, 479, 774; cancer of the, increased hydrochloric acid in, 206; cancer of the, in the young, 728; cancer of the, invasion of the lymphatic system in, 335; cancer of the, involvement of the anterior abdominal wall in, 28; cancer of the, lymphatic involvement in, 928; cancer of the, study of the blood in, 924; case simulating perforating ulcer of the, 836; circumscribed cancer of the, 464; condition of the, in early tuberculosis, 876; congenital hypertrophy of the pylorus, 176; diagnostic significance of the digestion of carbohydrates in hyperacidity, 1018; dilatation of the, 336, 845; early diagnosis of cancer of the, 242, 889; electrization of the, 242; excretion of pepsin in disease of the, 291; exploratory operation for dilatation of the, 420; extirpation of the, 241, 242; fatal parenchymatous hemorrhage of the, 1019; gastrectomy for adenocarcinoma, 179; gastrectomy for cancer, 467; gastro-jejunostomy for ulcer of the, 509; hour-glass, gastro-duodenostomy for, 375; indications for surgical interference on the, 242; intermitting hypersecretion in the, 553; latent cancer of the, 241; lavage of, preceding gastro-enterostomy, 600; method to determine the absorptive power of the, 461; motivity of the, 242; mould in the, 1025; neurosal conditions involving excessive secretion of the gastric juice, 71; nitrate of silver in hyperchlorhydria, 66; non-malignant ulcers of the, 485; operative treatment of dilatation of the, 246; pathological anatomy of cancer of the, 770; perforating ulcer of the, 68, 112, 199, 509; perforation of the, by a toothpick, 1010; perigastritis adhæsiva, 158; physical examination of the, 24; removal of a hairpin from the, 26; resection of the, 645; sarcoma of the, in a child three and one-half years old, 131; secretion of hydrochloric acid in the, with various food-stuffs, 163; surgery of the, 213, 510, 553, 598, 821, 844, 846, 992; surgery of ulcer of the, 693; surgical aspects of dilatation of the, 285; surgical treatment of cancer of the, 333; symptoms in disorders of the, 924; syphilis of the, 241, 1111; treatment of hemorrhage from the, 999; treatment of perforating ulcer of the, 129; treatment of ulcer of the, 514; ulcer of the, 241, 242, 379, 774; ulcer of the, case simulating, 766; ulcer of the, in pregnancy, 598; vertical, 242.
Stomach-tube, observations with the, in infants, 292; uses of the, 467.
Stomatitis and pseudomembranous angina in pneumonia, 121; gangrenous, antistreptococcus serum in, 330; treatment of mercurial, 165.
Stonham, Charles, notice of book by, 735.
Stools of nurslings, bacilli in the, 334; washing dysenteric, 694.
Storrs, Melanchthon, death of, 1040.
Strabismus, non-operative treatment of, 206.
Streptococcus, a peculiar, 842, 1011; serum, 612.
Streptomycosis, orrhotherapy of, 695.
Stricture, urethral, 379; urethral, massage for, 564; urethral, the urethroscope in, 117.
Strong, Albert B., death of, 506.
Stuart, William Henry, death of, 686.
Stuttering, principles of treatment of, 378.
Subclavian artery, ligature of the, for aneurism, 688; vein, ligation of the, for an arterio-venous fistula, 699.
Subphrenic abscess, 221.
Sugar, fermentation of slowly fermenting, 163; formation of, from albumin, 28; influence of, on metabolism in pregnancy, 120.
Sulphonal, large dose of, 200.
Summer, care of children during the, 1123; heat, effect of, upon the public health, 984, 1007.
Summers, John E., Jr., notice of book by, 734.
Sunstroke, pathology of, 1134.
Superfœtation, a case of, 212.
Suprapubic fistula following lithotomy in a prostatic subject, cured by Bottini's operation, 699.
Suprarenal body, hæmatoma of the right, 1008; extract, 1105; extract, hemorrhage following the use of, 868; extract, physiological properties of, 481; gland substance in asthma, 886; gland substance in hay fever, 886.
Surgeons, acting assistant army, complaints of, 456.
Surgery, relation of the clinical laboratory to, 212; review of, for the past century, 615.
Surgical operations, details in the care of patients during, 1041.
Suter, William Norwood, notice of book by, 520.
Suture, silver wire as a material for, 681.
Swimming, hygienic effects of, 163.
Sympathectomy in glaucoma and optic-nerve atrophy, 1017.
Sympathetic, diseases of the thoracic, 1031; ganglion, surgery of the superior cervical, 374.
Symphysectomy, a successful, 374.
Symphysis pubis, rupture of the, 115.
Synovitis, treatment of acute serous, permitting of joint motion, 198.
Syphilis, 966; acquired, in a child, 114; congenital, the offspring of the subjects of, 103; curability of, 695; from dental instruments, 197; hypodermic injection in, 157, 165, 572; in early life, 117; inhalation treatment of, 200; inoculation wound of, 445; interesting case of, 765; Justus blood test for, 174, 641; of the brain and spinal cord, 28; of the heart and liver, 26; of the nervous system, use and abuse of mercury and iodine in, 37; of the spinal cord, 153; othæmatoma due to, 863; peculiar features in cases of, 729; prophylactic treatment of, 29; relation of, to life insurance, 205; treatment of, 75, 582; wheal type of lesions of, 866.
Syphiloderma, hemorrhagic, 720.
Syria, letter from, 393.
Syringomyelia, hereditary, 516; trauma of the cervical region of the spinal cord simulating, 336.

T

Tabb, Sherrard R., death of, 922.
Tabes dorsalis, 541, 1092; and general paresis, 129; a rare complication of, 544; eye symptoms in, 509; instruction in co-ordination in, 506; organotherapy in, 961; ophthalmoplegia in, 199; recovery of a supposed case of, 285; relation of, to general paralysis, 42; sensory crises in, 769; spinal stretching in, 112; Thomsen's disease with, 117; with bulbar symptoms, 509.
Tænia and chorea, 343; black, 645.
Talmey, B. S., chorion epithelium and decidua in tubal gestation, 446.
Tannopin as an intestinal astringent, 730.
Taxation of medical practitioners in Turkey, 724.
Taylor, David N., death of, 594.
Teeth, anomalies of the, 976.
Telephone, partial paralysis of the vocal cords from over-use of the, 869.
Temperance congress in London, 1039.
Temperature in psychopathic states, diagnostic importance of the, 340; the border line of normal, 163.
Temporal bone, suppurative disease of the, 925.
Temporo-maxillary ankylosis, 118.
Tendon transplantation, 1071.
Tenement House Commission, 683.
Tenements and tuberculosis, 886.
Tenosynovitis, cause of suppurative, 564.
Testicle, cystic tumors of the, 943; round-celled sarcoma of the, 388.
Tetanus, 888; antitoxin treatment of, 467, 515; carbolic acid in equine, 422; cortical changes in, 297; cure of, by antitoxin, 510; epidemic of, following July 4, 1899, 1089; following nephropexy, 199; infection of, through the mouth, 363; nature and treatment of, 835; orrhotherapy of, 25, 192, 287, 769, 1064; orrhotherapy of, in the French army, 725; prognosis of, 264; puerperal, 425; recovery from traumatic, 240; treatment of, 162; valuation of the antitoxin of, 245.
Tetany, gastric, 152.
Teubner, Charles, methyl blue and methylene blue, 927.
Therapeutics, teaching of, 207.
Thermometer as a germ carrier, 586.
Thermometer fever, 281.
Thigh, rapid union in a case of fracture of the, 825.
Thirst, pathological, 769.
Thomas T. Gaillard, a memorial address upon Dr. Fessenden Nott Otis, 1073.
Thorne, Sir Richard, death of, 129.
Thomsen's disease with tabes dorsalis, 117.
Thomson, W. H., some points in the therapeutics of heart disease. 441.
Thoracopagus, 420.
Thorington, James, notice of book by, 823.
Thrush, treatment of creamy, 384.
Thymus extract, 1104; gland, functions of the, 116.
Thyroid extract, action of, 423; gland, cancer of the, 297; gland, functions of the, 1132; gland, lesions of the, in tuberculosis, 769; gland, relations of the, to the uterus, 58; poison, effect and after effect of the, 720; therapy, 375.
Thyroglossal duct, persistent, 31.
Thyroidin, toxic psychoses due to, 31.
Tibia, sarcoma of the, 523.
Tic douloureux, hereditary, cured by electricity, 556; operation on the fifth nerve for, 814; treatment of, 815.
Ticks, fevers caused by, 767.
Tinea tonsurans in Assam, 68.
Tinnitus aurium, 377; relief of, 86; treatment of, 30.
Tobacco amblyopia, 373; carbonic oxide in the smoke of, 162; congress against the use of, 18.
Todd, G. R. C., death of, 789.
Tongue, hemiatrophy of the, 422; hypertrophied, 556; papilloma of the, 340; removal of half of the, 699; tractions on the, 335; traction on the, in asphyxia of bulbar origin, 890.
Tonometer, a new instrument to determine the amount of blood pressure, 181.
Tonsil, hemorrhage from an abscess by the, 870; hemorrhage following removal of the, 418; infection through the, 1093; papillomatous growth on the, 378; spirillum occurring in false membrane on the, 460; syphilis of the lingual, 512; tuberculous infection through the, 1131.
Tonsillitis, endocarditis occurring in the course of, 71.
Toothache, mountain, 636; treatment of, 14, 128.
Toxins and antitoxins, 1093; from a chemical and pathological standpoint, 595.
Trachea, perforation of tuberculous bronchial lymph nodes into the, 654; sudden death from perforation of the, 859.
Trachoma, 923; immunity of the negro from, 329.
Transfusion of complete blood, a few experiments in, 687.
Transposition of vital organs, 738.

Traumatisms inflicted by animals, 692; treatment of minor, 461.

Tremor, hysterical, in an old man, 192.

Trichinosis, a case of, 885; a family outbreak of, 71; diagnosis of, suggested by examination of the blood, 478.

Trichobezoar, see *Hair-ball.*

Trichorrhexis nodosa, 1092.

Trional, administration of, 572.

Trochanter, tuberculous disease of the, 463.

Tropical diseases, study of, in the Philippines, 238.

Tropics, the soldier in the, 641.

Trudeau, E. L., sanatoria for consumptives, 792.

Truneček, C., radical cure of epithelial cancer by arsenic, 937.

Tubal sacs, peripheral, 291.

Tubercle bacilli and other bacteria in the sputa, diagnostic and therapeutic significance of, 690; germs and giant cells in human tissue, 23; growth of, on Hesse's medium, 387; in milk, butter, and margarine, 199.

Tubercle, solitary, of the heart, 377.

Tuberculin, diagnostic value of, 211, 1129; in the early diagnosis of tuberculosis, 645; test in cattle, 195; therapeutic and diagnostic value of old, 204.

Tuberculosis, 41; action of morphine upon the development and course of, 30; acute pneumonic form of, 768; a Japanese serum for the treatment of, 325; among the poor, 546; arsenic and iron in the chloro-anæmias of, 570; articular and osseous, pure carbolic acid in the treatment of, 1069; artificial immunity against, 895; bovine, 211; bovine, bill regarding, in the New York legislature, 237; bovine, communicability of, to man, 197; cacodylic acid in, 466; caseous infection in pulmonary, 163; chronic hyperplastic, of the cæcum, 1044; cinnamate of sodium in pulmonary, 202; complicating pregnancy, 305; congress in Naples, an incident of the, 1039; contagion of, 161; dampness of the soil in relation to, 828, 1081; diagnosis and therapy of pulmonary, 817; diagnosis of incipient, 423, 1138; diagnosis of pulmonary, in young children, 691; diazo reaction in, 1012; discussion on, 1058; drug treatment of, 1055; early diagnosis of pulmonary, 511, 815; early sign of, 764; educational and legislative control of, 828; French institute for the study of, 456; general miliary, 301; hereditary transmission of, 762; hetol in, 1043; hydriatic treatment of, 973; infectiousness of, 210; infectiousness of, officially proclaimed, 1039; international congress on, in Naples, 788; intestinal, 1009; intestinal, in a child, 387; in workingmen, 161; isolation in, 691; laboratory methods of diagnosis, 71; limitation of the prevalence and fatality of, 551; more rapid spread of, among cattle than in the human race, 732; night-air of New England in the treatment of, 453; intra-pleural injections of nitrogen gas in the treatment of pulmonary, 876; notification and state supervision of, 886; of serous membranes, 334; of the astragalus, 1071; of the female genital tract in children, 819; of the hip, early exploratory operations in, 338; of the kidney, without distinctive symptoms, 156; of the knee, treatment of, 1063; of the lymph glands, 288; of the male genitals, surgical treatment of, 202; of the mesenteric glands, 848; of the nasal duct, 115; of the nervous system, 601; of the urinary apparatus, 727; oil of camphor in pulmonary, 512; orrhotherapy of, 148, 771; pathology of miliary, 287; peritoneal, 161, 1068; postage stamps as carriers of, 70; prevention of, 470, 552; prognosis of, 210; prophylaxis of, in children, 203; prophylaxis of pulmonary, 514; public sanatoria for, legislation for the establishment of, 252; pulmonary, creosote in, 248; pulmonary, hospital treatment of, 893; pulmonary, sanatorium treatment of, 773; pulmonary, tracheal injections in the treatment of, 869; relation of pneumonia to pulmonary, 337; renal, 510; respiratory gymnastics in, 116; restriction of, 152; sanatorium for, in Sicily, 459; sanatorium treatment of, 152, 208; sanatorium treatment of, at home, 138; sanatorium treatment of incipient, 1017; sea-service in the management of, 768; serum diagnosis of, 729; significance of bovine, 322; specific treatment of, 115; study of four hundred cases of, 32; struggle against, 924; subsequent histories of patients apparently cured by anti-tubercle serum, 876; surgical, 156; surgical, treatment of, 25; the Alleghanies for sufferers from, 1084; thyroid extract in, 27; thyroid gland, lesions in, 769; treatment of, 247, 601; treatment of pulmonary, at the Charité, 645; treatment of surgical, 67; two therapeutic indications in, 418; various papers on, 1094; vertebral, 1106.

Tubo-ovarian adhesions, reflexes of, 1050.

Turbinated bone, treatment of hypertrophy of the inferior, 374.

Tumbe fly, 248.

Tumors, a study of, 350; classification of, 247; etiology of, 988; parasitism of, 424; syphilitic treatment of, 1111.

Turkey, medical schools in, 743.

Turners' palsy, 423.

Turner, Charlewood, death of, 392.

Tuttle, George M., notice of book by, 381.

Twin pregnancy with placenta prævia, 420.

Tympanites, hysterical neurasthenia, 556.

Tympanum, rupture of the, following a blow on the ear, 70.

Typhoid bacillus, 598, 889; and fever, 728; and typhoid fever, 642; cystitis due to, 405; duration of life of, in ice, 1010; in the blood, 246; in the gall bladder, 343.

Typhoid fever, 193, 418, 419; abortion caused by, 145; acute nephritis in, 243; Addison's disease following, 1091; among American soldiers, 1000; and appendicitis, differential diagnosis between, 1100; an epidemic of water-borne, 109; antitoxic serum of, 611; appendicular symptoms complicating, 844; bathing for, in childhood, 925; cardiac complications during convalescence from, 202; cold-bath treatment of, in children, 247; complicated with malaria, 284; complications in, 339; desquamation in, 1132; diet in, 1, 23, 157; disinfection of the urine in, 415; epidemic of, at Northville, N. C., 24; epileptiform attacks in convalescence from, 465; exanthematic forms of infantile, 925; experimental, 335; fœtal and infantile, 1053; gangrenous dermatitis complicating, 469; hypodermoclysis in, 362; in a leper, 156; in army camps, 236; in childhood, 860; influence of the toxin of, on metabolism, 340; inoculability of, 695; in Philadelphia, 324; in South Africa, 88, 105, 425; laryngeal affections in, 203; membranous laryngitis complicating, 654; mild types of, 365; ocular disturbances in, 335; ostitis in, 74; preventive inoculations against, 199, 816, 1042; priority in the serum diagnosis of, 787; prognostic value of rose spots in, 648; pulmonary complication of, 988; renal form of, 262; rubeoliform and scarlatiniform erythema in, 690; salophen in, 231; treatment of, 373, 1120; treatment of meteorism in, 292; unrestricted diet in, 697; urine as a culture medium in the diagnosis of, 69; Widal's serum diagnosis of, 466; without intestinal lesions, 886; without intestinal localization, 340.

Typhoid spine, 596.

Typhus fever, bacteriology of, 33; inoculation of, 1072.

U

Ulcer, duodenal, 494, 522; duodenal, treatment, 563: gastric, 774; gastric, case simulating, 836; gastric, gastrojejunostomy for, 509; gastric, in pregnancy, 598; gastric, surgery of, 693, 931; gastric, treatment of, 514; massage in, 145; non-malignant, gastric and duodenal, 485; non-perforating gastric, 992; of the leg, bacteriotherapy of, 375; perforating duodenal, 749; perforating gastric, 509; rodent, formalin in, 243.

Umbilical cord, hernia of the, 363.

Umbilicus, disinfection of the, in abdominal operations, 823; late spontaneous hemorrhage from the, 249; tumors of the, 163, 649.

Uræmia, experimental researches on bleeding in, 422; peculiar manifestations of, 687.

Uranoplasty, technique of, 1089.

Urate of sodium, fat, and action of acid, in the abdominal cavity and joints of rabbits, 762.

Ureteral calculus, 418.

Uretero-vaginal fistula, 499.

Ureters, anastomosis of the, with the intestines, 852; calculi impacted in the, 766; instrument for catheterization of the, 201; obtaining urine direct from the, for diagnostic purposes, 870; resection of the, 2068; rupture of the, 157; subjective symptomatology of disease of the, 873; surgery of the, 292; treatment of injuries of the, 1062.

Urethra, chewing-gum in the, 825; foreign body in the, 284, 421; obstructive diseases of the male, 71; stricture of the, 379, 886; stricture of the, with secondary cystitis and hydronephrosis, 302; suprarenal extract in diseases of the, 483; surgical asepsis of the, 1062; treatment of stricture of the, 1093; ulceration of the female, 330.

Urethrectomy, remote results of perineal, 160.

Urethritis, electrolysis in the treatment of chronic glandular, 543; picric acid in chronic, 784; treatment of chronic, 378.

Urethroscope in the treatment of strictures, 117; the modern, 784.

Urethrostomy, perineal, remote results of, 116.

Urethrotome, a new modified, 659.

Urethrotomy, external, 553.

Uric-acid diathesis, 589; production of, 528: relation of leucocytes to, 119; serious results of, when not eliminated, 640.

Urinary anomalies, 1092; infection, permanent sound in the treatment of, 925.

Urine, centrifugal analysis of, 284; chylous, 885; differentiation of, from each kidney, 31; disinfection of the, in typhoid fever, 415; estimation of mercury in the, 157, 287; forms and significance of the proteids in the, 517; poisonous effects of normal, 287; Rosin method for determining the reducing power of the, 464; significance of glyceronic acid in the phenyl-hydrazin test for sugar in the, 159; suppression of, treated by operation, 463; test for sugar in the, 161.

Urological instruments, lubricants for, 120.

Urotoxicity, relative, in children and adults, 30.

Urticaria, treatment of, 572.

Uterus, acute inflammation of a subperitoneal fibroid of the, 688; adenocarcinoma of the body of the, 639; backward displacements of the, 421; bicornate, with twin pregnancy, 924; bleeding from the, from sclerosis of the uterine arteries, 245; cancer of the, 568; cancer of the, operation in, 1137; carcinoma psammosum of the, 292; chronic total inversion of the, 422; clinical significance of retroversion of a movable, 120; complete inversion and prolapse of the, 332; conservative operation for fibroids of the, 638; dangers of coitus in inflammation of the, 70; decidual polyp of the, 292; early diagnosis of cancer of the, 115; emphysema of the, and gas-sepsis, 292; end results of operative treatment of retroversio-flexion of, 291; extirpation of cancer of the, 1065; fibroids of the, 161, 421, 996; fibroids of the, complicated by pregnancy, 212, 515, 595; fibroids of the, hysterectomy for, 218; fibroids of the, in members of the same family, 205; gunshot wound of the pregnant, 842; histology of adenomyomata of the, 468; hot-air douche in the treatment of inflammatory affections of the, 245; hysterectomy for fibroid of the, 341; imperforate, with hæmatoma of the ovary, 79; importance of cervical flexions, 289; importance of early recognition of cancer of the, 71; inertia and prolapse of the, 509; intra-abdominal amputation of the, 853; intra-abdominal method of treating retroversion of the, 1041; inversion of the, from fibroids, 117; labor complicated by abdominal fixation of the, 411; Mazzoni method of treatment of prolapse of the, 720; multiple papilloma of the cervix, 1018; natural history of fibroids of the, 199; operations for prolapse of the, 291; operative treatment of fibroids of the, 264, 331, 733; ossification of the, 418; post-partum sloughing of the, 375; relation of the, to the thyroid gland, 58; removal of a submucous fibroid by section of the, 286; removal of fibroids through an anterior vaginal incision, 304; removal of the cancerous, by the vagina, 732; removal of the, for cancer, 286; retroversion of, treated by "Belastungstherapie," 431; risk of unoperated fibromata of the, 422; rudimentary, castration in a case of, 249; rupture of the, 218; rupture of the parturient, treatment of, 898; rupture of the pregnant, 763; rupture of the, with placenta prævia, 420; sclerosis of the arteries of the, 648; serous infiltration of the para-uterine connective tissue, 733; spontaneous reduction of an inverted, after three years, 66; spontaneous rupture of the, 640; steam applications to the, 470; submucous fibroids, 608; suture of the round ligaments to the anterior wall for retroversions and retroflexions of the, 850; tolerance of the gravid, 601; treatment of cancer of the cervix complicated by pregnancy, 726; treatment of complicated fibroid tumors of the, 732; treatment of erosions of the cervix, 474; treatment of fibroids of the, 564, 852; typhoid infection of the, 655; ultimate results in treating cancer of the, 878.

Uvula, double, 462; elongated, 197.

V

Vaccination, 468; œdema following, 174; preparing the skin for, by denudation with caustic potash, 143, 174; technique of, 464.

Vaccine bodies, microscopical demonstration of, 884; weakened virulence of, in hot climates, 544.

Vaccinella, 361.

Vagina, atresia of the, 259, 286; atresia of the, with solid uterus, 285; cancer of the, 775; imperforate, 200, 249; prolapse of the, 648.

Vaginal cœliotomy *vs.* laparotomy, 334, 339.

Vaginismus, treatment of, 424.

Valk, Francis, the past and present of refraction, 716.

Valvulitis, aortic, 254.

Van Santvoord, R., the clinical uses of the sphygmograph, 313.

Varicocele, radical operation for, 288.

Varicose spinal veins, 508; ulcer, treatment of, 613.

Variner, Henri, notice of book by, 824.

Varix, abdominal, 825.

Vas deferens, suture of the, 25.

Vasectomy in enlarged prostate and bladder atony, 887.

Vegetable diet, therapeutic uses of, 768.

Veil, as a cause of erythema of the nose and cheeks, 382.

Veins, alterations of the coats of, in varices, 588.

Venereal diseases in Finland, 470; prevention of, in Norway, 369; treatment of, 32.

Vertebræ, ankylosis of the, of gonorrhœal origin, 769; fracture of the, or Pott's disease, 243.

Vertigo, aural, 161; therapeutics of, 1103.

Vesico-vaginal fistula, new method of closure of a, 696.

Vesiculæ seminales, excision of, for tuberculous disease, 199.

Vesiculitis, seminal, 247.

Vibbert, William Welsh, death of, 551.

Vibration, hypnotic and anæsthetic action of, 373.

Vienna, letter from, 431.

Vincent, Edward E., death of, 814.

Vineberg, Hiram N., the association of chronic appendicitis with disease of the right adnexa, 948.

Vinton, C. C., the use of kola in seasickness, 348.

Vir effeminatus, 246.

Virginity, anatomical proof of the loss of, 292.

Vitiligo in a baby three days old, 1110.

Vivisection at the Harvard Medical School, 418.

Vocal cords, flat condyloma of the, 930; partial paralysis of the, from over-use of the telephone, 869.

Volvulus associated with hernia, 602.

Vomiting, arrest of obstinate, 75; of pregnancy, pernicious, 924; periodical, in infancy, 202; periodic habitual, 1045; recurrent in children, 773; surgical aspects of, 598.

Vondy, Joseph H., death of, 595.

Vulva, hemorrhage from a varicocele of the, 157; ulcerative lesions of the, 81; varicose veins of the, 112.

W

Walmsley, William Edward, death of, 373.

Ware, Martin W., the cardinal pathognomonic sign of fracture of the lower end of the radius (Colles'), 540.

Warner, Francis, notice of book by, 653.

Warner, William R., notice of book by, 382.

Warren, Francis G., death of, 505.

Warren, J. Collins, notice of book edited by, 735, 1020.

Washburn, Wickes, a model dairy farm, 394; needed reforms in the ambulance system, 130; public service against private work, 651; rain baths, 1023.

Water, bacteria in, 72; internal use of, in hemorrhage, 103; mains, disinfection of, 743.

Water-gas, dangers of, 322.

Watson, James L., death of, 373.

Watson, J. K., notice of book by, 1020.

Watts, Alfred J., death of, 155.

Weber, Leonard, an appendicitis operation in 1867, 430.

Weil's disease, 207.

Weir, Robert F., on the treatment of the sliding hernias of the cæcum and sigmoid flexure, 309, 343; on the formation of an artificial anus, 661, 701; perforating duodenal ulcers, 749.

Welles, Charles Stuart, notice of book by, 735.

Wells, Clarence A., a case of rapid union in fracture of the thigh, 825.

Wells, J. Hunter, hospital and dispensary work in Korea, 219; unrestricted diet in typhoid fever, 697.

Wells, Walter A., indications for constitutional treatment of catarrhal affections of the upper air passages, 667.

Wendel, A. V., a contribution to the treatment of rupture of the parturient womb—with a critical review of the vaginal operation, 898.

Werlhof's disease, etiology and pathological anatomy of, 293.

West African medicine, 290.

Weston, E. Eugene, death of, 196.

Wetmore, Josephine M., a common case and its practical suggestions, 96.

Whistler, William McNeill, death of, 505, 559.

Whitbeck, John F. W., treatment of superficial wounds without sutures, 632.

Whitehead, R. W., notice of book by, 1021.

Whittaker, James T., death of, 1040.

Whooping-cough, antitussin in, 28; as seen in dispensary practice, 449; oil of gomenol in, 1132; pneumothorax complicating, 1044; treatment, 75, 128, 595, 731, 1092.

Wiener, Joseph, when shall we operate for appendicitis? 837.

Wilbur, Lloyd, death of, 239.

Winston, Gustavus S., death of, 22.

Witmer, Abraham H., death of, 154.

Witness, the physician as an expert, 507.

Wittemeyer, Annie, death of, 239.

Wolff, Lawrence, notice of book by, 824.

Wolseley, Lord, incompetence of, as a commander, 166.

Women admitted to the University of Heidelberg, 313; as surgeons, 1081; brains of, 1138.

Wood, E. L., the treatment of corns, 384.

Wood, H. C., notice of book by, 565.

Word-blindness, congenital, 1018.

Worms, intestinal, nervous symptoms caused by, 511.

Worthington, S. M., identity of diphtheria and membranous croup (?), a country protest, 345.

Wounds, gunshot, infection and disinfection of, 121; gunshot, in the Santiago campaign, 156; hermetic sealing of aseptic, 692; in modern warfare, 16; of the head, pistol-shot, 65; suturing of, 564; treatment of superficial, without sutures, 632.

Wright, Andrew R., death of, 373.

Wrist, congenital dislocation of the, 1108.

Wyeth, John A., a review of the history and literature of appendicitis, 44.

X

Xanthoma tuberculatum diabeticorum, 866.

Xiphopages, 417.

X-rays, see *Roentgen rays.*

Y

Yandell, William, death of 551.

Yeast, therapeutic uses of, 916.

Yellow fever, 1002; antitoxic serum of, 612; bacteriology of, 328; hæmogastric infection in, 676; in Cuba, 326, 1126; in Mexico, 108, 789, 1087; in San Salvador, 921; orrhotherapy of, 112.

Young, Rev. Alfred, death of, 686.

Z

Zadig, method of, in the advancement of medicine, 514.
